Takeall and Oats.—Mr. J. Gray read a paper, in which he said—"Takeall has been the cause of much loss in recent years in many of the old settled as well as the new districts of the State. In this paper, however, I wish to confine myself to the problem as it concerns the development of mallee land. Takeall is a fungus growth known as *Ophio bolus graminis* which attacks the wheat plant near the roots. This fungus has the power of reproducing itself and spreading from one plant to another. Thus it is found spreading in rings, and frequently so rapidly that acres of the crop in places succumb to the disease, and sometimes a promising crop is so reduced by its ravages that there is little left but thistles, wild oats, drake, and other weeds. The seriousness of the problem is realised when the farmer sees a crop of wheat that promises to average 12bush. dwindle down to 2bush. or 3bush. per acre. Of course, I am well aware there are other things that arrest the development of the wheat plant that may be mistaken for takeall, such as grubs, white ants, and root failure. Very often, too, through the crop there will appear a number of white or dead heads, as the ears of the corn fill up and begin to ripen. The cause of this I am not prepared to discuss. The roots of plants affected by takeall will be found dry and brittle, and between the roots and the first node the stem appears black and sooty. The disease did not appear in our own crops until we had put land under cultivation for three years in succession, and then only in small patches. One paddock of 50 acres was sown with wheat three years in succession. This was grazed closely each year. The last year it was so treated, viz., 1911, I noticed what I considered an evidence of takeall, but as the field was fed off, of course the extent of the damage could not be gauged. The following year half the field was sown with Algerian oats and the balance with Golden Drop and Huguenot wheats. It was first ploughed in a dry condition, then worked after the heavy rains in June with a tine cultivator, drilled, and harrowed. The condition for tillage was ideal. The whole field made a splendid start. Later on, however, the disease manifested itself in both varieties of wheat, with the result that the Golden Drop returned about 6cwts. or 7cwts. of hay per acre, and the Huguenot yielded 3bush. of grain per acre. The oats were entirely free of the disease and gave a return of 20bush. per acre. Wheat on the light sandy soil suffered the most. The disease does not seem to spread so rapidly on the stiffer soil, although crops on this kind of land are not proof against takeall. Most of our stiff land receives a shallow working, for the reason that the subsoil is very stiff and considerable pressure is necessary to get the ploughs into it. It may be that the firm land prevents the fungus spreading rapidly from plant to plant. Last year a piece of stiff land, sown with wheat for the fifth time in succession, was ploughed early and dry, then worked after the June rains with a tine cultivator, drilled, and harrowed. This showed many patches of takeall as the wheat matured, but they did not spread to any extent. The yield was 15bush. to 16bush. per acre. Adjoining the 50-acre field already referred to, we have a field of about 180 acres in extent. This is intersected with three fairly large sandhills, one of which runs into the corner of the 50-acre field. From the central hill we took three crops of oats in succession—each crop averaged about 15bush. per acre. The balance of the field carried three successive crops of wheat. The crops on the flats were usually cut for hay. The stubble was burnt off with a fire rake, and the field was fallowed early. This year, while in a moist condition, it was worked with the tine cultivator. Wheat was sown on the hills and on two of the flats, two flats being sown with oats. The whole field started immediately, and for a time gave promise of developing into a very fine crop. When the wheat was well into ear it was noticed that the hill nearest the 50-acre field that suffered so badly last year was rapidly developing the disease. At the present time the average cannot be more than 3bush. per acre. The hill that carried the oats is entirely free of the disease; not even a whitehead is to be seen. It carries a nice even crop of wheat, which I estimate will yield 12bush. per acre; this I regard as a good return for poor white sand. The third hill is badly affected by the disease, but not to the extent of the first hill mentioned. On the central hill one can tell exactly where the oats have been grown. The wheat always suffers most at the foot of the sandhill where the hill runs out to the flat. Another large hill in another field that is now carrying a crop for the fourth time in succession showed signs of the disease last year, consequently this year the hill, the half of which was fallow, was sown with oats. That portion of the crop on fallow is very fine; at the foot of the hill, I should judge the hay cut to be quite 2 tons per acre, and the crop on the hill itself, which is being left to be stripped, at 25bush. of oats per acre. The oats on the adjoining fallowed flat, which is stiff land, are not nearly so good. Judging by the foregoing experience the remedy for takeall appears a very simple one, *i.e.*, take a crop of oats, then fallow the land, and so simply starve out the disease. In the cure, however, it is patent to every farmer that we are up against another problem. If every farmer grows oats on an extensive scale where will the market be found ? Yet, if we do not grow oats, we cannot grow wheat on the light sandy soil. In the first place it is necessary to decide at what figure a bushel of oats can be profitably produced ? After due consideration, in view of the takeall problem, I shall be prepared to sell oats at 1s. 3d. per bushel. The usual price is 1s. 9d to 2s. in Adelaide, and 1s. 9d. per bush in Adelaide means about 1s. 6d. at Parilla. I would rather grow wheat and sell it at 3s. per bushel, but I have to bear in mind that on 'takeall' infested soil I can grow 20bush. of oats, but only 3bush. of wheat. Even if I have to sell the oats at 1s. per bushel, there is a balance of 10s. per acre in favor of the oats. It must be remembered also that it is not necessary to place on the market all the oats grown. A very large quantity can be used on the farm for feeding purposes. 'Cocky' chaff can be sifted to take out the rough stuff and added to hay in the proportion of one part of cocky chaff to one of hay chaff, sufficient oats being added to give the feed the required quality for working horses. The hay thus saved can be sold at a remunerative price. Then oats can be sown for feeding off purposes. They will give a larger body of feed and last longer than wheat. For this crop on stubble land a light disc implement will be sufficient to stir the land. A bushel of oats per acre will cost 1s. 3d., ½cwt. super. 2s. 6d., and the cost of disking and drilling should be 2s. 6d. = 6s. 3d. If the right class of stock is kept the feed will be worth 6s. 3d. per acre, and probably the value of the next crop will be improved to the extent of 10s. per acre. Some sort of rotation of crops is necessary. In this connection it must be borne in mind that on most farms it is necessary to cultivate large areas for the purpose of getting stubble to burn the shoots. More than three crops of wheat should not be taken in succession from new land. The last crop should be oats. The heavier parts can be cut for hay, and the stubble burnt off that which has been stripped. Then it can be sown with oats again for feeding off, and fallowed the following year; or, if the farmer cannot afford to do this, it is safe to fallow after a crop of oats has been stripped and the stubble burnt. On most farms, however, the sowing of oats to prevent takeall has been neglected. Where stubble land has been fallowed, and there is a suspicion that the lighter soils are likely to develop the disease, no risk should be run, and oats should be sown. One can always rely on getting a good cut of hay from oats sown on well-tilled fallow. The binder will work better in a crop of oats in sand than in wheat on sand. The former grows denser and the roots firm the ground and bind the sand better. The binder can be put to work well up the sides of the steep hills, and the lighter portions of the crop only need be left for the stripper or harvester, as the case may be. Cut as much as possible of the oat crop for hay, because a stack of hay, even if not required for immediate use, is always a good asset on a farm. Past experience proves that every four or five years hay chaff reaches famine prices. Where sheep are kept, and the precaution to sow oats as a preventive of takeall has been neglected, it is a good plan, where a stubble field has to be fallowed, to plough the sandhills and lighter soils early, say in the month of June, sow with oats, and allow the sheep to feed it down close. They will eat all the weeds that are likely to grow after the land has been tilled, and it can be worked early for the following seeding, left until a rain falls, and sown in a damp condition. There are other crops that are immune to the fungus, such as lucerne and peas. The former, however, is too expensive to be tried on a large scale. So far as this district is concerned it is only in the experimental stage. My little experience with peas indicates that they are not going to be a profitable crop on poor sandy soil without a heavy dressing of nitrogenous manure. They will, no doubt, grow profitably on the heavier soils and may do well at the base of sandhills, where there is always an abundance of moisture. It will be wise to continue experiments with these and other fodder plants. Experience indicates that it does not matter how the land is worked, if the takeall is in the field it will develop in the crop, always, of course, bearing in mind that the loose soil seems more favorable to its development. In some districts, in years gone by, farmers ceased fallowing altogether. They found that they could grow more wheat by tilling the grass land. Land so treated did not seem so susceptible to the disease. It is possible that the fungus may be starved out in that way. After the experience of this year, however, there can be no question about the benefit of fallow. There are host plants, on which the fungus may live through the following season, such as barley grass and spear grass, and it is wise to destroy these, if possible, on the fallow field. It is very difficult to destroy all weeds on fallow in this district on account of the retentive nature of the sandy loam. When the disease makes its appearance steps should be taken to wipe it out along the lines indicated. Every farmer must arrange his own plan of campaign. It may be that the disease will be a blessing in disguise, in that it drives the farmer to work his land with the view of growing grass as well as grain. It is well known that the light sandy soil is lacking in humus, and no better means can be devised of supplying that humus than by growing crops of herbage and feeding them off with sheep." Members discussed the subject. The disease was said to be worse in dry seasons than in wet. Mr. E. Colvill said ploughed in shoots and stubble provided a harbor for the fungus, and he advocated burning the stubble, wheat being followed with oats and peas. Mr. Gray recommended leaving the fallow open, to allow the sun to sweeten the land.

COOMANDOOK (Average annual rainfall, 18·01in.).

November 8th.—Present: 15 members.

Harvesters and Strippers.—In a paper dealing with the advantages of the harvester, the Chairman (Mr. Ninnis) said this machine would effectively take off and clean a crop much more cheaply and quicker than a stripper. Time was lost in taking the latter to the heap, emptying the grain and throwing it up. He estimated that the former machine would take a 9bush. crop from 200 acres of land for £9 3s. 4d. less than the stripper. The Hon. Secretary (Mr. C. M. Wilkin) also contributed a paper. He favored the use of the stripper, especially in new mallee country. The draught was lighter, it was better in rough and stony ground, and the cocky chaff was saved. Whilst the harvester could be put into the crop earlier, it was a mistake to bring in and bag up damp grain The majority of members favored the stripper for this locality. It was thought that in anything less than a 9bush. crop it paid better to use the stripper than the harvester.

COONALPYN (Average annual rainfall, 17·49in.).

November 14th.—Present: 10 members and five visitors.

Preparation for Harvest.—Mr. H. Bone read a short paper. All machinery and tools necessary in connection with the hay harvesting, he said, should be in readiness to commence immediately the crop reached the proper stage. As soon as the stacks had settled they should be thatched, or otherwise protected from the rain. Reaping machines, winnowers, &c., should be overhauled and repaired; swings and chains should be inspected, eyebolts fixed; bags looked over and repaired. Bags of corn left in the fields should be stacked off the ground. Earth floors should be cleaned up so that they could be thoroughly dried before they were required for use. White Tuscan was the best variety of wheat for hay in this district. Mr. G. E. Venning advised the following:—White Tuscan, Dart's Imperial, and Clubhead.

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).

November 8th.—Present: 15 members and two visitors.

Harvester and Stripper.—Mr. A. Schenscher read a paper. He preferred the stripper, as with this machine the draught was lighter, the cocky chaff was saved, and weed seeds were not distributed over the paddocks A better sample of wheat was secured. Mallee stripped with the wheat would dry in the heaps, but when the harvester took up mallee leaves these were shredded and passed into the wheat, with the result that the sample was depreciated.

Mr. C. F. Altmann also read a paper. His experience had been that one 6ft. harvester was equal to two 5ft. strippers. The harvester could frequently be put into the crop two hours earlier than the stripper, and time was lost in taking the latter to and from the wheat heaps. The harvester effected a saving of about £2 10s. per week compared with the stripper. No trouble would be incurred with weevil if storerooms were kept clean and well ventilated. The use of the harvester enabled the farmer to grow the tougher threshing wheats, which would not shake out in the event of winds during harvest. These could only be gathered with the stripper in the middle of the day, but the harvester would take them off without trouble. The wheat could be moved from the paddocks immediately where the harvester was used. If the machine were handled properly weed seeds would not be blown over the land, they would be gathered in the screening box. Straw was better than cocky chaff for young stock.

WILKAWATT (Average annual rainfall, 16in. to 17in.).

November 8th.—Present: 18 members and seven visitors.

Wheat Floors.—Mr. F. W. Altus read a short paper. He advised the selection of a small hard rise, from which the stumps should be cut level with the ground during the winter. Five or six horses should be driven around this until it was well beaten. At the time hay-making was in progress the floor should be gone over with the mower, cutting as close as possible. Some members advised selecting a site for a floor, and retaining this uncropped.

CULTIVATION OF MALLEE LAND.—A paper on this subject was contributed by Mr C. Sorrel. He mentioned that crops on fallow land in this district at present were not a success. He recommended the following procedure :—After taking off the crop, the stubble should be fire-raked, and the land left out for two years for grazing. During the second winter or spring the shoots should be logged, and the springbacks and young shoots cut in February. This should be fire-raked and the land ploughed immediately to a depth of 3in. if the soil were firm, and 2in. if it were sandy. If rain should fall and weeds germinate, the land should be cultivated before being drilled, the harrows following the latter operation. In the absence of rain after ploughing, the roller and harrows could be put over the firm ground before drilling ; it would then be unnecessary to harrow after the drill. Crops on land treated in this manner would not be so liable to takeall. One member had tried the method recommended in the paper, but the crop was as badly affected with takeall as those sown on stubble land.

WILKAWATT.—HOMESTEAD MEETING.—The meeting was held at the homestead of Messrs. Bowman Bros. It was noticed that most of the stubble paddocks were badly infested with takeall. A crop on fallow looked very well, and was estimated to yield about 15bush. per acre. Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S. (Superintendent of Agriculture in the South-East), delivered an address. He did not favor the practice of ploughing back fallow, but recommended rolling light land after ploughing. Fallow should not be worked more than was absolutely necessary. Seed should be carefully graded and heavier dressings of manure applied.

ANNUAL REPORT.—The Hon. Secretary read the annual report, which showed that the Branch was in a flourishing condition.

MORGAN, November 8th.—PIG-RAISING.—A discussion took place on the paper on this subject read by Mr. O. Hausler at the last meeting, and printed on page 551 of the November issue. Mr. H. Wohling preferred the Berkshire. The Chairman thought a great deal depended upon the manner in which pigs were treated and fed. Members generally agreed with the ideas expressed by the writer of the paper.

WYNARKA, October 31st.—HOMESTEAD MEETING.—The meeting was held at the homestead of Mr. G. G. Pitt. Members inspected the crops. It was noticed that those on ploughed land looked far better than crops sown on cultivated land. Mr. Pitt gave some practical hints on blacksmithing which were much appreciated, as Mr. Pitt thoroughly understood the trade.

SOUTH AND HILLS DISTRICT.

FOREST RANGE (Average annual rainfall, 35in. to 36in.).

November 13th.—Present: Eight members and one visitor.

POTATO-GROWING.—Mr. Dollman reported that he had secured best results from potatoes planted on old ground. Mr. McLaren said the rows for this crop should be 2ft. apart, with the sets 14in. apart. Snowflakes should not be given too much room or they would grow coarse. He used bonedust with the crop, putting it direct on to the seed. The results of potash did not justify its use in this district. He made a practice of planting new ground, working it well before putting in the crop, which was best done during the first week in September. Each set should have at least one good eye. Snowflakes had been the best yielding crop with him. Mr. F. Green also thought it advisable to plant Snowflakes close together, and he preferred putting them on new ground. Mr. H. Green thought well-worked old land equal to new. He put the manure in the furrow with the seed. Mr. Schultz's experience was that better results were secured by giving the seed plenty of room. The general opinion of members was that early crops should be planted in October and the late varieties in December, so that they would benefit from the autumn rains.

INMAN VALLEY (Average annual rainfall, 26in. to 27in.).

October 8th.—Present: 12 members and two visitors.

FARM MANAGEMENT.—Mr. H. J. Meyer read a paper as follows :—" It is impossible to lay down any hard and fast rules as to farm management, for one has to take into consideration the varied climatic and soil conditions, and therefore it can be quite readily understood that what might be suitable for one part of the State would be quite the reverse in another. I know of no district in which mixed farming can be carried on so admirably as in this. We have an assured rainfall, and therefore if in my paper to-night it should seem that I have not paid very much attention to the actual growing of grain I am sure members will readily understand the reason. To successfully manage a farm from small beginnings and little cash at starting is not as easy as a number of people may imagine. They see in places fine farm homesteads, with good fences, up-to-date implements, well-bred stock, &c., and then imagine what a fine time the farmer has. They very often lose sight of the fact that it has perhaps taken years and years of hard work, thrift, practical experience, careful breeding and culling of stock of all kinds to bring the farm to its present satisfactory condition. If the man has to depend mainly on his own efforts it will be well for him to go slowly for a few years. A small holding well managed is better than a large area badly managed, and a small number of good stock well cared for is better than a large number of inferior animals. It is a very near-sighted policy to overstock. The necessity for carefully planning out the work of the farm from time to time is of vital importance, as by so doing time will not be lost in the event of the weather proving unsuitable for certain operations. Care should be taken that when the busy time is at hand no delay should occur in getting implements, harness, &c., ready. All this should be done some time before. The working horses are a very considerable asset to the farmer. It is of the utmost importance that they should have the greatest attention and care as to feeding, not only during the working days, but it should be seen that the team is in good condition before that time arrives, and also that the harness is well oiled, and that the collars fit; otherwise it is impossible to get the most out of the team. Every farmer should breed his own foals. I find in a district like this, where the work is not so continuous, that the mares will do all that is required of them, and breed a foal also. The stallion which we consider the best travelling the district has far too many mares, and therefore the results as a rule are very disappointing. The only way that I can see to overcome this difficulty is for a number of farmers in the district to club together and buy a stallion. A first-class horse could be procured which, on account of the big price, one individual would be unable to purchase. By this means the farm horses would be very much improved. I am of the opinion that it pays to have the very best stock that one can afford, whether it be horses, cattle, or sheep, for land values are far too high to allow one to keep inferior stock. There is a difference of opinion as to the class of horse most suitable for the district, but I prefer the Clydesdales, for the reason that they are active, strong, good workers, and have the advantage of being very docile. I have tried the lighter sorts, but found, though willing, that too great a strain was put upon them in the hilly and heavy lands of the Bald Hills; hence they suffered in condition. All the young stock on the farm should have very careful attention, and should on no account be allowed to get low in condition, especially in the yearling stage. Therefore it is advisable during the cold weather especially to feed them on hay at least once a day. If the pastures are good they will thrive. Otherwise, if allowed to become low in condition, their digestion becomes impaired, their constitution weakened, and consequently their future usefulness is very much curtailed. These remarks hold good even to a greater extent if possible in the future dairy cow. It is not within the province of this paper to advise which is the best breed of sheep to keep. Each man having regard to the size and locality of his farm must decide for himself, and then having decided stick to that breed and keep the best of its kind. Due regard should be paid to the property itself, keeping fences in order and generally improving the appearance of the homestead. There is no truer axiom than that 'bad fences make bad neighbors.' Every farm should be made sheep-proof and subdivided into fairly small paddocks, as the stock like a change of pasture occasionally. I strongly advocate running a few head of young cattle in every sheep paddock, as they will eat up the rough tufty grass which the sheep will not touch, thereby sweetening the pastures for the latter. Sheep thrive very much better on short feed. No farm in a district like Inman Valley is properly equipped without a dairy. The number of cows to be kept must be determined by the number in the family, because I do not think that it pays to hire labor for the dairy. Each cow should be tested as to her qualifications, so that one sees that the cow keeps the farm and not the farm the cow. At present prices nothing is returning more profit than pigs. Poultry well managed is another valuable asset to the farm; but to keep fowls of all colors of the rainbow, fed on screenings, allowed to roost on machinery of all kinds, in trees, and wood heaps is to court disaster. It should be the aim of the farmer to keep the breed of fowls which will lay well when eggs are a good price. Almost any fowl will lay when eggs are 6d. a dozen. It is a prudent man who looks upon the by-products as a great source of income, for one has to take into account the seasons varying and prices fluctuating. There is always some particular line selling well, therefore it is wise not to have all one's eggs in one basket. This district is certainly not an agricultural one, but every man should at least grow enough hay to tide his stock over the wet, cold months of the winter and early spring. Algerian oats give better returns than wheat, as they are not nearly so likely to feel the effects of the wet seasons. Whatever cereal is grown too much attention cannot be paid to the choice of seed. No well-conducted farm should be without a blacksmith's forge. It fills in wet days, and it is astonishing how handy the ordinary man can become in making bolts, S hooks, &c. It not only saves a great deal of time in running to the blacksmith, but it is a money saver also, for I take it that a farm to be successfully managed must be as self-contained as possible. The home should be well supplied with fruit and vegetables of the farmer's own growing. They are healthful and help to curtail expenses. No difficulty should be experienced in growing them all the year round in a climate such as ours. My paper would not be complete if I were not to impress on members the importance of having all implements, &c., well protected from the weather, and all haystacks well thatched, or, better still, covered with iron." In reply to a question Mr. Meyer said he preferred the Babcock tester for testing dairy cows. He considered that four good cows would return sufficient to meet the household expenses of a family of five.

IRONBANK (Average annual rainfall, 33in. to 34in.).

November 14th.—Present: seven members and one visitor.

Cleaning Strawberry Ground.—Mr. C. Morgan dealt with this subject in a paper. To clean old strawberry ground, he said, the best method was to break or plough over the ground to a depth of about 4in. as soon as the crop had finished. It should remain rough, and at the end of a month or six weeks should be scarified, which operation should be repeated every fortnight or three weeks during the summer. During May or early June field peas, at the rate of 2bush. or 3bush. per acre, should be ploughed in, together with 3cwts. or 4cwts. of bonedust. After the pea crop was taken off the ground should be ploughed to a depth of about 6in. and left rough. After a month or six weeks it should be scarified, this operation being again carried out monthly through the summer Prior to replanting the ground should be well ploughed and harrowed, about 10cwts. or 12cwts. of bonedust per acre being ploughed or dug in. The plants should be put 10in. or 12in. apart in rows 24in. apart. The roots could be put well down with the aid of an old trowel. Sorrel should be destroyed immediately it appeared. Strawberries would not do well with pear or cherry trees.

Rearing Calves.—Mr. Reuben Coats also read a short paper, in which he said young calves should be fed twice daily at regular hours. They should be kept clean and comfortable, extremes of heat and cold being avoided. A light chain with a free-running swivel should be attached to a strap loosely encircling the neck of the animal. On no account should it be tied near a fence, as there was a danger of its learning the habit of crawling through, which practice would cause considerable trouble in after years.

KANMANTOO (Average annual rainfall, 17·90in.).

November 6th.—Present: 14 members and one visitor.

Sheep-Dipping.—Mr. H. G. Pym read a paper on this subject. Sheep which were infested with tick and lice, he said, would not do well. The staple of the wool was often broken, and it became discolored and lustreless. The dip should be kept up to the full strength and free from mud, &c. It was advisable that dipping should be made compulsory, otherwise sheepowners would never be rid of the trouble. Some contended that it was best to dip the flock off the shears, as after shearing the tick quickly left the sheep and took refuge under cover afforded by the pasture, returning to the sheep again after the wool had grown. A suggestion had been made that the law should be amended to provide a penalty for neglect to dip infected sheep after shearing. Some members favored this proposal, whilst others thought compulsory dipping more likely to be effective.

MENINGIE (Average annual rainfall, 18·87in.).

November 15th.—Present: 14 members and one visitor

Sheaoaks.—Mr. W. H. Mincham read a paper. Whilst gums and pines grew fairly well in this district, he said, the sheaoak was the tree most suited to the climatic conditions. This reached maturity in about six or seven years. The timber could be used for fencing in water or pipeclay flats, but it would not stand in dry soil. It also made good firewood. He advised landholders to fence off an area of sandy or hilly land and plant it with these trees. The "apples" should be gathered when hard and left in a box or tin in a dry place for a few weeks. The seed could then be broadcast or sown in rows on the land, which should have been already ploughed, and covered to protect them from the birds. Rabbits were also very destructive to the young trees. If put in with the first rains the trees would stand through the summer. They sent down a deep taproot, and throve well if they received a good start. In dry seasons the foliage could be cut for stock feed. After being clipped the trees sent out a supply of fresh tender leaves. These trees should be more profitable than wattles. They should not be planted too close to orchards, as the rough bark provided a harbor for insects, and small birds congregated in the trees. Mr. Wright mentioned that as stock readily ate the female oak, but not the male, it was advisable to cut leaves for fodder only from those bearing "apples." Mr. Hiscock recommended broadcasting the seed on ploughed land and turning on sheep to tread it in. If the seedlings were to be transplanted they should be removed as soon as the first shoot appeared, otherwise the taproot would develop to such an extent that this would be difficult.

MORPHETT VALE (Average annual rainfall, 23·32in.).

November 18th.—Present: 13 members and two visitors.

Zealand Blue Wheat.—A sample of this variety of wheat in the hay stage was tabled by Mr. O'Sullivan. It was of splendid growth, 3ft. 6in. in height, but was too late to sow with oats for hay.

Hay Crops.—Mr. F. Crittenden read a paper. After five years' experience, he said, he believed it would pay to purchase an improved farm of 500 acres at £12 per acre, if an average crop of two and a half tons of hay per acre could be secured; interest at the rate of 5 per cent. per annum on capital being allowed, and all labor paid for. Two hundred acres could be cropped each year. The land should be fallowed in July or August, and worked as frequently as possible, excepting in dry, hot weather. Carefully selected seed wheat should be sown, and heavy dressings of manure were advisable. The harvesting should be well distributed. King's Early was a good early variety, but required thick sowing, *i.e*, 2bush. per acre. White Tuscan was the best wheat, either sown by itself or with oats. It kept its color, and handled well in hot weather. Two hundredweights of manure per acre was not too much for hay crops. Members generally did not favor growing early wheats on fallow. If dressings of 2cwts. of manure were applied to land that had not been fallowed and worked well, there was a danger of the crop blighting off in a dry season.

BLACKWOOD, November 10th.—**Pruning.**—Mr. Geo. Quinn (Horticultural Instructor) gave a spring pruning demonstration in the afternoon and a lantern lecture on the formation of the fruit tree in the evening.

MacGILLIVRAY, November 11th.—**Sheep-Dipping.**—An article from an agricultural publication was read by Mr. R. Wheadon. Members agreed that it was advisable to dip sheep, and it was noted that by using a powder in the dip instead of a liquid preparation there was less likelihood of the effect being lost in the event of rain falling on the sheep after they were dipped.

SOUTH-EAST DISTRICT.

MOUNT GAMBIER (Average annual rainfall, 32in.)

November 8th.—Present: 14 members.

Spraying Fruit Trees.—Mr. R. Fowler, Inspector under the Fruit and Vegetable Acts in the lower South-East, read the following paper:—"Spraying with arsenate of lead for codlin moth, and fumigation with hydrocyanic acid gas for red scale of the orange and lemon, have been made compulsory, and it is the duty of anyone owning fruit trees to have those trees properly attended to for the prevention of codlin moth and other diseases. It is necessary first of all to know something about not only the spray to be used, but the insect or disease to be combated, and the manner in which the spray acts upon it. Insect and fungus pests can be divided into two classes, requiring different methods of treatment. The two classes of insects are—those which chew their food with their mandibles or jaws, such as beetles and the larvæ of moths, and those which seek their food through their suckers (*haustellata*), such as the aphides and scales. The easiest way to attack the chewing insects is by poisoning their food. For this purpose there is nothing better than arsenate of lead. This preparation has been in use some years now, and has proved a remedy for codlin moth in Australia, America, and elsewhere.

The larva of the codlin moth eats its way into the apple, so that if the apple is coated with an arsenical poison at the time the grub attacks it, the young grub must be poisoned. The success of the spraying for this pest depends on whether the fruit has been properly covered with spray. If the grub once gains an entrance into the fruit no spray can reach it. The codlin larvæ do not long remain on the outside of the fruit, therefore it would be hard to kill it with a contact spray. That explains why kerosene emulsion is not a success against codlin moth. The first spraying is the most essential, and this should be applied just after the blossom petals have fallen, within three or four days. The calyx of the apple and pear is then open, but this, in some varieties particularly, soon closes up, and if the poison has not been placed there previously the larvæ of the codlin moth is given a safe entrance. This is the part of the fruit most liable to attack from the first brood of codlin. As the young fruits at this time grow rapidly it necessarily follows that portions of the fruit soon become exposed, so that it is important to renew the spraying at fairly short intervals—a fortnight or three weeks separating the first and second spraying, and three weeks or a month the second and third; and with late varieties of apples it is well to apply even a fourth spraying. The bandage trap should also be put around the trees this month, and examined every seven or nine days for the purpose of killing any grubs hiding there. This should be done till all the apples and pears are gathered, and even once or twice during the winter months, to catch any grubs that may be driven by the cold and wet from their former shelter. The second class of insects secure their food by suction. They do not eat the plant tissues or fruit, but by thrusting their proboscis or rostrum through the outer tissue of the bark, leaf, or fruit, suck the juices. They are usually very sluggish, and generally remain stationary unless violently removed. They cluster thickly upon stems, leaves, and fruit, and can be directly reached with a spray, which will kill them by causing suffocation or internal irritation. This action of the spray will be better understood when it is remembered that insects have no lungs. Their respiratory system is of the simplest description. An insect breathes not through the mouth, but through a number of minute openings on the two body segments. These openings connect with the vital organs, and, if clogged with some contact spray, suffocation will result. Most contact sprays kill in this manner, although perhaps a certain amount of internal irritation is also set up. It will be seen, then, that for sucking insects, such as peach aphis, woolly aphis, red spider, and any of the scale family, a contact spray is the only remedy. Arsenate of lead would be useless. Some of these insects are coated with a sticky resinous compound, some with a downy covering like wool, and some with a waxy shield, all of which coverings are impervious to water. A spray of a very penetrating nature, driven with sufficient force to break up or dissolve this outer covering, to get the insect beneath, is therefore necessary. Contact sprays mostly used in the orchard are kerosene emulsion, tobacco wash, and red spraying oil, the latter preparation being much used during the winter, its action on the young leaves making it unsafe to use when any foliage is on the trees When spraying with red oil it is necessary to be very careful in preparing the mixture, or injury may result. See that all the vessels are perfectly clean, and with all spray mixtures use only rain water. Any trace of lime will break up an oil emulsion, and will cause arsenate of lead to precipitate very quickly. If no rain water is available, a hard water may be softened by the addition of a little washing soda. The fungus diseases are of two classes. First there are those which grow upon the surface of the trees and absorb their food from the superficial cells of the host plant by means of suckers, examples of which are the mildews, of which the oidium on the vine is typical. They are termed epiphytic external, because the fungus threads grow on the outside of the leaves, and may be destroyed by dusting flowers of sulphur upon them during hot weather, or by spraying with either Bordeaux or Burgundy mixture. Then we have the endophytic internal fungus, that which grows inside the plants and leaves, and cannot be reached by any spray. These are best represented by black spot of the apple and pear, curl leaf of the peach, shothole and scab of the apricot, and also Irish blight in potatoes. It is obvious that to kill these fungi when visible, the leaves and fruits must necessarily be destroyed, so that spraying for this class of fungus can only be regarded as a preventive, and to be at all effective should be applied when the spores of the disease are germinating on the outside of the plants, as the spray will prevent the spores when disseminated over the plants from germinating and starting fresh outbreaks of disease. The proper time to spray for black spot on apple or pear, shothole, and scab is just when the blossom buds are bursting, and at a slightly later period. Two sprayings are usually given for these diseases, but for curl leaf, once this disease appears in the leaves it is useless to spray: the fungus is inside and canot be reached. If only a few

are usually given for these diseases, but for curl leaf, once this disease appears in the leaves it is useless to spray: the fungus is inside and cannot be reached. If only a few

leaves are affected they may be pulled off and burnt. A few points to remember about spraying are:—Have a good outfit; one that will give sufficient power to do the work properly, and keep the mixtures well agitated. See that all vessels used are perfectly clean. It is not advisable to mix sprays, though sometimes this is done, arsenate of lead being added to Bordeaux to make a combined insecticide fungicide. Spray on time, with the right material, and of the right strength. See that every portion of the tree has received a thorough dressing, remembering that it is the fruit and the calyx of the fruit that requires attention, and as the fruit grows with the calyx standing upward and outward, it follows that the spray is better applied from above than from below. A tree at the first spraying for codlin moth should be thoroughly soaked from top to bottom, so that every calyx on it is filled. The spray nozzle should give a fair driving spray, not a sort of shower bath. Spray with the wind as much as possible, it helps to drive the spray. Second and subsequent sprays may be applied more as a mist, as the idea is to leave the poison on the fruit, not wash it off by a too heavy application. By carefully following these methods it is possible to save 95 per cent. or more of fruit from the codlin grubs, and it is to the advantage of everyone with fruit trees to carefully attend to the spraying for the numerous pests that now attack them. With trees like those at Mount Gambier it may hardly be possible to get as good results as in some places, because they are so high and hard to get at, but 80 per cent. to 90 per cent. of clean fruit should be easily obtained." In reply to questions Mr. Fowler said it had been estimated that it would take the poison off 895 apples to be dangerous to man. He had heard of trees being heavily sprayed, and the grass underneath fed to cattle and sheep without injuring them. For curl leaf on peaches the Bordeaux mixture should be used. The spray should be applied when the trees were coming in blossom, and if bad, again next day. For shothole in apricots they could not spray too often. Spray before the blossom came, and then soon after. When trees were badly affected shothole was hard to get rid of. Most of the pumps used had agitators, but with the smaller ones it was necessary to stir the mixture frequently. The codlin grub took about three weeks to mature, and would then get into the bandages, where it would remain for eight or nine days, or perhaps a shorter period. Then it would, as a moth, go on with the laying of eggs, and there would be two or three broods in a year. He had found grubs as late as December 26th. He had used, at Coonawarra, a mixture known as Fremer. The preparation was diluted and hung up in vessels in the trees. It had a sweet odor, and was said to attract codlin moths. In five bottles at Coonawarra he had taken 20 moths, but had not had sufficient experience with it as yet. The Government Entymologist in Victoria (Mr. French) spoke highly of the mixture.

Mouth Disease in Sheep.—Mr. D. A. Collins reported that the lips of some of his weaners had become thick, the animals could not feed, and lost condition. In some cases their mouths became quite raw through being rubbed against posts and stones. A mixture of one part Little's sheep dip with 25 parts water, sprinkled on the affected parts from a bottle with a V-shaped aperture in the cork had effected a complete cure within 10 days. In bad cases he had dipped the head of the sheep into the mixture.

NARACOORTE (Average annual rainfall, 22·60in.).

October 11th.—Present: 15 members.

Horses.—Mr. W. J. Colebatch, B.Sc., Agric., M.R.C.V.S. (Superintendent of Agriculture in the South-East), delivered an address. Serious injury or disease in farm stock, he said, demanded just as much care and skill on the part of the practitioner as in human beings, and a fully trained and equipped veterinary surgeon able to devote his whole time to the district was urgently needed. The lecturer then gave some of the leading points which constituted a good sound horse. The cornea of the eye should be free from opacities, and the pupil clear and transparent. If they found a horse with one of the eyes small they might conclude that it was subject to recurrent ophthalmia. They should also notice the alertness of the eye and the hearing, and also examine the ears for small cancerous growths. They should look beneath the jawbone to see if there was an open wound due to a rupture of the satirary gland duct. This was a troublesome injury, and horses so affected were rarely good buying. He would not place too much stress on the lampas. He did not believe in burning them out. They should look down the neck for any lumps and examine the jugular vein. A good deal of bleeding was still done in parts of England, but in modern veterinary practice it was hardly ever resorted to. Sore shoulders were sometimes caused by a fungus. Big tumors, broad based, with pus issuing from depressions all over their surfaces, would sometimes be found on the shoulders. They usually required surgical treatment, but when widely spread it was often wise to resort to counter-irritants first. The effect of blistering them was to contract them, and then they were more easily excised. He advised particular attention to the forearms, as their development indicated the natural shape and symmetry. The points in the leg to which particular attention should be paid, then came under review, and the ailments of the cannon bone were explained. Well placed splints were no detriment to a horse. Three kinds of splints had to be looked for. First, the knee splint, which was placed so close to the joint that extension and flexion resulted in painful pressure and lameness. Second, the posterior splint, situated at the back of the cannon bone and interfering with the free play of the suspensory ligament and flexor tendons at the back of the leg. Third, the bridge splints, which resulted from the development of a ridge of bone across the posterior face of the cannon bone from one splint to another. Splints were the result of hereditary disease, but were not regarded as serious hereditary defects except so far as their presence in large numbers was indicative of a soft spongy type of horse. He also counselled an examination of the back of the forelegs. Flat bone, he stated, was a misnomer. He explained the anatomy of the foot or hoof. Ringbone was a development of bone round the coronet joint, and should be examined closely. He would not buy a horse with greasy heels, because there was no certain cure for it. They should see that the frog was good, and wide heels were necessary for a good strong horse. The bars on the foot should never be touched. There was a danger of foundering caused by overfeeding. Fistulous withers, poll evil, and quittor were touched upon, and he further explained that in the case of grey or white horses an inspection under the dock for malignant tumors should always be made. The stifle required examination. The various forms of the disease of spavin were explained. In connection with the dropping of foals there were a good many losses which could be avoided by a little prompt attention. They required to get the foals under treatment at once. Bleeding of the navel was one of the troubles of young foals that required attention, and it might occur under the most favorable conditions of birth. Sometimes it was the result of the cord being snapped off. He advocated washing it with an antispetic, first of all tying it round with a piece of tape about an inch wide. This should be taken off after 24 hours. They could either apply to the wet part perchloride of iron, which would cause a clotting of the blood, or grip the skin around the navel with a clamp and sear it. Another ailment which sometimes led to serious trouble was the running of urine from the navel. As there was no immediate danger they could leave it for a fortnight, and if the flow had not stopped they would have to take action. The first thing they would have to do was to see that the natural passage for the urine was opened. They should wash the affected part, put a ligature on it, and leave it for a week. If it then did not heal up they could apply a blister, which would cause a swelling and then grip it with a pair of clamps. Under normal conditions the navel should dry up and the cord drop off, but when it kept in a moist condition it gathered dirt and germs, and he believed that this was the cause of the death of several foals in the district last year. It was necessary to use internal antiseptics such as formalin. They should also carefully watch the bowels of foals after birth, for often certain material accumulated in the intestines before birth which required to be moved. For this they could use a lukewarm water injection and allow it to soak for half an hour. They could also use soap or oil and pass it in with an enema, with an opening drench of castor oil and laudanum. A number of questions were asked and replied to.

T. PASCOE,

Minister of Agriculture

POINTS FOR PRODUCERS.

Farmers' Conference.

The Annual Conference of Northern Branches of the Agricultural Bureau is to be held at Gladstone on Thursday, February 19th, 1914. The opening ceremony will be performed by the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), and addresses will be given by the undermentioned officers of the department:—The Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.), the Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.), and the Dairy Expert (Mr. P. H. Suter). Papers will be read by members of branches situated in the Northern districts. General arrangements are in the hands of the Gladstone Bureau, and, as usual, the proceedings will be open to the public.

New South Wales Harvest.

The wheat harvest of New South Wales for the present season is estimated by the Government Statistician at 41,800,430bush., or 8,313,094bush. more than the actual yield last year. The acreage to be reaped for wheat is given as 3,136,071 acres, or 905,157 more than last season.

Argentine Wheat.

In his report for 1912 the Minister for Agriculture of the Argentine remarks that the diversity of the quality of Argentine wheat is notorious. This variation arises not only from its being grown in regions in which the climatic conditions are so different, but from degeneration and the process of adaptation which it has undergone. With the object of overcoming the disadvantages at which Argentine wheat is thus placed in foreign markets, the Ministry of Agriculture has commenced the work of selecting seed, and has engaged an English expert for the purpose. The experimental cultivation of wheat will be carried on at Pergamino for the first year and afterwards will be extended to the principal wheat-growing districts of the Republic in order to produce sufficient stocks of the selected variety.

Scheme for the Improvement of Livestock.

The British Board of Agriculture and Fisheries have had placed at their disposal a sum of £37,000 by way of grant in aid of the improvement of livestock in England and Wales for the current financial year. The main object of the scheme, says the *Journal of the Board of Agriculture*, is to afford means of demonstrating to groups of farmers, especially the smaller farmers, that it is sound economy and of pecuniary advantage to use only sound and high-class sires, and to keep records of the milk yield of their dairy cows, with a view to getting rid of poor milkers and improving, by judicious selection and breeding, the productiveness of their herds. The assistance will take the form of financial help, preferably to farmers' clubs or societies, for the provision of high-class bulls, stallions, and boars at the same low fees as are usually paid for the use of an inferior type of sire; and the Board are also authorised to pay one-half of the expenses of associations of farmers formed for the purpose of taking and checking the milking records of the herds of their members, but such grant is not to exceed £50 to each association.

Animal Foods and Egg Production.

The 1912 report of the Ontario Agricultural College contains particulars of an experiment to ascertain the effect of feeding Buff Orpington, Rhode Island Red, and Leghorn hens and pullets on various kinds of animal food. It was found that buttermilk produced the most and the cheapest eggs. In all cases birds which received no animal food produced the smallest number of eggs, but these eggs had the greatest hatching power. The Leghorns supplied with the ration containing no animal food developed the habit of feather eating to a great extent, and of the three breeds they appeared to be most in need of this class of food.

The Value of the Pig.

"I know of no more powerful agent in transforming poor land into rich," states a writer in the *Agricultural Gazette*, "than the domestic pig. Give a man a few acres of poor land (not bad, but poor) and plenty of pigs, and I venture to say that there will be a more or less sudden conversion. The pig is in itself profitable, but the manure it leaves behind is of even greater value to the feeder than its increase in weight. Pigs are the best kind of stock for a man who has a small tract of poor land, and there seems to be no limit to the improvement which may be effected by and through their presence."

Breeding from Sound Sires.

Some interesting particulars are given in the September issue of the *Journal of the Board of Agriculture* (Eng.) of the Castle Eden and District Cart Horse Society. The society, which has been in existence for over 50 years, was established with the object of giving farmers in the Castle Eden District the opportunity of breeding from sound sires on reasonable terms. A deputation of members visits stallion studs and selects two horses each year for the purposes of the society. The horses must be passed as sound by a qualified veterinary surgeon, and proof must be given that they are safe stock-getters. The owner is required to enter into a written agreement with the secretary of the society promising to carry out its rules and conditions under a penalty of £60. He receives from the society a premium of £60 for each horse, and, besides this, he is paid by the owners of the mares £1 for each mare served at the end of the season and £2 when a mare proves to be in foal. The owner of the mare also pays the groom's fee. Non-subscribers using the horses pay 10s. extra for each mare. The season commences in March and ends in July, and the horses are not to serve more than 90 mares each. During each of the last five years the society has secured the services of two horses, pure Clydesdales, of a market value varying between £200 and £350. The approximate number of mares served has been 176 per season, that is 88 per horse. It is estimated that the number of foals has averaged from 50 to 60 per cent. of the number of mares covered, which would give an average of 88 foals per annum. At this rate the horseowner received on the average in premiums £120, in service fees £176, in foal money £176, total £472, or an average of £236 per horse. The expenses of the society averaged for the last five years £144, and the income (including subscriptions, £99, and an annual grant of £25 from the county agricultural society) £124, thus showing a loss each year of £20.

Agricultural Returns for England and Wales.

The preliminary agricultural returns for England and Wales collected in June last have recently been published. Compared with the figures for 1912 they show a decrease in the total area under crops and grass of 45,308 acres. The area under wheat was less by 162,000 acres; oats also decreased by 98,000 acres, but the area under barley increased by 102,000 acres. Most of the other crops show a decline, probably owing to the difficulties of the sowing season. Potatoes declined by 21,000, mangolds by 66,000, and clover and grasses by 27,000 acres; but the area reserved for hay, whether seeds or meadow, increased by 273,730 acres. The livestock returns show decreases among all classes of animals. The decline in horses is slight, but the total number of cattle, 5,716,944, is less by 124,776. Sheep have declined by over 900,000, and pigs by over 390,000.

Method in Grazing.

Recklessness in grazing operations will never pay if the pastures that are being grazed are worth the average rent. Cattle, horses, and sheep grazing together make a pretty picture in either water-colors or oils, but allow all these to run slipshod over a piece of rich pasture which has just thrown up a good thick bottom of spring grass, and a very large portion of the feed is trodden down and spoiled, and that in far less time than it would have taken for all these animals to have grazed the piece, having sufficient all the time if the correct method had been put into practice. We have long been convinced that it is essential to our progress and profit as farmers to bring system and method to bear in feeding our root crops, and it is hardly necessary for me to mention here the work that would accrue were cattle and sheep permitted the liberty of a piece of swedes with which to dispose as suited to their immediate conveniences.—*Agricultural Gazette.*

Common Salt as a Fertiliser.

In agriculture salt is often used as a manure. It starts chemical changes which set plant food free, and it attracts moisture, but its use requires care. When strong it poisons plants and it is often used on garden paths for killing weeds. Even when employed as a fertiliser it often acts as a check on vegetation at first. It has been remarked that the general effect of salt on kitchen garden vegetables is to increase the thickness and size of the leaves, and it has been proposed to use it systematically in the case of those vegetables, such as cabbages, where the leaves are eaten. European experiments, Rothamsted amongst others, have shown that quite a remarkable quantity of chloride of sodium is carried far inland and comes on the land with the rain.—*Mark Lane Express.*

A Suburban Road.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c.. diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

A member of the Yadnarie A. B. inquires the cause of a horse's foot swelling, the swelling subsequently extending to the head and body.

Reply—The symptoms are altogether too indefinite to venture an opinion on. The main causes of such swellings are—Blood-poisoning, arising from an injury or snakebite ; invasion of the system by germs, generally called influenza or lymphangitis ; and the most common of all swellings arising from interference with the circulation caused by the development of blood and stomach worms. Recovery often occurs without treatment, or if this is given it may be simply saline laxatives, such as an ounce or two of Epsom salts or hyposulphite of soda once or twice daily till the swelling subsides.

" Mikkera," Port Lincoln, has a cow which has large teats, but which is exceedingly hard to milk. He asks for advice.

Reply—Probably it would be best to fatten and sell the cow ; otherwise draw the milk with a teat syphon, but be careful to boil the syphon each time before and after use.

" W. S." has some horses which at times blow so as to prevent their being worked. They are fed on oaten chaff.

Reply—The diet is wanting in certain constituents. Feed a little crushed wheat or wheaten chaff with the oaten and, if possible, molasses or oil cake.

" E. T. C.," Parilla, requires treatment for a pony which is suffering from a slipped shoulder of four months' standing.

Reply—If possible give a swim daily in a dam and well hand-rub the shoulder for quarter of an hour afterwards, or well rub in a blister made of red iodide of mercury 1 dram, lard 7 drams ; keep the pony tied up for 24 hours after so that it cannot bite the blister.

"X. Y. Z." has a cow which calved seven weeks ago. She is in good condition, but gives milk which has a sediment of blood. There is nothing visibly wrong with udder or teats.

Reply—This trouble is common, and in a case like this is probably due to a slight congestion of the secreting membrane of the udder, and will gradually get right; but 10 drops of tincture of arnica given morning and evening in a mouthful of bran or pollard will hasten the recovery.

"J. F. W.," Macclesfield, asks—(1) Is there any method of destroying mice in haystacks? (2) How to destroy lice on pigs?

Reply—(1) There is probably no practical way of getting rid of the pests. Poisoning with advertised preparation such as Battle's vermin killer baited about the stack may reduce them, but care must be taken in regard to other animals. Ferreting the stack will help to disturb them, and cats are useful. Tarred boards around the stack will help to keep them out. (2) Spray the pigs with Cooper's sheep dip, or lysol, or cyllin; the dip prepared as on packet. Use 3ozs. of the disinfectants to the gallon of water, preferably soapy. Then oil them with any cheap oil, such as train oil, to each gallon of which add 4ozs. of sulphur. Three applications at intervals of a week should free the pigs; but they must be watched afterwards, as any lice that have escaped will be breeding in a fortnight again. Take precautions that the poisonous dip does not drain into stuff the pigs or fowls can get at. The pigs' houses will also want spraying with disinfectants and limewashing.

"J. P. H.," Waukaringa, states that a number of horses in the north-east district have become blind through eating paddy melons. He asks—Can you recommend any cure?

Reply—Blindness following the eating of paddy melons is very common, and prevention is better than cure—keep the horses off them. As treatment, a brisk purgative is advisable—5 to 8 drams of aloes given as a ball after preparing the horses by giving bran mashes only for two days. Bleeding, 1 to 2 quarts at the neck or arm vein is also recommended. Local applications to the eyes are not much good, but cooling lotions such as methylated spirit and water, half and half, may be used. An ounce of sulphur daily in the feed is sometimes of use in preventing the blindness.

"J. P. H." writes in regard to the effect on stock of paddy and pie melons.

Reply—There is very little doubt that the constituents of pie melon are more digestible than paddy, but the balling in the stomachs of ruminants is a nuisance; it can, however, be mitigated to some extent by feeding roughage, such as cocky chaff, with it. Indeed, in some countries it is practically the only feed available. The paddy (*Cucumis myriocarpus*) and the pie (*Citrullus vulgaris*) undoubtedly cross, and the poisonous constituents of the former are lessened thereby, but the hairy nature of the latter produces the trouble referred to. Both bring on diarrhœa and stomach irritation followed often by obstinate constipation and blindness, due to substances like elaterine and colocynth.

" J. E. W." asks for a definition of the terms " piebald " and " skewbald."

Reply—Technically a piebald is a black horse with large splashes of white, or *vice versa*, and a skewbald is a horse of any other color with splashes of white ; but popularly both are often termed piebald, incorrectly, however, as the name originates from the black and white of the magpie. Books on the subject—" Book of the Horse " (Axe) ; " Horses and Stables " (Fitzwygram) ; " Horses : Breeding to Color " (Gilby).

" J. P. S.," Tarcowie, inquires as to the age when a foal suffering from a bad rupture should be castrated.

Reply—Presumably the rupture is in the purse, in which case the sooner the foal is castrated the better, for two reasons. First, the longer it stays the larger the ring becomes. Second, there is a risk, and the earlier in life the less this is ; also if it dies less keep has to be accounted for. If valuable, it would be best to have a qualified veterinary surgeon in to operate ; if of little value, starve for 24 hours, put on back, get bowels well up ring into belly, make small cuts in skin and inner skin so that they are not in the same line, and sew them up separately after operating.

HORTICULTURE.

(Replies supplied by Mr. G. QUINN, Horticultural Expert.)

" J. F. W.," Macclesfield, asks—(1) For particulars regarding a preparation placed in bottles and hung on the trees said to destroy codlin moth. (2) For a remedy for a fungus pest which attacked and destroyed cauliflowers saved for seed.

Reply—(1) There is a preparation sold for trapping codlin moths into bottles. It is prepared in Victoria and sold under the name of " Frenler." Messrs. E. B. Cox & Co., of East End Market, are the local agents. Its efficacy has not been proved in this State, but it is under trial this season. (2) It is not possible to say what destroyed the cauliflowers you grew for seed, nor to devise a remedy. You should always forward a specimen of the diseased plant when seeking advice respecting methods of prevention.

SOME PARASITES AFFECTING FARM ANIMALS.

By F. Murray-Jones, L.V.Sc., Veterinary Department.

The subject of parasites and their effects on the lower animals is of extreme importance. Losses from this cause are very heavy, and in some years amount to a veritable scourge.

Parasites are organisms which pass the whole or part of their life living on or being nourished by other organisms. They may belong to the vegetable or animal kingdom, and in these attacks a distinction is made between those that only by accident, as it were, live on animals, and those which are unable to live or complete their cycle of existence in any other way. The former are called facultative or occasional, and the latter obligatory or constant parasites.

Animal parasites may be divided into two classes; those that live outside and those that live within the body. Zoologically, they are divided into three classes—(1) *Arthropodes,* (2) worms, (3) *Protozoa. Arthropodes* are jointed insects, *i.e.*, ticks. *Protozoa* are single-celled organisms, *i.e.*, group of *Trypanosomata,* some species of which are responsible for diseases affecting horses and other animals, *i.e.*, surra, dourine, &c.

HELMINTHS OR WORMS.

The object of this article is to deal more particularly with the second group, known as *Helminths* or worms, for it is to this group that many of the important parasites or worms affecting our stock belong. Now, the *Helminths* are divided again into two groups, the broad line of differentiation being that one are flat worms and known as *Platyhelminths,* and the other more rounded and spoken of as round worms, or *Nemathelminths.*

Reference to the following tables will quickly explain how these groups again are divided into sub-groups and families :—

Group.	Sub-Group.	Examples found in.
Platyhelminths (flat worm)	*Cestodes* (tapeworm)	Dog, cat, sheep, rarely horse
	Trematodes (fluke worm)	Sheep and cattle
Nemathelminths (round worm)	*Acanthocephalid* (thorn-headed worm)	Pig and fowls
	Nematoda (common round worm)	Dog, cat, horse, cattle, pig, and fowls
	Oxyuridæ (pin worm)	Man, dog, horse, rabbit
	Strongylidæ (strongylus worms)	Horse, cattle, dog, sheep
	Trichotrachelidæ (whip worm)	Man, dog, pig, fowls
	Filariidæ (filariæ)	Horse, cattle, dog, fowls

Illustrations from Neumann's Parasitology.

A few examples of some of these worms will be dealt with, giving a brief account of their life history, habitat (animal and organ invaded), effect and treatment where possible, and, in addition, a few general suggestions as to the means of prevention.

CESTODES.

The group of *Cestodes* present to us not only a group important from a scientific and economic standpoint, but one exceedingly interesting as to the mode of development of the individual from the time of the worm's inception to its more mature or adult existence. First of all we observe two develop-

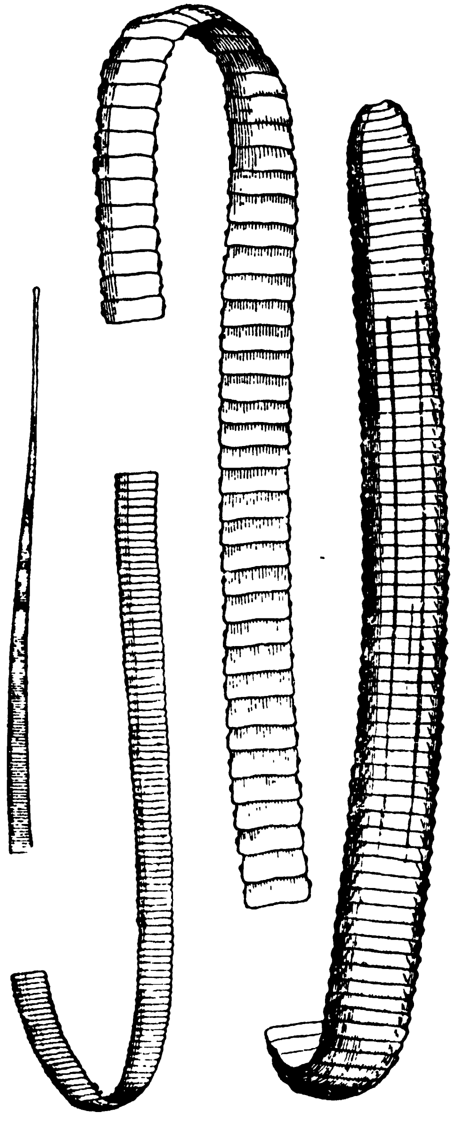

FIG. I.—TAPEWORM IN SECTIONS (*Tænia expansa*, often 20yds. to 30yds. long).

mental phases. The first, as a bladder worm and called a *Cystercerci*. Secondly, the fully matured worm. So that between one mature worm and the next one we get a cysterci. The cystic stage is found in one animal and conveyed to another as the result of ingestion of an infected organ. This cyst contains a scolex, or head. This head is armed with several hooklets, by means of which it attaches itself to the lining of the alimentary canal. From this head there grows, by a system of budding, a number of segments, and known as *Proglottides*. Those nearest the end of the worm ripen first; by this we mean, are ready to break away and discharge the eggs contained within. Now, each segment is so provided that it is able to produce the eggs of the future worm. That arrangement is one containing both male and female organs. Each segment is so furnished quite independently to the next. After ripening, the segment breaks away and may be conveyed to the outside world loaded with eggs, or it may rupture inside and so allow the actual eggs to escape. Finally, the eggs reach the ground, and, as the result of rain, may become washed into the watercourse and eventually into dams and drinking water.

A brief summary of the life cycle is as follows :—The egg, reaching the drinking water, being conveyed to another animal with water. The egg changing into an embryo in this animal becoming encysted, *i.e.*, surrounded with a bladder-like structure. Finally, the eating by another animal of organs infected with this cyst, and followed by freeing of the armed head, and from which then grows the worm composed of segments and called *Proglottides*. The point to remember is that at least two animals are needed before the tapeworm can reach maturity. To quote a few examples of the above—

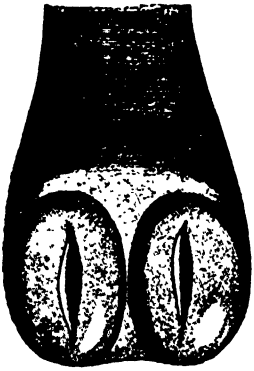

FIG. II.—HEAD OF TAPEWORM (*Tœnia expansa*). Magnified 40 diameters.

1. The tapeworm of man (*Tœnia solium*) passes its cystic stage (*Cysticercus cellulosœ*) in the pig.

2. Another of man (*T. Mediocanellata*) pass the cystic stage (*C. Bovis*) in the ox.

3. Tapeworm of lamb (*Tænia expansa*), often 60ft. long. The cystic stage is found in dogs, hares, and rabbits.

4. The tapeworm of dog (*T. Cucumerini*), most frequent of all. The cystic stage of this one is found in body of dog flea (*Pulex seraticeps*).

5. Another of dog (*T. Serrata*) lives its larvæ stage in the abdomens of hares and rabbits.

6. The *T. Marginata* of dog forms the *Cystic tenuicollis* of cattle.

7. The *T. Cœnurus* of dog, the larvæ stage being found in the brain of sheep (*Cystic cerebralis*).

8. The *T. Echinococcus* of dog has its larvæ stage in the liver and lungs of ruminating animals, and known as *Echinococcus veterinorum*.

PREVENTIVE MEASURES.

The cystic disease of pig and ox is caused by consuming food contaminated with human excreta from human beings affected with those two varieties of tapeworm. This fact argues for the higher standard of sanitation being maintained, and as far as man is concerned, the thorough cooking of meats used for human consumption. Care should be taken to prevent dogs frequenting slaughterhouses, especially in country towns, in order to minimise the chances of their obtaining offal from infected animals whereby they are likely to so further the spread of infection.

Dogs harbor the greatest number of varieties of tapeworm, and are the means of infecting sheep and cattle with the *Cœnurus cerebralis*, and cattle with the *C. Tenuicollis* and *Echinococcus.* All dogs employed with sheep should be treated periodically with worm-expelling medicines. They should be chained up whilst under treatment, and all their excreta should be carefully collected and burned. Children should be discouraged from the practice of allowing dogs and cats to lick them during affectionate embracing. The writer on more than one occasion has *post-mortemed* dogs and cats infested with worms, and yet these animals had been the constant playmates of young children where their mouths had been in mutual apposition.

Care should also be taken, where possible, to wire off kitchen gardens, especially where those edibles such as lettuces, onions, and radishes are grown. These foods are not boiled in preparing for the table use, and so the danger of infection along this path is obvious. The writer has a lively recollection of destroying a fox terrier whose constant playground had been the lettuce bed. In this case the animal's intestine was teeming with parasites. The significance in that case is apparent.

TREATMENT.

Horses are not subject to this variety of parasite to any extent.

Cattle.—Free access to salt and sulphur licks and the administration of oil of turpentine and linseed oil (1oz. turpentine to 4ozs. linseed), mix, and give in feed every second day for a week.

Sheep.—Remove sheep, especially lambs, away from infected paddocks. Place the following mixture in troughs easy of access as a lick :—Sulphate of iron 1lb., sulphur 8ozs., salt 2lbs. The best way, perhaps, is to make up this mixture in a kerosene tin and give 2ozs. per head per day for 10 days with food.

Dogs.—Strict attention to prevent eating diseased offal. This will apply more to country than to the city with a strict system of meat inspection. Chain animal up for a day or two before treatment on starvation ration. Administer from 1oz. to 3ozs. of castor oil, according to size of dog. Give ½oz. to 2ozs. of turpentine beaten up in yolk of an egg. Follow up next day or two with 1oz. to 2ozs. castor oil. Regulate dose to size of dog.

Cats.—Teaspoon to tablespoonful castor oil. Follow with 6 grains areca nut in saucer of new milk. Give two doses and follow with another dose of castor oil.

River Murray Reclamation Works.

FARM BUILDINGS.

STABLE, MACHINE SHED, AND BARN.

At a meeting of the Green Patch Branch of the Agricultural Bureau, held on October 24th, Mr. C. J. Whillas (Hon. Secretary) read a paper on and submitted plans of a farm building, including stable, barn, and machine shed, as follows :—

" No standard type of building can be laid down to suit all farms, for conditions vary in almost every case, such as building material most cheaply available, the depth of the owner's pocket, and his notions of what is necessary and expedient for his purposes, and the owner's experience and ability at construction work, for in most cases he has to do his own building.

" A farm stable should protect the horses from rain, extreme cold and heat, be perfectly dry, and well drained underfoot, be economical of labor for feeding and handling horses and cleaning out, and, in addition, should have a feeder that will not waste chaff, should have stalls so that the strong horses cannot bully the weak, and should be, but seldom is, fowl proof.

" The barn and chaff shed should be of ample dimensions to store more than a season's supply of seed, grain feed, and super., and at least five tons of chaff ; keeping all perfectly dry and mouse proof. For the barn and chaff shed I prefer iron to stone, as the latter is difficult to keep mouse proof. A brush or straw shed for this purpose is quite unsuitable.

" When the material is close at hand and can be had for the cutting, no doubt a well and strongly built shed of heavy forks and rails, and covered with straw for stables, walling in the end and back behind the feeder with a stone wall, would prove the most suitable. The stalls should be 6ft. wide, with a separate feeder for each horse of 3ft. x 2ft. x 2ft. deep, made of old cases and fitted with a lid, and seated between posts and rails at 1ft. above the ground, so that it can be taken out and upset for cleaning out. Stables, where possible, should have their back wall behind the feeders facing the coldest winter storms.

" My own stable is of stone walls and iron roof, and faces the opposite way ; but is walled behind the horses, with a door and gangway behind the stalls wide enough for a dray to come in to clean out the stables. On the open side, behind the feeder, is wire netted, and the building is therefore fowl proof when all the doors are kept shut. The main thing against straw-roof stables and machine sheds is their danger to fire ; also they give no water catchment where the same is required.

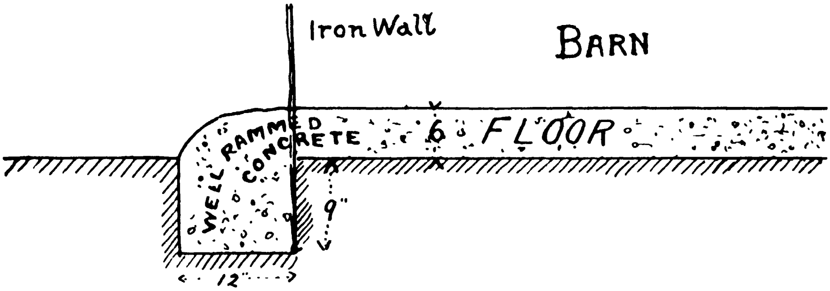
" NOTES ON PLAN.

" The design is for one galvanized iron building of 64ft. x 31ft. over all dimensions, in which will be stabling for 12 horses, a machine shed 48ft. x 16ft., barn and chaff room 15ft. 6in. x 23ft., and cover for chaffcutter, and which can be used for shearing if necessary. Throughout I have endeavored to cut the cost down to the finest limit. All uprights shown are for bush timber —pine, gum, sheaoak, mallee, or whatever may be available, provided it will stand in the ground and can be got fairly straight. If bush timber is not available then substitute jarrah, using 4in. x 4in. for the main uprights supporting roof, and 3in. x 1½in. for the studs that just have the wall iron to carry. In the plan the latter are shown as a round post split in two. Using jarrah uprights would add about £5 to the cost of the material. The wall iron is shown nailed on horizontally, this requires less timber and better stays the building than iron on vertically. The roof iron should be given 1½in. corrugation lap.

" All the roofing timber shown is V.D.L. (Tasmanian stringybark). This is stronger and much cheaper than oregon, but is not so nice to work, nor will it make so neat a job. The stalls are shown 8ft. wide, each for two horses ; 4ft. is plenty wide enough for a horse to feed, but not to lie down in. If single horse stalls are required they should be 6ft. wide. The barn and chaff room as shown are floored with concrete. Over the concrete in the chaff room put a removable floor, made of old packing cases nailed to 1½in. x 1½in. V.D.L. slats. In the barn, of course, dunnage would be used under any grain, etc, stored therein. To make the barn more or less mouse proof, trench for iron walls 9in. deep x 12in. wide all round the outside walls, then iron from the bottom and fill up the trench with concrete to 6in. above the ground level, as shown in the sketch.

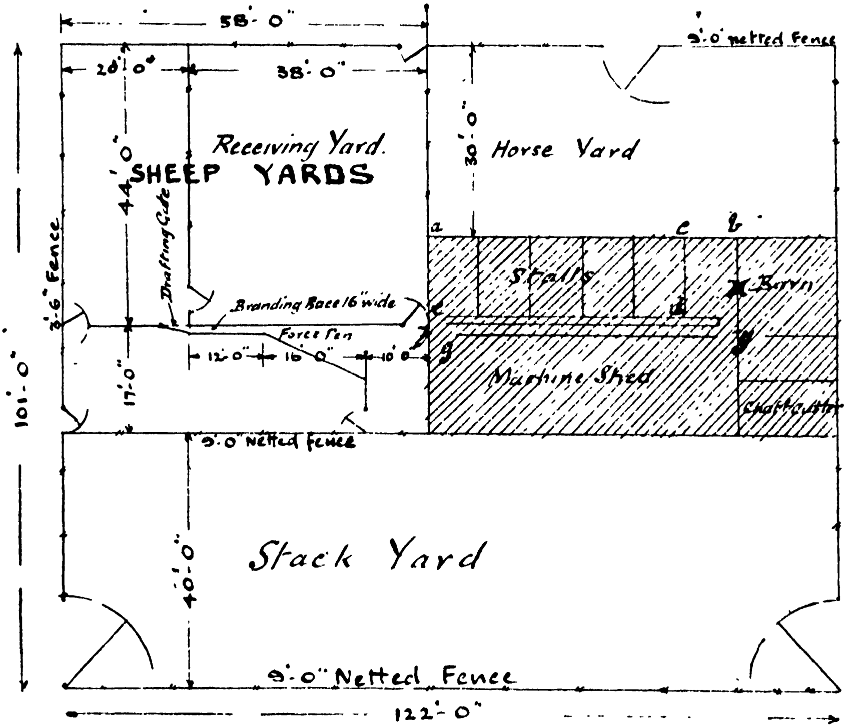


" Also cover all roofing timber leading to the barn from other parts of the building with plain galvanized iron, or any old tinned iron, for at least 18in. of its length. The doors to the barn would require to fit neatly to the door sill. A surer mouse-proof barn could be constructed by using a strong wooden floor supported by a number of short posts 2ft. above the ground level, all posts being covered with plain galvanized iron for 18in. of their height. This would be an expensive floor and would lessen the head room of the barn and chaff room.

" To use the building for shearing, follow the general plan, and erect a hurdle across the front of the stable *a b* and first stall *c d*, put grating in this stall for catching pen. At *x* in barn wall have a removable panel, say 6ft. x 3ft., which must be made a fixture when shearing is not being done and the horses have the run of the stable. Put the removable wooden floor from chaff room down in the barn for shearing on. Then operate as follows :—Force the sheep from the small yard through door *z* in end of feed gangway into the horse stalls *a c d e*, using this as a sweating pen, and the first stall as a catching pen. Pull the sheep through panel *x* into the barn and shear in the barn, letting the shorn sheep back through the door at *y* into the gangway behind the feeder, and thence to branding yards.

GENERAL PLAN SHOWING YARDS.

Scale, 20ft. to 1in.



- " Should the stable and barn be required at shearing time, shearing should be done at *g*, in the machine shed, making a small catching pen in the gangway behind the feeder, and using a tarpaulin to shear on.

"The material required for this building, omitting bush timber for uprights, is as follows:—33cwts. 26 gauge 8ft. sheets corrugated galvanized iron; eight sheets 6ft. x 3ft. plain galvanized iron, 26 gauge; 12 lengths 12in. ridgecapping, 26 gauge; V.D.L. timber as under—6/16ft. of 9in. x 1in., 18/16ft. of 4in. x 2in., 9/14ft. of 4in. x 2in., 32/16ft. of 3in. x 2in., 8/16ft. of 9in. x 2in., 7/16ft. of 1½in. x 1½in.; bolts, ½cwt. 9in. x ½in. and ½cwt. 4½in. x ½in.; 17 packets of 2in. spring head nails; 10lbs. 5in. wire nails; two packets 1in. clouts; 4/7ft. x 3ft. ledge doors of ⅞in. Baltic, fitted with T hinges (doors could be made of old packing cases if necessary). The cost of this material in Adelaide would be about £50."

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

The Year 1913.

Many events, interesting to poultry breeders, have happened during the year. Space does not permit any extended reference. A few of the salient features are—

Excellent Prices for Eggs and Poultry.—On the whole the prices for eggs were lower than during the preceding 12 months; but at no time has the market precluded profitable production. The quality of an increasing proportion of the eggs sent to market has shown satisfactory improvement. Despite the strenuous efforts to educate producers and the collecting trade, it is noticed that city merchants are still complaining of the large numbers of inferior eggs coming to the city. The unfortunate part of the business is that the careful breeders suffer, while the grossly careless people come off scathless. The superiority of the infertile egg is well, but still insufficiently, recognised. It would seem that some city and suburban stores would rather sell eggs of doubtful quality, to the annoyance of their customers, than give a little extra to encourage the production of infertile, high-grade eggs.

The price for table poultry shows a decided advance on the previous year. The growth in the quantity of poultry consumed in the city and suburbs is a sign of the times. Householders are becoming aware of the dietetic value of poultry, and also appreciate the benefits derivable from a change of the old-time constant *menu* of butcher's meat, which is now dear. Old hens and birds of generally inferior quality have sold at prices which must be more satisfactory to the seller than to the buyer. Plumper and younger birds have changed hands in thousands at prices which would, a few years ago, have been deemed absolutely prohibitive. So far we have been classed as an egg-producing State ; the future will witness a strong movement in the direction of production of better quality table birds, through the distribution of the recognised all-round, or general purpose breeds.

Country Breeders.—A few years ago in most country centres there were fanciers who bred for exhibition chiefly ; many of these remain. Farmers generally kept fowls and other poultry, and paid but scant attention to questions of breed and strain. During the 12 months under review a large number of country residents have devoted attention and some capital to the breeding of poultry on modern lines. At times it has been difficult to keep pace with the demand for information, and for plans of yards and houses. This is a most satisfactory state of affairs. It is due to the fact, mainly, that it has been demonstrated that there is a science in handling poultry, and that the results are as sure as the results of any other agricultural operation, and are very profitable. There is every proof that the demonstration work on the poultry station, the articles in the *Journal*, official reports, and the general work of the department are chiefly responsible for the excellent movement now in such strong evidence.

Concentration of the Poultry Stations.—This important event received Government approval early in the year, and ever since the whole poultry staff have experienced most strenuous times. The justification of the centralisation of all educational and demonstration work is evident, and time will add ample proof. A few local people may feel grieved that a certain station is no more, but it must not be forgotten that most country people visit the city at intervals, and the facilities for visiting the conveniently central poultry station at Parafield will be availed of by hundreds, where previously the numbers could be counted in scores only. Duplication of any experimental work is unbusinesslike, and serves no good purpose. Experiment on the larger scale now possible will be more in accord with commercial requirements. To be of high value all such work requires constant supervision, so that all facts may be noted and recorded.

Country Lectures.—In former years one addressed small audiences of the chosen few, as a rule. During the last few years the attendance has largely increased, and has been thoroughly representative of the whole producing community. Many localities have been, by special invitation, revisited, generally for the purpose of giving an address on the higher and often complex scientific features of poultry-breeding. There is perhaps no sign more pregnant of future advancement than the growing inclination now so prevalent among our producers to learn the exact why and wherefore. Unfortunately, science, which precisely means knowledge of facts, is by some confused with theory, which may not deal with ascertained facts.

Unlimited Expansion.—Some people have timorously expressed the opinion that the great growth of poultry-breeding establishments may mean a general state of overproduction, and consequent low prices. Such an idea is erroneous. There is room for unlimited expansion. Our production is barely in the infant stage as yet. When we have ten or fifty times the quantities of good eggs and table poultry, there will be more organised effort in exploiting the many excellent markets. It must be always remembered that poultry products are chiefly eggs and meat, *i.e.*, food. The people of the earth are increasing and multiplying, and to feed them is the problem of the future.

GENERAL ADVICE FOR 1914.

Resolve to improve your methods generally. In breeding you cannot stand still—you must go forward, or you will recede.

Breed only from the very best specimens for the purpose you have in view.

House your birds on modern principles, and remember this is of high importance. Feed your birds scientifically, and remember that table birds and layers need different treatment.

Read all you can, but be careful that you select wise teachers.

Cultivate the faculty of observation. Note all details, and commit them in concise form to writing. Recorded facts are of the highest value for future comparison—some memories are treacherous.

Do not blunder along in ignorance. If you do not know, it is not at all derogatory to ask advice. Many who would fain pose as experienced breeders would derive much benefit from the advice of those who know.

Eradicate all vermin. Wage ceaseless warfare against these parasitic disease distributors. Deal promptly with diseases. You must stamp these out by following nature's plan. The unfit should not be assisted to survive, but should be absolutely eliminated. Learn this lesson; it is perhaps the most important.

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

HEALTH.

The general health has been good. There have been a number of deaths due to various causes, such as vent gleet, oviduct troubles, wasting, two from heat apoplexy, and two found dead from no apparent cause.

BROODINESS.

As might be expected at this season of the year, there are numerous cases to record ; but the total, 153, is less than during November, when there were 160 cases. The various sections contributed as follows :—Section 1, 64, as against 68 ; section 2, 70, as against 75 ; section 3, 19, including four Black Orpingtons and four Langshans. All the Leghorns which become broody are marked, so that their owners can discard them as breeders later on.

MOULTING.

A few of the pens are showing signs of a light moult. It is probable that moulting will be early this year. An early moult is desirable from the breeder's point of view.

WEATHER.

The weather, generally, has been seasonable ; there were a few very hot days, and heavy rain, 1·97 points, most of which fell during a short period, when 83 points were recorded.

VISITORS.

Twenty-two persons visited the station—a total to date of 776.

LAYING.

The ninth month has now passed, and although there is a seasonable falling off in the grand total, viz., of 1,048, as compared with the yield for November, the averages are still better than for the same period at Roseworthy last year. The scores are :—Section 1, 11,244 ; section 2, 1,754 ; section 3, 2,713 ; total, 15,711 ; as against November. 16,759. For the corresponding period last year at Roseworthy Poultry Station the pen average was 863·6 from 103 pens of White Leghorns. This year from 102 pens of the same breed the average is 886·3, that is an increase per pen of of 22·7 eggs. The heavy section pen average last year was 688·8, and for the same period this year it was 732·7 ; an increase per pen of 43·9 eggs. The outstanding feature so far is the consistent laying of the leading pen, which has for the period, viz., nine months, established a fresh record for this State. This pen's total for nine months is 1,164, as against the previous highest, 1,158. Of course much may happen during the three months before the termination of the test. Whether a new record will be made is a matter for the future. What appears likely and, to my mind, far more satisfactory from the larger point of view is that the general average will be high, and that there will be a good many pens with large scores. When it is remembered that this is the biggest competition ever organised, and containing 300 more birds than have elsewhere competed, the results to date may be deemed satisfactory and the prospects encouraging.

1914–15 LAYING COMPETITIONS.

Section 1 is open to the world. Breeders are requested to make their entries as soon as possible, as the number of pens is limited. Ten pullets in a pen. Entry fee, 10s.

Section 2 is for competition among farmers, pastoralists, fruit and vegetable growers. Producers should support this section by entering ten pullets ; fee 10s.

Section 3—Single testing light breeds. Only 30 entries in this section can be received. Six birds each entry. Fee 20s.

LADS FOR SOUTH AUSTRALIAN FARMS.

By Thos. E. Sedgwick.

No better example could be shown of an ounce of fact being worth more than a pound of theory than to state the history of placing town lads on farms. When the idea was first mooted, four years ago in England, it was decried by social students and others, who regard themselves as experts, as impossible—foredoomed to failure. It was alleged that the boys would drift back to the town, that they would not take kindly to farm work, and that the farmers would illtreat them in every way. A committee of managers of lads' clubs, brigades, and other associations was formed to draw up a scheme and to advance the idea as far as possible at home. They were convinced that the securing of permanent prospects and employment and good conditions of life were far more desirable to the recipients than merely affording them an opportunity for relaxation and physical development in some of their spare time. As, however, there were and still are far too many workers at home for the situations available, and casual work is the rule rather than the exception in many callings, it was obvious that no improvement in this direction could be attained without the co-operation of the Governments over seas. As a 12 month's correspondence produced no tangible result, it seemed to me to be necessary to come out to Australia to plead the cause of the lads in person. The New Zealand Government agreed to try a small party of 50 lads as an experiment, and to the proposal that these should be apprenticed to selected farmers under Government supervision, they tacked the banking of wages (except for pocket money), so that each lad at the conclusion of three years will have from £80 to £100 saved. Within the first two months of their arrival applications were received from farmers for another hundred similar lads, although there were no applicants at any of the labor exchanges throughout the country for farm work. The farmers with whom the 50 boys were placed are more than satisfied, and the lads themselves cannot speak in too high terms of praise of the treatment they have received since arriving in New Zealand.

The value of town lads for farm work having thus been proved, the matter has been advocated in the different dominions of the Crown. The Government of Victoria, who, in the middle of 1909, were unable to do anything with regard to the immigration of lads, are now prepared to place 3,000 British lads in the current year, provided they are of good character, intelligent, healthy and well-developed, and willing to take up farm work. They at first received small contingents of unemployed lads from England who gave considerable satisfaction, and they find that those who are willing to relinquish situations they hold in order to come out to Australia give even better results. The great difficulty has been that the people in England do not like to advance money to lads unless they are assured of its being collected back by officials in Australia ; and provided the money is so collected back, there does not seem to be any reason why it should not be advanced by the Government responsible for so recalling it. The younger the lads are brought out, provided they are over 15, the better they will settle, and the more useful they will be in the house as well as on the farm. As wages are too low in England to enable the lads to save their fares this can only be done by advancing the amounts, to be collected back out of wages ; which is quite easy to do under apprenticeship.

It is evident that junior migration is now becoming the leading feature in the better distribution of the population of the Empire. The cost of supervision is greater, but the added advantages compared with adult migration more than compensate for the extra expense involved. The State gets a longer life for the same fare ; young people settle best, and adapt themselves most readily to new environment. They also act as centres of immigration to their friends and relatives from home. They learn to save, settle, and, in the natural course of events, marry. Being young, they can take up virgin land in the back blocks, which men with families find it impossible to do. All their children being born under the Australian sun are healthier and their fares are saved. Lads are better able to repay their fares after arrival than are married people, and they can make a sufficiently good place in the world to keep them free from the old age pensions. Coming to the country before they are fully grown they are able to expand to their fullest development. Town lads, especially, have nothing to unlearn, learn quickly, and are willing and speedy. After a month on the land they know more of rural work than lads who were born in the country at home have ever learned. The latter also are never able to acquire that quickness, both of mind and body, which can only be engendered by life in a busy city.

Perfection in junior migration is only to be attained by care in the selection at home, in the supervision on the voyage, and in placing out lads.

Every young person should know the conditions under which they will have to work and live, and should understand the hours, distance from town, and climate. The picture should not be painted in too rosy colors. Supervision on the voyage keeps the young people fit, keen, and out of mischief.

The best form of placing out is apprenticeship to carefully selected employers, those from one place or district at home being placed in the same area of distribution here. Before any agreement is signed, the boys should be tried with their employers for a month, and the agreement should stipulate—

(1) That the employer should be at liberty to request the official responsible for the young people to remove them if they are guilty of misconduct sufficient to justify an ordinary employé being dismissed.

(2) That the official should be at liberty to cancel the agreement and to remove the boy if he considered they were in any way not being properly treated.

(3) That the wages should be banked (except pocket-money) in the joint names of such official and the individual employé. This encourages thrift, prevents a panic, running away to town, and provides a nucleus for future settlement.

Apprenticeship secures the workers to the employers who have trained them, and assures their being properly taught. It is of advantage to all concerned, especially those in the town.

The South Australian Government have now decided to develop this form of migration, and have recently passed an Act of Parliament to enable it to be done more efficiently. The amount of the assisted fare will be payable out of wages after arrival, and for the next few years the wages will be paid to the Treasury on the boys' account, where the amount so deposited will bear interest at 4 per cent. In the event of the boys being guilty of serious misbehaviour or of wilful neglect of duty the Minister of Immigration is empowered to fine a boy out of his wages, the money so forfeited being applied to payment of bonuses to other boys, having regard to their behaviour and attention to duty. The Minister can also place any boy in an institution if he thinks that such a course is desirable. Any persons who counsel or induce lads to abscond from their employer, or to break their agreement, or in other ways assist them therein are liable to a fine of £20 or imprisonment.

At the conclusion of the apprenticeship, which will be for at least 12 months and not more than three years, the lads will be able to take up farm work at men's wages, and will have a nucleus saving of about £30 a year on the average, to which they will be able to add sufficient in a few years to enable them to take up some new country on their own account; and it is hoped that many of the boys will join their forces and take up adjacent holdings, so as to avoid the loneliness which is usually experienced by pioneers, to exchange their labor, and so keep down the cost of clearing, and to purchase requisite machinery on a co-operative basis.

A small experimental party of 81 of these boys were tried in South Australia this year without apprenticeship, and after they had been in the country for four months a satisfactory report was received from the Immigration Officer as to their repayment, behaviour, and general results.

THE APPRENTICESHIP AGREEMENT.

The Commissioner of Crown Lands and Immigration (Hon. Fred. W. Young) has arranged for full particulars with regard to the conditions of

apprenticeship of lads to be placed with farmers under the Immigration Act Amendment Act of 1913, and copy of proposed apprenticeship agreement to be published in the next issue of the *Journal.* Farmers and other producers desirous of obtaining a boy are invited to communicate with the Immigration Officer, Crown Lands Office. The first party of lads will probably arrive in May, 1914, and to avoid disappointment early application is advisable.

Excavator, Mypolonga Reclaimed Area.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, December 10th. In the absence of the Chairman (Mr. G. R. Laffer), Mr. F. Coleman (Vice-Chairman) presided. Others present were Professor Perkins, Col. Rowell, Messrs. C. J. Valentine, A. M. Dawkins, C. E. Birks, and J. Miller, and the Secretary (G. G. Nicholls).

Fruit Exports.

The following resolution from the Forest Range Branch of the Bureau was tabled :—" That the Advisory Board be asked to bring under the notice of the proper authorities the weakness of the Commerce Act in allowing small and unsound fruit to be shipped to oversea markets, and that the inspectors be given power absolutely to prohibit the shipment of unsound fruit." In an accompanying note the Branch remarked—"At the present time it is possible to ship any sized apples, providing they are branded as being under 2¼in. According to a circular issued by an exporting firm, apples shipped have been as small as 1½in. in diameter. This stuff must be injurious to the trade." It was decided to refer the matter to Col. Rowell and Mr. Laffer for a report. The former explained that a full description of the fruit was marked on each case, and, personally, he was convinced that when they realised that they got little or nothing for it growers would cease sending unsound or undersized fruit.

Experiment Farm in Drainage Area, South-East.

The Penola Branch intimated that it was in favor of a proposal for the Government to establish an experiment farm in the drainage area on the heavy land, and suggested " that about 1,000 acres adjoining and including Yallum House, which is available, would fulfil all requirements of suitable soil and central position." The communication was referred by the Board to the Director of Agriculture for his consideration and opinion.

Water for Stock.

The Secretary stated that recently, following upon a report from the Agricultural Chemist at Roseworthy College (Mr. J. H. Phillips), the Principal (Professor Perkins) had forwarded a minute to the Director of Agriculture (Professor Lowrie) suggesting that the co-operation of the various Branches of the Agricultural Bureau, particularly those in the drier areas, should be sought with a view to obtain samples of water used for stock for the purpose of ascertaining the quantity of dissolved salts which might be contained in water suitable for stock. In communicating with the Advisory Board on the subject, Professor Lowrie had remarked :—" I consider this a good suggestion. I had some inquiries made some time ago in respect to the degree of salinity of water that could be tolerated by stock, and I submit a memorandum from Mr. J. W. Jones (Secretary to the Commissioner of Public Works), giving very useful information. As evidence that the Agricultural Bureau might be used to advantage for the furthering of information on this matter among farmers, I may say that last month I received a letter from a farmer to this effect :—' I am sending you a parcel containing a bottle of water. Can you get it analysed for me ? I have a grazing property north of Darke's Peak, and water supply is from open dams. This water is taken from one of them. The dam is 320ft. long, 135ft. wide, and 16ft. deep, and when about 6ft. of water had been used out of it the remainder went bad, and we do not know what is wrong with it. It made the cattle vomit badly, and about a dozen of them died in great pain. The dam has been down several years, and this is the first time anything has gone wrong. As it was it put us in a corner, and we had to shift the cattle away quick and lively, or we would have lost the lot. It made them all bad, and besides 12 dying the others fell away badly in condition. I should like to find out what is wrong with the water.' On analysis this water was found to contain 1,122 grains of sodium chloride per gallon, and total solids 1,368 grains per gallon, which, I think, sufficiently accounted for the farmer's loss of cattle. I replied to him to that effect, and pointed out that with a little more concentration due to evaporation this water would have approximated in salinity to sea water. I shall be very glad if samples can be secured from the Branches in those districts where stock water more or less saline is used. I think it would be well to start getting samples from one or two districts only in the first instance, and working it as the analyst at the College can find time to undertake the analyses."

FOUR TESTS.

The memorandum from Mr. Jones contained analyses of water from four distinct localities, and of entirely different qualities. It stated, among other things—" No. 1 is a sample of water from Shaw's dairy farm near Woodville. The water was pumped from a depth of about 30ft. The remarkable fact is, notwithstanding that it contained a large percentage of sodium and potassium chlorides (83·40 grains per gallon) and other salts, the water was used successfully, and probably is still used, for the irrigation of lucerne. No. 2 is an analysis of water from the bore at Hergott. This water has been used for many years in watering dates, and now is used for general purposes in the township, although it shows sodic and potassic chlorides to the amount of 85·69 grains per gallon. No. 3 is an analysis of water from Nullarbor Plains, near Eucla. The water is both bitter and saline, and contains sodic and potassic chlorides aggregating 716·10 grains per gallon. It is a remarkable fact, however, that this water has been used for many years, and, indeed, is the only water available (1911) for sheep, cattle, and horses. The well is a wonderful success, and there has never been a complaint regarding the quality of the water for every purpose but that of drinking. The herbage on which the stock feed is chiefly saltbush with a little grass. No. 4 is an analysis of water from Tonkin's Well, near Tarcoola, which contains sodic and potassic chlorides totalling 646·71 grains per gallon. It is slightly better than the Nullarbor Plains water, but in this instance and this particular district the water was considered too saline for horses. It was used principally for sheep and to a small extent for cattle. I consider, and my opinion is supported by the officers of the Engineer-in-Chief's Department, whose work calls them to the country in connection with the wells and borings, that the maximum salts for sheep water should be 2ozs. per gallon, and for horses 1½ozs. per gallon. The latter is too high for horses well used to fresh water." At the instance of Mr. Jeffrey, the Secretary was instructed to ask the Northern Branches to forward samples of water that were being used and had been used for some time for livestock without ill effects.

Demonstration Plots.

The Secretary reported that half a dozen or more Branches had determined to lay down demonstration plots in their respective districts, and that others had deferred consideration of the matter until after the harvest. The former included Parilla, Myponga, Wilmington, Nantawarra, Pine Forest, Crystal Brook, and Whyte Yarcowie.

New Members.

The following gentlemen were approved as members of the Branches shown, viz., Wynarka—A. M. Thomson, S. O. Thomson, V. F. Klose; Canowie Belt—G. Heinrich, G. U. Young; Mallala—G. W. Lindsay, K. Oliver; Two Wells—E. Jenkins, jun.; North Booborowie—J. C. H. Lange, A. C. Simpson; Port Elliot—J. Brown, jun., F. E. Hargreaves, S. Trestrail; Green Patch—G. Merchant; Monarto South—P. B. Frahn, E. Leishman; Blackwood—H. A. Banks, J. S. Treloar, R. Cook; Bute—A. Bridesen, A. E. Bryans, R. W. Herbert; Georgetown—C. Wilkins; North Bundaleer—M. J. McCarthy, W. Burgess; Lyndoch—G. Wilson, G. H. Stevens; Mount Pleasant—R. Walsh; Wepowie—E. F. Brown, J. G. Crocker, F. Hetzel; Mitchell—G. Mayhew, A. Gosden; Blyth—N. O. Williams; Meadows—E. B. Ellis; Clare—W. Muller; Berri—F. R. Clark, W. Morey; Miltalie—D. Ramsey, L. Aunger; Glencoe—H. A. Agnew.

Life Members.

The distinction of Life Membership was conferred upon three members of the Meadows Branch in recognition of extended and valuable service to the Bureau, viz., Messrs. J. Catt. T. B. Brooks. G. T. Griggs.

THE WHEAT MARKET.

The English wheat market was very quiet in tone during the greater part of December. Few sales of cargoes were reported, and trade generally was characterised as dull. Locally the market was irregular, as while the average price offering was about 3s. 5½d., several buyers were prepared to give fully a penny more for prompt delivery.

Under date London, December 5th, *Beerbohm's Evening Corn Trade List* states:—"Shipments last week were again on a large scale; the proportion to the United Kingdom was only moderate, but somewhat larger than in the previous week. Unless the United Kingdom receives a much larger proportion of the Russian exports than has been the case for a long time past, it does not appear probable that the weekly shipments to this country will be really large until Australia commences shipping freely.

"One third of the season is now over, and the exports to Europe in the four months, August to November, have amounted to 25,395,000qrs., or at the rate of 1,490,000qrs. per week, against estimated requirements of about 1,275,000qrs. per week, or for the four months 21,675,000qrs. The increase has been entirely in the Continental figures, the proportion of the shipments to the United Kingdom being just about equal to the estimated requirements, as is borne out by the stocks, which now amount to 2,250,000qrs., against 2,250,000qrs. on the 1st of August. Unless native wheat has been coming forward much less freely than the official estimates of this year's crops led the trade to expect, stocks on the Continent must have increased appreciably. So far as the United Kingdom is concerned the excess in farmers' deliveries, compared with last year, has amounted to only 240,000qrs., or at the rate of 720,000qrs. for the whole season, whereas, if the official estimate of the yield was correct, the increase in the deliveries of English wheat ought already to have amounted to about 700,000qrs. Some authorities claim that there is a larger proportion of this year's English wheat unfit for milling purposes than generally believed.

"It will be seen by the tabular statement given below that the world's visible supply has increased during November by 2,050,000qrs., against an increase last year of 3,665,000qrs., and a decrease of 425,000qrs. in 1911.

THE WORLD'S VISIBLE WHEAT SUPPLY ON DECEMBER 1ST.

	European. Qrs.	U.S./Canada. Qrs.	Total. Qrs.	Eng. Average Price.

Steamer Freights.—(January 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, medium size, Jan.-Feb., 30s. per ton (9⅗d. per bushel), March, 28s. per ton (9⅒d. per bushel); to South Africa, 26s. 3d. to 27s. 6d. per ton (8⅖d. to 8$\frac{9}{10}$d. per bushel), prompt or new season. Parcels, Port Adelaide to London-Liverpool, or Continent, 30s. per ton (9⅗d. per bushel); Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel); to Sydney, 10s. 6d. per ton (3¼d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 28s. 9d. to 30s. per ton (9⅕d. to 9⅗d. per bushel), new crop; South Africa, 25s. to 26s. 3d. per ton (8d. to 8⅖d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on January 1st—

Butter.—The weather during December was, on the whole, very favorable for the forwarding of produce, as no long spells of heat were recorded. Values in top grades of butter firmed appreciably, best factory and creamery, fresh in prints, selling at from 1s. 1½d. to 1s. 2½d. per pound; choice separators and dairies, 10½d. to 1s.; stores and collectors', 7½d. to 8½d.

Eggs.—The quantities arriving still continue heavy and prices rule a little easier, hen being 8d. per dozen; duck, 9d.

Cheese.—Very extensive business has been put through in this line, buyers operating freely for the Christmas demand, while the heavy figures also attracted heavy export orders. Present quotations—5d. to 5½d. per pound for large to loaf.

Bacon.—Values are a shade lower than the previous month, with good inquiry, hams as usual meeting with speedy quittance. Present rates—Best factory-cured sides, 10d. to 10½d. per pound; hams, 1s. to 1s. 1d.; well cut and cured farm middles and rolls, 7d. to 9d.; country hams, 8d. to 11d.

Honey.—Small lots of new season's take are now on the market, and all parcels coming to hand clearing. The present price for prime clear extracted is 3½d. per pound.

Almonds.—Last season's stock are practically finished, and the trade awaits the arrival of the new crop. Quotations—Brandis, 6d.; mixed softshells, 5½d.; hard shells, 3d.; kernels, 1s. 6d.

Live Poultry.—The month of December always brings heavy quantities of poultry for the Christmas festivities, and supplies this season far exceeded former years. However, demand was very good throughout and good prices were secured, especially for quality lots. Good table roosters brought 3s. 6d. to 4s. each; nice conditioned cockerels, 2s. to 2s. 6d.; hens, 1s. 4d. to 1s. 9d., a few coops of light sorts selling under; ducks, 1s. 6d. to 3s.; geese, 3s. 6d. to 5s.; pigeons, 5d.; turkeys, from 7d. to 1s. per pound live weight for fattening to good table birds, a couple of coops of very choice quality selling higher.

Potatoes and Onions.—There has been an active inquiry for potatoes, and the month ended with the relation between supply and demand sufficiently close to indicate that the Adelaide plains crops are approaching exhaustion, and prices have firmed a little. The early Gambier crops have been much benefited by recent rains, but this has delayed ripening to some extent, and in consequence deliveries during January may not be so heavy as usual. Onions—Although local crops have proved to be lighter than was expected, under the influence of forward quotations from elsewhere, prices have not quite held to the closing November level. Potatoes—New locals, £5 to £5 10s. per ton on rail Mile End; 4s. to 4s. 6d. per cwt. in the market. Onions—£8 to £9 per ton on rail Mile End; 7s. to 8s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of December, 1913, and the average annual rainfall.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

February 11th and March 11th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

HOOKINA (Average annual rainfall, 12in.)

December 9th.—Present: seven members.

Hay-Making.—Mr. S. Stone read a paper as follows:—"Where large quantities of crop have to be cut with one machine it is advisable to commence as soon as the wheat is in flower. This will give the grower a chance to finish before portion of the crop becomes too ripe. If some of the sheaves are dry and some a bit green it will make a good sample of chaff when mixed. Another way of working the crop at the most opportune time is to sow both early and late samples, so that by the time the early varieties are finished the late will be ready for the binder. King's Early, Fill-the-Bag, and Bluey can be worked in this way, and are also excellent wheats for hay. The binder is by far the most economic and labor-saving machine to deal with large quantities of crop. It is a good plan to leave sheaves on the ground for a day after being cut before stooking. They will then be ready to go into the stack much sooner than if stooked immediately. The sheaves will also keep a better shape. Sometimes when they are stooked green a heavy wind will twist them and make stack-building difficult. About a dozen sheaves will be sufficient for one stook. When stack-building keep the outside sheaves as level as possible, especially where short sheaves have to be dealt with. There will then be little chance of the stack slipping. The centre should be kept higher than the outside." Members agreed with the paper generally, but were of the opinion that methods were dependent on prevailing climatic conditions. Farmers would need to use their judgment as to the best time to stook and stack hay.

WEPOWIE (Average annual rainfall, 13in. to 14in.).

November 19th.—Present: 14 members and three visitors.

Horse-Breeding.—Mr. J. Orrock contributed a paper on this subject in which he stated that many farmers favored the so termed "mongrel" horses in preference to the well-bred draught. The former were generally less costly and more lively and active, and would thrive better than the latter. In districts where the soil was sandy a light team was more serviceable. For breeding he would select a mare that was staunch, shapely, quiet, and free from blemishes such as ringbone, stringhalt, or splints. She should have a roomy frame, with hips sloping somewhat, be a little above average length, wide chested, deep in the girth, and possess strong quarters. The animal should be in good condition prior to being put to the horse. He believed in steady, constant, and light work to within a few days of foaling. During gestation the mare should be carefully treated, and not overfed with rich food. This, and excitement, often caused abortion. He preferred the Clydesdale type for use in this district, as strong and active horses were needed to work the heavy soil.

WILMINGTON (Average annual rainfall, 18·16in.)

December 10th.—Present: 14 members.

Co-operative Marketing of Produce.—Mr. G. Shuppan contributed a paper on this subject, in which he stated that it was necessary, in order that they might receive the full value of their produce, for producers to co-operate in selling. One difficulty in connection with the application of this system to the wheat harvest was that the majority of farmers would not feel disposed to wait for payment until returns were secured from the oversea markets.

WIRRABARA (Average annual rainfall, 18·91in.)

December 13th.—Present: 13 members.

Marketing Orchard Produce.—The Hon. Secretary (Mr. A. R. Woodlands) read a paper. First quality fruit only, he said, should be marketed fresh. Second grade stuff should be dried, canned, or manufactured into jam. Co-operative jam factories were recommended. Every grower in a large way should export portion of his crop of pears and apples each year in order that prices in the local market should be kept at a remunerative figure. Co-operative packing for export had proved an absolute success in Victoria, and it might with advantage be tried in this district. The use of the standard case should be enforced. Members agreed that there was a much more ready sale for first quality than second quality fruit. Co-operative packing sheds were favored.

DAWSON, November 9th.—**Exhibits.**—The Chairman (Mr. J. Thomas) tabled samples of lucerne. One cut from a manured plot showed splendid growth, and was at least 6in. higher than a crop on unmanured land.

Crop Reports.—It was reported that the crops in this district would probably be very light owing to the scanty rainfall. Those on stubble ground would not be worth reaping. There were good crops, however, nearer Hallett and Mount Bryan.

MORCHARD, November 15th.—**Summer Fallowing.**—Mr. R. Kitto contributed a paper on this subject. He advocated burning the stubble, then working the land with a spring cultivator. It would then be found that after seeding there was a good crop of rubbish on the land, and it could be worked in the opposite direction. Another cultivating should follow in the spring, and the harrows should cross the cultivating after every rain.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

BURRA (Average annual rainfall, 17·82in.).

November 14th.—Present: four members.

Hay-Making.—Mr. H. Cullen contributed a paper. Wheat sown for hay, he said, should be of an early variety. It was necessary to exercise every care in stooking the early-cut hay, as it was very liable to sweat. When stooking close behind the binder the stooks should be made long, and not more than five sheaves wide; in cool weather four sheaves was sufficiently wide. Carting should not be commenced until the hay had been a fortnight in the field. A stack that was only to stand for a month or two did not need such careful building as one that was required to last for an indefinite period. The latter should be carefully batted, and the centre should be kept higher than the sides whilst it was being built.

CANOWIE BELT (Average annual rainfall, 20·04in.).

November 13th.—Present: 18 members and one visitor.

Farm Management.—Mr. C. O'Mahony read a paper under this heading. Stables should be divided into 5ft. stalls. Working horses should be cleaned in the morning and at midday. Buildings should not be put too close together, as there was then less damage in the event of fire. If the paddocks were left unworked within 3ft. of the fences, the latter would be less frequently damaged, especially where iron standards and droppers were used. In throwing out the furrow when fallowing it was a mistake to work the same way each year.

Hay-Harvesting.—Mr. A. Noll read a paper. The more evenly the binder was worked, he said, the better the results. The reel should not be worked too low on to the knife. The sheaves should be tied about one-third from the butt end. The hay should be left for a day or two after mowing. It could then be put into upright stooks, not too large. He would commence carting three weeks or a month after cutting, the operations being performed as quickly as possible. The stack should be gradually sprung out to the eaves, the centre being kept higher than the sides. Thatching should be done immediately after harvest.

WHYTE-YARCOWIE (Average annual rainfall, 13·91in.)

November 17th.—Present: nine members.

Stock-Carrying Capacity of a Northern Farm.—The Chairman (Mr. G. F. Jenkins) read a paper, from which the following is extracted:—"The number of stock carried on the Roseworthy College Farm has been an eye-opener to many people, particularly as the land cannot be considered by any means high-class grazing country. Most of the grain crops there are cut with the binder and threshed. While this lessens the carrying capacity of the stubble lands there is a large amount of fodder in the shape of cocky chaff and broken straw saved, which is used to tide the sheep over hard times, thus enabling more stock to be carried than when the grain is reaped with the harvester. Of course, a great deal of the stubble and cocky chaff left is eaten by the stock, but the first heavy rain that falls spoils practically all the cocky chaff and lessens the feeding value of the stubble also. Hence my opinion—more stock could be carried on our farms if we used the binder and thresher and saved the straw and cocky chaff for fodder. The addition of a little molasses would make this very palatable to sheep in times of scarcity, and would often enable us to sell our surplus stock to better advantage than we do at present. During the month of September the fallows at Roseworthy carry half a sheep to the acre, and during September and October approximately one sheep to the acre is carried. Here the average farmer has the whole of his fallow land cultivated and in a clean state by the end of October, and the best that can be looked for is for our fallows to carry about one sheep to the acre for one month only, with an occasional day through the summer months. In this district, on a 900-acre farm, a farmer who follows a three years' rotation, *i.e.*, fallow, crop, and graze, without the growth of fodder crops, can keep a flock of about 200 ewes. Given an 85 per cent. lambing this would mean that for about six months of the year, say from April to the end of October, he would have 370 sheep grazing on his land. Of course, one cannot lay down any hard and fast rule, as in good seasons many more sheep can be safely carried, and under such conditions store sheep can be bought and fattened and sold at a good profit; but in seasons when feed is not over-plentiful he will find that 200 ewes are enough. I have followed the practice of feeding off my crop every year since I have been farming on my own account, and I am convinced that it has paid me to do so. This year particularly, when the crops came up so unevenly, the sheep were turned in about the second week in August and had a fortnight of really good feed just at a time when the ewes were beginning to suffer and the lambs were going off. The result was that the ewes were given a really good filling up and a good flow of milk, much to the advantage of the lambs, which I would have had difficulty in getting into freezer condition had I kept them on the pasture land. Taking the sheep off the ordinary pasture at that time allowed the feed to get a good start, and so the ewes went out of the wheat into a good paddock, and the lambs went right ahead in condition. I feel sure, too, that the crop benefited from the feeding off, as it gave the later wheat a chance to come up to that which started early. I noticed also that the plants which were eaten off stooled out better and made stronger growth afterwards. I consider that not only did the crop save the flock, but the flock, by feeding off, helped the crop considerably.

"*Fodder Crops.*—The growth of fodder crops has not been tried to any great extent in this district. There are natural conditions which interfere very considerably with the growth of many fodders which can be profitably grown elsewhere. These highlands are subject to such severe frosts during the winter months that it is only under very favorable conditions, such as those given by good early autumn rains, that we can hope to grow such a crop as rape to any advantage. Once the winter frosts set in such crops will make little headway unless they are already firmly established in the soil. If we were to sow 5lbs. to 6lbs. of lucerne to the acre in our cereal crops we would be following a losing proposition, considering the high price of lucerne seed. The present value of this is about 1s. 6d. per pound, and if we sow 5lbs. or 6lbs. per acre that means from 7s. 6d. to 9s. per acre for seed alone. I am very doubtful if the additional feed grown would compensate for such a heavy outlay. Again, the heavy frosts of our winter months would kill much of the young lucerne. Having regard to this fodder, I should say that the Roseworthy experiment of sowing lucerne with the cereal or hay crops did not pay for the cost of seed. Professor Perkins stated that it is only in about one season in three that a good stand of lucerne can be expected, and if we go to the expense of sowing 5lbs. or 6lbs. of seed to the acre each year for one crop in three I do not think such would be a profitable investment. In the Roseworthy experiments the average grazing capacity of lucerne sown in this way was only 1·35 sheep per acre, which is apparently little if any better than the ordinary pasture. In considering the grazing capacity of our farms we must not lose sight of the fact that in this district it is a general practice to turn all working horses out to pasture as soon as fallowing is completed, and they are usually worked on such feed during the spring months, that is from September to December, say three months. In addition all the young and idle horses have to get a living during the greater part of the year on the grass and stubble lands. A farmer with 900 acres would need about 16 head of horses, equal to over 100 sheep; besides which there is the dairy herd to be carried. The man who stocks carefully has always fat sheep to sell, and is not obliged to get rid of his fat stock when the market is glutted, but can hold and market such to the best advantage. He can take advantage of a temporary slump in prices to buy, and can sell when prices have recovered. If he rears fat lambs, and I think there is no better paying proposition for the farmer, he can market his lambs early and secure top prices, while his less fortunate neighbor who stocks heavily will have to hold until prices have dropped considerably. I believe, with the Professor, that more stock can be carried in small paddocks than in large ones, but they must, through the summer months at any rate, have a plentiful supply of drinking water in the paddocks. The farmer who drives his sheep to water suffers in many ways. First there is the time lost in doing so; secondly, the sheep never thrive so well as when they can drink when they will; and again, the dirt raised in driving the flock to water considerably lowers the selling value of his wool. In conclusion, let me say that I think every farmer who keeps sheep should conduct some experiments with fodder crops. I do not mean that he should attempt to grow any particular kind of fodder on a large scale, but should experiment with one or more fodder plants each year on a small piece of land in the hope that he will be successful with some of them, because there is no question that the meat industry is going to be a more sure and paying proposition in the future than in the past." Mr. Hunt had tried lucerne and other fodders, but had not been successful with them, and agreed with the writer that in the long run, all things considered, the growing of fodder or catch crops was a losing proposition in this district. Mr. Lock recommended members to try some of the more drought-resisting native shrubs and fodders. Lucerne with irrigation would be a success, but without the water he was very doubtful of the result. Mr. G. D. Mudge had not been successful in his attempts to grow lucerne with the wheat crop, but was trying it alone with more promise of success. Mr. Robinson considered there was nothing to equal lucerne where it could be grown. He gave an instance, from another district (Mannanarie), where they had sown the seed with the wheat crop. Heavy rains followed the cutting of the wheat, and the lucerne did well and provided good fodder for several years.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

CLARE (Average annual rainfall, 24·30in.).

November 14th.—Present: 20 members and two visitors.

Hay Making and Stacking.—Mr. C. Neate read a paper. He said—" Land intended for hay-growing should be well worked and sown at the rate of 1½bush. of wheat and 2cwts. of super. to the acre; or, if oats are sown, 2bush. and 2cwts. of super. should be used. On a small plot it is a very good plan to drill in 1bush. wheat and 1cwt. super. to the acre, and cross drill 1½bush. of oats with 1cwt. manure. In such case a late wheat is necessary, otherwise the wheat will be too ripe by the time the oats are ready to cut. Good hay wheats for this district are Majestic, Neumann's Early, Baroota Wonder, King's Early, Yandilla King, and Marshall's No. 3, in the order named. These varieties, while making good growth, retain a nice green color, and make very heavy hay. The time to cut hay depends a good deal on whether it is intended for home use or for market. If for the former, leave it till the grain has reached the dough stage; the grain being full and soft, and the lower stalk and flag losing color; but if for market, it should be cut when the grain is in the milk stage, to get that nice green color which is the ruling factor in the hay markets Oats should not be cut until they begin to turn from green to purple, or they will be bitter. Use only the best twine. The sheaves should be tied as tight as possible; they will always shrink as the hay dries. Hay stooked as soon after cutting as possible has a better color than if left to lie on the ground for a day or two. The stooks should be round, and the sheaves placed well together. The hay should be left in the stooks at least 12 or 14 days before it is stacked. Do not make the stack too wide; from 15ft. to 18ft. is quite enough Keep the centre at least a foot higher than the outside, with an even slope from the centre to the outside walls. Build with the fork, and place the outside sheaves slightly on edge; this will prevent them slipping. Place the rest of the rows with the head out, and give them plenty of lap. See that every sheaf is placed, and have the centre of the stack firm and solid. The last two layers when the eaves are reached should project at least 6in. or 8in. I do not favor the method of building the outside rows with the hand and kneeling on them and filling the centre loosely with the fork, for the reason that when the stack settles, the outside, being built more solidly, does not settle to the same extent as the centre. Therefore, instead of the sheaves having a dip outward, they dip towards the centre, carrying the water into the stack instead of out. If it is intended to thatch the stack—and all stacks should be thatched—roof with the butts out, but if it is to stand for a time without thatching, roof with the heads out. By placing the heads out and using ordinary care in building, very little, if any, water will get into the stack. If one only cuts enough hay for his own use every year, a hay shed will undoubtedly prove a good investment." Mr. F. Pink agreed that it was advisable to stook hay as soon as possible after it was cut. Mr. I. C. Radford considered it best to cut when it was in the flowering stage when required for home use, and add grain to it if necessary when feeding to horses. The animals relished the hay more. If cutting hay for market he would allow it to ripen, then it would weigh more. Mr. Scales thought King's Early the best variety to grow for hay in this district. Mr. Pattullo considered the best time to cut wheat for hay was when the grain was in the milky stage. In replying, Mr. Neate said that King's Early seemed to be the favorite in this district, but he advised farmers to try Majestic.

SALISBURY (Average annual rainfall, 18·57in.)

December 4th.—Present: seven members.

Poultry on the Farm.—Mr. W. R. Day read a paper on "Egg-production," from which the following has been extracted:—"A few years ago special inducements for poultry-keeping were to be found in the low price of grain and other foods. This had the effect of causing a number of people to start in the industry, but with a rise in the price of wheat, &c., at about that time the majority of them gave up the business. When we had the cheaper foods, however, we had the lesser price for our eggs in the open market, and simultaneously with the higher price of all foods during the last few years the market value of the egg has also advanced, until last year we obtained an average weekly market value of 1s. 1·06d. per dozen. The industry was never on a better footing than it is at present. In South Australia we have a good climate and are within easy distance of good markets, either for local consumption or for export. The latter can easily be arranged through the Government Produce Depôt at Port Adelaide, which is no doubt responsible to a large extent for the upward tendency in prices during recent years. One advantage gained by the producer through the export business is that he receives payment on the per grade system. Eggs should be sold by weight, as this would tend to the production of a better sample, and consequently better returns. A good laying strain of the White Leghorn appears to be able to give a fair return for the capital expended. The choice of bird or birds has been the stumbling block to a good many in the past, for it is upon the ability of the poultry man to select and maintain the laying strain that success depends. I consider it is quite possible for the farmer to keep a flock of fowls for the sum of one penny per head per week, or approximately 4s. per head per year. A flock under ordinary conditions should produce an average of 144 eggs per hen per year, and these at 8d. per dozen will give him 100 per cent. profit over the cost of feed. I feel sure if farmers were to keep the right sort or class, keep an eye on them generally, and cull out occasionally to keep them within the age limit, and yard them away from the mangers, haystacks, and implements, they would soon learn to look upon them as a much more desirable asset than at present."

At a previous meeting Mr. Bagster gave a demonstration of rope splicing and knotting, which was of much interest to members

BLYTH, November 15th.—LAND SETTLEMENT.—Mr. T. Dunstan read a paper under this heading. He drew attention to the difficulties in the way of the person who was without much capital securing land in this State before the introduction of the present system under which the Government supplied land, the payment being extended over long periods. He advised young men intending to take up land to secure it under the more liberal conditions now prevailing.

LYNDOCH, November 13th.—HAY.—Mr. H. Springbett tabled a sheaf of hay consisting of White Tuscan wheat and New Zealand Cape oats, about 5ft. 6in. in height. The sample was clean and free of rust, and the seeding had consisted of three parts of wheat to one part of oats.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

MINLATON (Average annual rainfall, 17·46in.).

November 13th.—Present: 13 members and one visitor.

PREPARATION OF SEED.—Mr. Ewens contributed a paper under this heading in which he said it was advisable to purchase grain for seed from a reputable farmer or seedsman. A change of seed from another district was often of advantage. He would rewinnow and grade all seed wheat so purchased. Grain reaped while still a little green should not be used for seed, and no amount of labor would make smutty, dirty, or mixed grain suitable. The importance of grading could not be over estimated. There was no doubt that the plumpest grain produced the strongest plant, in spite of the fact that rusty and small seed had produced good crops. He would do all cleaning and grading as soon as practicable after harvest. The seed should be placed in new bags turned inside out, which would enable the farmer to mark the bags without spoiling them for future use. They should be stacked end on end in a dry place to avoid damage by mice. He would pickle only sufficient grain to furnish seed for the following year. He preferred seed which he had produced himself. Members generally agreed with the ideas expressed by the writer of the paper.

PINE FOREST (Average annual rainfall, 14·15in.).

November 17th.—Present: eight members.

HANDLING WHEAT IN BULK.—Mr. H. Dolling read a paper, from which the following is taken:—"The main argument in favor of the system of bulk handling is the saving of the cost of bags. Under the method of harvesting adopted here, it is impracticable to dispense with the bag on the farm. It is patent to any farmer that about 60 per cent. of bags would be required to take off a crop; more would be required if good harvesting weather were experienced. Of course all bags would be used until they were worn out. The life of the bag could be fairly put down at two years, showing a saving of 50 per cent., that is if wheat in bulk would sell at the same price on the London markets as wheat in bags. So far I find that such is not the case. The section of the Chamber of Commerce which deals with the grain trade disagrees with the report of the Wheat Commission. Upon the alleged saving of bags in the bulk system it furnished some statements worthy of consideration, for the expectation of being relieved of the cost of bags had much to do with the favorable evidence collected by the Commission. Bagged wheat brings 3s. per quarter more in London than bulk wheat. An extra 2s. 6d. per ton freight, and 1¼ per cent. insurance would be incurred, thus absorbing the amount saved in bags. If these statements are correct (and the Commission furnishes no evidence to the contrary) there would be no saving in the item of bags, and nothing to compensate for the cost of the elevators. Upon the surface is a fair inference that a system which is adopted in such advanced countries as the United States and Canada would be an improvement in Australia, and this was the attitude of mind with the present writer when on two occasions he investigated the system in the countries referred to. It was disappointing to meet with evidence which necessitated a verdict against the desirableness of adopting the American system. On the first investigation it was found that although the Pacific coast had been exporting wheat for more than a generation, every bushel had been sent away in small bags. Further, that the elevator or bulk system was unquestionably economical, and the best for the Atlantic trade, while the best and most economical system for the Pacific was to use the bag. The second investigation confirmed these conclusions. It was found that the introduction of the bulk system had nothing to do with the saving of bags, but had been developed as a means of reducing the cost of handling grain when frequent handling of large quantities was necessary. Take, for example, the extreme case of farm to railway, from railway to lake boat, from lake boat to railway, from railway to ocean liner. A bag of wheat could not pay its way on such a journey of transhipment, and the bulk system was evolved as a means of rendering the transportation practicable. While Atlantic shipping arrangements were organised to suit it, no such frequent handlings were necessary on the Pacific slopes, and consequently the bulk system was not necessary. If there had been anything to gain the wheatgrowers of California would have gone after it as promptly as those shipping in the opposite direction. If under the elevator system 25 per cent. of wheat has to be bagged for shipping purposes, with the 50 per cent. needed on the farm and the lower price for wheat, there would be a loss to the State on the bag item for a start. Of course half of the 25 per cent. has to be deducted from the 50 per cent., making the amount of bags needed 62 per cent., not including home requirements or seed wheat. So far I have dealt with wheat for export. Wheat for home consumption must also be taken into consideration. If the miller gets his wheat without a bag, he will have to buy bags for his flour, bran, pollard, &c. He will then either give less for wheat or charge more for flour. There would be no saving in bags, anyhow. Advocates of the bulk system say that a cleaner wheat would be shipped, and consequently a better price would be obtained. I admit that South Australian wheat is not as clean as it should be. What with covering the screens, or allowing them to become choked, sowing wheat mixed with barley, and growing smut, it is no wonder there is some rubbish in our wheat. But why erect costly machinery to clean it when we have the machinery on the farm now? Sow clean seed well pickled, give the harvester or motor winnower fair play, then a sample of wheat will be obtained that will need no more cleaning. The cost of handling wheat under the present system is not great. If it is shipped direct from wagon to truck, from truck to ship, the cost is one-third of a penny per bushel; if into stack, then truck to ship, ½d. per bushel. These figures are approximate. I do not think it is possible to handle wheat more cheaply under the elevator system, because our vast coastline and the small quantity of wheat to be handled are against the system being worked economically." Mr. Edwards thought a better price would be secured in the English markets for a cleaner sample marketed under the bulk handling system, but Mr. Adams thought it unfair that the farmer who produced a good sample should have to assist in erecting elevators and machinery to clean the wheat of the indifferent wheatgrower. Messrs. A. Hewett and R. Barr thought it unwise to erect elevators at present, and a motion to this effect was carried by the Branch.

WESTERN DISTRICT.

KOPPIO (Average annual rainfall, 22·40in.).

November 11th.—Present: 10 members.

Harvesting.—Mr. J. Newell contributed a paper on this subject. He preferred oaten to wheaten hay for horses, the favored varieties being Algerian and Calcutta Cape. The oat crop should be cut just when the tops of the heads were beginning to brown off. The practice of mixing oats and wheat for sowing in this district was not advisable, as it was sometimes found more profitable to leave the crop for grain. The hay should be put into long, narrow stooks directly after the binder, stacking being commenced 12 days later. The centre of the stack should be kept slightly higher than the sides, the sheaves being put butts outward until roofing was commenced, when the heads should be placed outwards. Thatching grass would be found very useful, and with care would last for a number of years. Barley should not be stripped until it was quite ripe, as it was likely to heat and discolor. The most profitable way of harvesting oats was to cut and thresh them. The damp-weather stripper and winnower constituted the best method of handling the wheat crop, a small engine being very useful in conjunction with the latter machine. Wheat heaps should not be made in watercourses or in stony ground. A good marketable sample of grain should be produced. Mr. Gardener preferred wheaten to oaten hay, but a mixture was best. A small engine was of great assistance in winnowing and in other ways on the farm. Mr. T. Richardson thought wheaten hay preferable, especially if it were fed long.

MILTALIE (Average annual rainfall, 14·55in.).

November 8th.—Present: 10 members and four visitors.

Working Teams.—Mr. P. G. Wilson read a paper. He thought it unreasonable to expect eight horses to work evenly and smoothly abreast on one bar. The centre horses could do none of the work, and a fast horse could not be tied back. He preferred to work them in two lots of four, with equalisers. When there were long lands and the paddocks were free of stumps, it was a good practice to attach the horses to a perpendicular swing at the end of the long swing. Mr. J. S. Jacobs preferred working eight horses abreast, as the driver had more control over them, and they were nearer their work. Messrs. W. E. Heir, W. G. Smith, J. P. Storey, and M. D. Searle also took part in the discussion.

COORABIE, November 16th.—Prospects.—Members estimated that in the hundred of Scherk there was an increased area under crop over that of last year of 1,600 to 1,700 acres. Probably the yield would be 3bush. per acre. The area cut for hay showed a decrease of about 75 per cent. on last year's figures. The yield would probably be about 5cwts. per acre. In the hundred of Wookata the increased area under crop was estimated at 1,800 acres, and the average yield 3½bush. The area cut for hay was about the same as last year, the average yield being approximately 7cwts. per acre. It was recognised that these very unsatisfactory results were not only due to great shortage of rain during the winter months, but also in a very large measure to the exceptional gales of wind which visited the district almost continuously during the months of July and August, and which ruined numbers of promising crops, particularly on new scrub land.

GOODE, November 13th.—Homestead Meeting.—Members took the opportunity of inspecting the farm of Messrs. Will Bros. This constituted one of the best laid out farms in the district. The crops were well grown and consisted of Late Gluyas, King's Red, Thew, King's Early, Early Gluyas, Carmichael, Pratt's Comeback, and Alpha wheats. However, all were badly affected with rust. On the farm of Mr. C. Will, adjoining, manurial tests were being conducted, and members were much interested in these.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

LAMEROO (Average annual rainfall, 16·55in.).

November 22nd.—Present: 14 members and two visitors.

The Evolution of the Farmer.—An interesting paper under this heading was read by Mr. Mayo. He outlined briefly the growth of methods and appliances used at certain epochs of the world's history, and analysed the underlying causes which apparently had been responsible for the initiation and development of farming.

Wheat Crops.—Mention was made of the fact that in some cases the straw of the wheat was brittle and the chaff white, whilst the grain was still soft. Mr. E. J. Trowbridge attributed the trouble to the weather conditions, which had unduly forced the plants. Golden Drop and Walker's Wonder had suffered most. Mr. Jericho thought feeding down would be beneficial, but Mr. F. W. Eime had tried this without effect. Members generally considered the trouble due to the unusual season.

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.)

December 13th.—Present: 14 members and two visitors.

Hay-Making.—Mr. A. Patterson read a paper. The best time to cut the crop for hay, he said, was just after the bloom had fallen. It should be immediately put into stooks four sheaves wide, in which it should be left for 15 or 20 days. If carted too soon it was liable to become mouldy in the stack. He strongly recommended the erection of hay sheds, as the hay first cut could then be carted in immediately it was ready. Hay from a good galvanized iron shed, also, was superior in quality to hay from a stack. In building stacks the centre should be kept well up and thatching should be done as soon as possible.

PARILLA (Average annual rainfall, 16in. to 17in.).

November 6th.—Present: 19 members and two visitors.

Harvester v. Stripper.—Mr. G. E. Gregory read a paper. He favored the stripper. With three of these machines in three years he had taken the crop off 2,000 acres. Repairs had cost about £1 per machine annually. The cocky chaff mixed with molasses and fed to working horses had saved £40 worth of hay during the year. The chaff could also with advantage be mixed with bran and fed to ewes rearing lambs.

Mr. P. Harrip also contributed a paper. He had used a harvester for three successive seasons, and thought it the best machine. It saved a good deal of labor. He did not think cocky chaff worth saving. An interesting discussion followed, in which Messrs. M. Shannon, J. H. Daniel, H. G. Johnston, Millsteed, Stevens, E. J. Kenley, J. Roachock, Neindorf, C. E. Moyle, P. W. Lewis, and Stevens took part. A vote was taken on the subject, and resulted in 11 members favoring the harvester and six the stripper.

PARRAKIE (Average annual rainfall, 16in. to 17in.)

November 8th.—Present: 10 members.

Marketing Wheat.—In a paper on this subject Mr. H. Diener said it was a good plan for the farmer to sell part of his wheat crop for forward delivery if a satisfactory price were obtainable. It was a mistake to store with the buyer. If a shed or barn were not available he could place it in the open on plenty of good dunnage and cover it with iron. The writer of the paper favored the erection of an elevator at the Outer Harbor. The f.a.q. system offered no inducement for the producer to clean his grain. He thought the f.a.q. standard should be fixed by an equal number of representatives of the buyers and sellers, with an independent chairman approved by the Government. It was a bad policy to buy bags for and pay freight on drake, cracked grain, &c., which could be more profitably utilised on the farm. The bulk-handling system would eliminate a number of the transport difficulties which were encountered at present. It would save time, labor, and cornsacks, and ensure a better price for the cleaned wheat. Mr. J. Temby favored immediate delivery to the railway siding. If held on the farm there was frequently difficulty in getting the grain to the railway when it was sold, and there was generally loss through mice and other vermin. Mr. Jose preferred to hold the wheat. Farmers should attend to their stubble and stump burning immediately after harvest, and cart the wheat later.

SUTHERLANDS (Average annual rainfall, 10·60in.).

November 8th.—Present: six members.

Care of Implements.—A short paper on this subject was read by Mr. J. B. Thiele. He stated that adequate shelter should be provided for all implements and machinery on the farm. Grease, oil, &c., should be immediately removed from harvesting machinery after the harvest was completed, and the machinery overhauled generally. Occasional coatings of paint were advisable. He preferred iron sheds to thatched, on account of there being less danger of fire and a very appreciable water catchment with the former. Mr. G. Geyer made a practice of placing a block of wood underneath the wheels of his harvesters, as he had found that in the event of sand being blown against the machines there was a probability of white ants causing damage. Mr. Twartz recommended supporting the comb with a prop in order to preserve its shape.

Handling Wheat in Bulk.—Mr. Thiele initiated a discussion on this subject. Members were of the opinion that the best policy to adopt in this connection would be for grain stores to be erected at shipping ports, the wheat being delivered to these in the bag.

SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.)

December 8th.—Present: 22 members and five visitors.

Wounds in Horses.—The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) gave an address on the treatment of wounds and injuries in horses. He dealt first with what was usually known as "broken knees," an injury to which horses in the hills district were rather subject. He recommended first of all a thorough cleansing with clean water in order to remove all dirt and foreign matter from the wound. A little soap in the water would do no harm. Dressings that had a tendency to dry up the wound should be used rather than oils which kept the wound moist. Powdered boracic acid, or Condy's crystals, at the rate of one flat tablespoon to a gallon of water, or powdered washing soda, or preparations containing alcohol were all useful for the first applications after injury For healing purposes, and to encourage the growth of hair, once or twice a day a tincture of iodine might be applied, mixing one dram of pure iodine in one pint of methylated spirits. Sometimes, when the wound had filled up and was looking healthy, there was a tendency for it to crack. In such cases carbolic oil, or a similar dressing which would keep it soft, should be applied. In the summer-time it might be necessary to apply something to keep off the flies, and a little Stockholm tar or hog's lard, or a weak solution of lysol, or other coal tar preparation, would prove effective for this purpose. Should there be any sign of proud flesh a pad of wool or tow sprinkled with boracic acid, or boracic acid and flowers of sulphur mixed, should be applied and secured by means of a tight bandage on the wound. Where there was a good deal of loose proud flesh on any wound of this character it could be removed with a knife or searing iron, the latter for preference, as bleeding followed the use of the knife, and must be stopped by the application of hot iron. An old table knife made "cherry red" in the fire would prove very useful for this purpose. Sometimes it would be found that joint oil ran from the wound for a week or more, and that there was a small pipe formation which showed no sign of healing. The application of a little dry chloride of lime daily would check this. In the case of wounds caused by "staking," the veterinary surgeon said that it was essential that the bottom of the wound should be thoroughly cleansed, for if any foreign matter remained trouble was bound to occur. By means of a syringe a plentiful supply of disinfectant, such as 2ozs. of washing soda in a gallon of water, or a 2 per cent. solution of some coal tar disinfectant or Condy's fluid, should be forced into the wound. Absorbent wool or gauze should then be worked into the bottom of the wound by means of a piece of clean wire which has been disinfected by heating until nearly red hot. This wool should be removed each day and replaced with a fresh lot. It should be remembered that the wound must be allowed to heal from the bottom upwards, and not from the top. Sometimes pouching of the skin followed the healing process, and where this occurred it was necessary to make a hole at the lower end of this pouch in order to keep it drained. A piece of tape passed through the lower end would serve this purpose. The tape should be dressed daily with a little turpentine. Where the foot had been bruised and cut by a stake or stone it was generally found that the wound was larger in the interior than on the outside, and it was necessary to prevent the outside closing up until complete healing had taken place, otherwise there was great danger of tetanus or lockjaw. He advised opening out the entrance of the wound, to allow of discharge, and plugging the opening with wool or tow dressed with Stockholm tar. The wound itself should be dressed with a volatile antiseptic, such as turps, benzine, or petrol, and not with any heavy oily substance, and might be plugged with wool or tow soaked in benzine or petrol. Some of the most difficult injuries to deal with were those caused by horses getting their feet caught in barbed wire, and not infrequently it became questionable as to whether it would pay to treat them. Where the fetlock was very badly injured he was doubtful that it would pay in the case of an old horse of comparatively little value ; but in the case of a young horse he advised dressing twice daily for a week with tincture of iodine, then covering the wound with Stockholm tar and turn the animal out for two weeks. If, after that period, any part of the wound required dressing, turpentine or benzine should be used, and a dressing of Stockholm tar again applied. A complete cure was slow, but he had had a number of instances where such injuries had been very satisfactorily cured under this treatment. Wounds known as "fistulous" were very difficult to heal owing to the presence of dead tissue at the bottom of the wound. The only effective treatment was to use the knife to remove the cause of the mischief, and then apply plenty of cold water for an hour or more daily. Sometimes they were troubled with ulcerating wounds, probably due to foreign matter, which must be removed as well as the proud flesh surrounding it. Burning with a hot rod, or the application of a tight rubber band above the wound for 10 or 15 minutes the first day, for one hour the second day, and two hours a day afterwards would probably be effective. At the conclusion of Mr. Place's address a number of questions were asked and answered. In the case of a horse whose teeth and mouth were apparently good, but who slobbered a good deal and vomited up a portion of its food, Mr. Place recommended using a dessert spoonful of Fowler's solution of arsenic in the chaff night and morning for two weeks. The trouble was rather common, and was due to contamination of the chaff with microscopic vermin which bred in the gullet and stomach. When the food was taken into the gullet irritation was caused and portion of the food was ejected. Greasy heels should be prevented by leaving the hair at the back of the fetlock and drying the heel well after exposure. In mild cases an ointment composed of camphor 1oz., lard 4ozs. could be applied. When the heels crack a dry dressing of camphor one part, oxide of zinc four parts was recommended. When really bad and grape-like growths existed, white lotion consisting of sugar of lead ½oz. and sulphate of zinc ½oz. to a pint of water, or better, equal parts of methylated spirit and water should be applied frequently, and followed by a dry dusting of sulphur one part, boracic acid seven parts.

CHERRY GARDENS (Average annual rainfall, 35·03in.)

December 9th.—Present: 15 members and a large number of visitors.

Social.—A social gathering was held to celebrate the coming of age of the Branch. Addresses were delivered by Messrs. S. W. Chapman, T. Jacobs, C. Ricks, S. H. Curnow (Cherry Gardens Branch), W. H. Hughes (Longwood), A. Phelps (Clarendon), and C. Morgan (Ironbank), and the following officers of the Department:—Mr. W. L. Summers (Secretary to the Hon. Minister of Agriculture), C. G. Savage (Manager Government Experimental Orchard, Coromandel Valley), and G. G. Nicholls (Secretary Advisory Board). The remarks of the evening showed that the Branch had played an important part in the development of the immediate district, and had not been without its influence upon the Bureau generally.

HARTLEY (Average annual rainfall, 15in. to 16in.).

November 5th.—Present: 18 members and 10 visitors.

Annual Inspection of the District.—On Wednesday, November 5th, members met at the council hall and drove in the direction of Callington. The crops inspected presented a somewhat uneven appearance, rather poor crops being close to those that were good. Although this feature was clear to the observer, it could not be accounted for, as in many instances the land seemed to be similar. At Mr. A Stein's a splendid crop, the best seen for the day, was noticed. Here haycutting was in full swing in a crop of Silver Baart. Sixty acres of White Tuscan also looked well and was estimated to yield nearly 3 tons to the acre. Passing on to Mr. F. Lehmann's farm, the visitors spent a good deal of time inspecting his lucerne plots. These were looking very well, being irrigated from the river, the water being conveyed along a channel at the high side of the lucerne. The channel was tapped at intervals and the water supplied to the lucerne where required. A hydraulic ram pump, which had a lifting capacity of 80ft., was also seen on this farm. At an early date Mr. Lehmann proposed to convey the water to the house and stables from this pump. After lunch, which was kindly provided for the visitors by Mr. Lehmann, the farm of Mr. F. Bruns was inspected. Here the land was irrigated by means of a 6-h.p. petrol engine and a centrifugal pump. Mr. Bruns used the river water, and could supply his lucerne with 12,000galls. an hour. Mr. B. Wundersitz was the next place of call. Here the crops were looking fair; rust was noticeable, but mostly on the flag of the wheat. Lucerne presented a nice appearance. Mr. Wundersitz proposed to graft on to his hardshell almonds the softshell variety. There was a fine growth of wood on the old stumps, and should the grafting prove successful it would not be long before the trees were profitable. The evening was spent in a social manner. Mr. Wundersitz placed his large barn at the disposal of the members and friends. Here they partook of the hospitality of Mr. and Mrs. Wundersitz. After dinner had been served the Secretary of the Advisory Board of Agriculture (Mr. G G. Nicholls) delivered an address. He advised the farmers to ascertain by accurate experiments the requirements and capabilities of their various soils, and to let their neighbors know the results. He expressed pleasure in being present, as he could see that this Branch of the Agricultural Bureau was well to the front from a social aspect, and he had seen, in passing from farm to farm during the day, that they were live members, and possibly the better farmers for being connected with the Bureau. He wished the Branch every success, and expressed indebtedness to Mr. and Mrs. Wundersitz for their hospitality. Mr. Pyne indorsed the remarks of Mr. Nicholls as to the value of the Bureau in this State. The farmers owed a good deal to the Roseworthy College, as, no doubt, many practices that they were adopting to-day sprang from that centre. Mr. Taylor, on behalf of the visitors, and Mr. Beavis, on behalf of the members, heartily thanked Mrs. and Mr. Wundersitz.

INMAN VALLEY (Average annual rainfall, 26in. to 27in.).

November 12th.—Present: 17 members.

Hay-Making and Grain-Harvesting.—In a paper on this subject Mr. E. A. Scarfe said wheaten hay should be stooked in long rows, not too wide, directly after cutting, but oats might be allowed to lie for a few hours. Wheat for hay should be cut when the bottom of the straw had become white and the flower or pollen had fallen. If cut too green it would be spongy and light. Oats should be left until the grain was forming and turning brown. Sheaves should be of good size, and not tied too close to the heads, The hay should be left in the stooks for at least 10 days, and longer if it were to be put into a large stack. If hay taken from the centre of the sheaves would crack at the nodes there was no danger of it sweating. The stack should be gradually built out to eaves and be kept high in the middle, especially when nearing the roof, in which the sheaves should be placed heads outward. For harvesting the grain crop the damp-weather stripper and winnower were better than the harvester for this district. With the stripper the chaff was saved, and the land was kept much cleaner. Whilst on level land the grain was bagged much more quickly by the harvester, it did not do such good work in hilly country. When harvesting operations were completed, it was a good policy to cut straw and place a stack in the paddock for shelter and feed for stock during winter. Federation wheat straw was not suitable for this purpose. The average weight of a sheaf was about 8lbs. The saving of hay effected amply compensated for the cost of erecting a hay shed. Mr. Jagger thought a stack thatched too soon after carting would probably settle and allow the ingress of water.

LONGWOOD (Average annual rainfall, 37in. to 38in.).

November 15th.—Present: 11 members and a number of visitors.

Homestead Meeting.—The meeting was held at the homestead of Mr. W. H. Hughes. Plots of fodder plants and grasses were inspected with interest. Crimson or Italian clover, planted in one plot with barley and vetches, and with field peas in another, was doing well. The barley, vetches, and peas had been cut for green feed. Yorkshire fog was almost ready for cutting for hay. It grew splendidly, and was considered one of the most reliable grasses for this district. Red clover or cow grass was ahead of all the other clovers. *Trifolium subterraneum* was hardy and splendid for pasture.

Bee-Keeping.—This subject was treated in a paper by Mr. J. R. Coles. He mentioned the importance of the products of honey and beeswax, and the value of the insects in effecting the fertilisation of blossoms in the orchard. Whilst generally there was the objection to apiculture that the stings of the bees were painful, competent beekeepers were agreed that when properly managed these insects rarely stung human beings. Serviceable hives could be manufactured from kerosine cases. Frames were best procured in the flat. Spare hives should be placed in sunny positions in the apiary, as young colonies would then in all probability swarm into these. If a swarm should cluster on a tree or bush, a hive containing one frame of brood and honey, with three or four empty frames on either side, should be placed directly beneath it, the bees being shaken off the bush into the hive, which should be quickly covered. Immediately the colony became settled it should be removed to its proper situation in the apiary. The colonies, which each consisted of a queen (which laid eggs to supply the brood), workers or undeveloped females, and drones, should be kept of equal strength by the weaker being supplied with combs of brood from the stronger.

Life Member.—Members took the opportunity of presenting a certificate of life membership to Mr. W. H. Hughes. This had been framed and engraved as a mark of appreciation of the services rendered by Mr. Hughes during his 21 years of membership. Several members made eulogistic references to the good work of the recipient.

MOUNT PLEASANT (Average annual rainfall, 26·87in.).

November 15th.—Present: six members.

Care of Harness.—This subject was dealt with in a paper by Mr. Tapscott. Only the best harness, he said, should be purchased, and this should be given an oily dressing before being used. When it was necessary to clean it it should be taken to pieces and washed in hot water with a little extract of soap added. After drying in the sun it should be oiled, this being allowed to dry in. Leather and copper rivets should always be kept on hand to effect repairs. Mutton fat was not a good dressing to use, as it became hard in the winter and collected dust in the summer Well-fitting collars were absolutely necessary for the horses. The Chairman (Mr. H. H. Giles) mentioned a mixture of the best neatsfoot oil and lampblack as a suitable dressing.

Stock and Crops.—It was reported that stock were doing very well. The crops were fair to good.

MYPONGA.

November 17th.—Present: 11 members and three visitors.

Sheep.—Mr. E. Everard read a paper. For this district, which experienced cold and wet winters, he said the crossbred secured by mating Merino ewes to a long-woolled British breed of ram was the best sheep. The Lincoln ram was generally favored It was well adapted to a wet climate, and produced a heavy fleece of bright, lustrous wool, although coarse. It was not so susceptible to footrot and fluke as the Merino. The crossbred combined to a certain extent the best qualities of both breeds. With the opening of the Panama Canal and the revision of the American tariff, the increased demand for crossbred wool should enhance its price, which was now little short of that of Merino. Mated with a Shropshire or Southdown ram, the crossbred ewe produced an excellent lamb for market, although the fleece would not be so good as that of the first cross. Members generally agreed with the writer. The Chairman (Mr. G. Hunt) tabled several very fine samples of wool, one from a two-year-old crossbred ewe, which cut a fleece weighing 13lbs., and one from a Merino ram which produced a fleece weighing 28lbs., being particularly admired. Flockowners could not expect to get uniform lambs, he said, when they used rams from several different flocks.

NARRUNG (Average annual rainfall, 17in. to 18in.)

November 22nd.—Present: 25 members and visitors.

Homestead Meeting.—The meeting was held at the farm of Mr. Bowyer. Six years ago this country comprised part of Narrung Station, supporting a few men and stocked with sheep, horses, and cattle. To-day it supported a large number of families, mostly engaged in the dairying industry. There were three schools on the settlement, where there were none before, testifying to the increased capacity of the land when under closer settlement. Mr. Bowyer's farm stood out as one of the best on Narrung, and was well subdivided and improved. The dairy cattle, comprised largely of the Jersey strain, were yarded and inspected by the members. These were milked by machinery. The machines were seen at work, and undoubtedly they were a great improvement on the hand milking. The shed, comprising stables, chaff shed, implement shed, engineroom, etc., was next inspected, and the chaffcutter was seen at work. This was fitted with a long elevator and carried the chaff into a loft. From there it ran down a chute fitted with a trapdoor, from which it need not be taken till required for use. The cutter was a 4-h.p. Bagshaw driven by a 5-h.p. Regal engine. One man and boy could work the plant comfortably, and thus a big saving in labor was effected. The separator and milking machines were driven by the same engine. The building and fittings were built by a local man under Mr. Bowyer's direction, and were a credit to the designer and builder. There were about 70 acres under lucerne, divided into four paddocks, all of which looked extremely well. This was cut for hay a fortnight previously and already had another good growth. The soil varied from a dark, deep sand to a red sand over limestone, and the growth seemed equally good on all soils. This has been drilled in during the last few years, mostly with the aid of light cover crops, and thrived without any irrigation. Potatoes and maize were seen to be doing well, and nice crops of oats just ready for the binder were noticed. After the inspection of the farm and stock was completed the members partook of afternoon tea, kindly provided by Mrs. Bowyer.

On December 22nd the Government Dairy Expert (Mr. P. H. Suter) delivered an address dealing with the different types of dairy cows, the secretion of the milk, &c.

STRATHALBYN (Average annual rainfall, 19·28in.)

December 9th.—Present: 12 members.

Red Rust.—After discussion, members concluded that the wheats which had suffered least damage from red rust were John Brown and Crossbred No. 52. Early sown crops suffered most, Federation especially.

URAIDLA AND SUMMERTOWN (Average annual rainfall, 44·35in.).

November 3rd.—Present: 11 members and two visitors.

Rhubarb.—Mr. G. Prentice read a short paper on the cultivation of rhubarb. Land for planting with this crop should be broken or trenched to a depth of at least 18in., he said. One hundredweight of bonedust should be dug into each rod of land, which should be planted with the crowns 3ft. apart each way. The first crop should be allowed to die back. The best selling variety was the very red Cherry rhubarb, but this was not a good cropper except in swamp land, where it did well under irrigation. One bag of bonedust should be applied to each four or five rods annually, and after each pulling the soil should be well hoed. Carefully cultivated a crop of 12lbs. per crown per season should be secured. Members generally agreed.

CHERRY GARDENS, November 11th.—**Crops in District.**—It was reported that in many instances the hay crops in this district were very good, the late rains having had a very beneficial effect. Some of the late-sown crops, however, were thin and light. The pea crop promised well.

KANMANTOO, December 11th.—LECTURE.—An interesting address, describing a trip to West Australia, was delivered by Mr. W. G. Mills.

MEADOWS, November 11th.—An interesting paper dealing with submarine photography, insect life, &c., was read by Rev. J. W. Williams.

MENINGIE, December 20th.—Members discussed the subjects of "Noxious Weeds" and "Diseases in Sheep," with the result that a profitable evening was spent.

MOUNT BARKER, November 12th.—WOOL.—Mr. Henshaw Jackson (Wool Instructor attached to the School of Mines) delivered an address and demonstration on the preparation of wool for market. A number of questions were asked and satisfactorily answered.

PORT ELLIOT, November 15th.—FARMYARD MANURE.—Members were of the opinion that it paid to preserve farmyard manure (by placing it on a layer of seaweed and covering it with the same) for green fodder crops and potatoes, but the use of chemical fertilisers was more profitable with cereals.

SOUTH-EAST DISTRICT.

KEITH (Average annual rainfall, 19·20in.).

November 5th.—Present: seven members and three visitors.

INSPECTION OF DISTRICT.—Members made their annual inspection of crops in the district. A well-grown crop of oats, but rather thin, and estimated to cut about 1¼ tons of hay to the acre, was noticed on the farm of Mr. Wilmitz. Adjoining was a crop of oats estimated to return 20bush. to the acre, and one of wheat expected to return seven bags to the acre. Mr. Graves' crops were looking well, and on Mr. Dall's property a small paddock of rye was standing about 4ft. high and promised a good return of seed. It had been fed off until September. Barley which had been fed off until the beginning of October, was expected to yield from 15bush. to 20bush to the acre. Mr. Dall estimated that feeding down these two plots, which were each 10 acres in extent, had saved chaff to the value of £30 during the year. The wheat crops, sown on well-worked fallow, stood about 5ft. high. Hawkes' Rustproof was estimated to yield 27bush. to 30bush. to the acre. Mr. J. Bice's crop, on land ploughed, drilled, and then harrowed, promised a return of 15bush. to 18bush. per acre. At Mr. Makin's, where afternoon tea was served, the fruit, flower, and vegetable gardens looked extremely well. A paddock which had been cropped with hay last year carried a nice growth of barley and oats. One hundred acres had been fallowed and drilled with barley and rape, on which 500 sheep were fattened. The area was now carrying a heavy crop of wheat and oats for hay. A crop at Mr. Pearson's, sown on new land during the third week in August, looked well. Members were convinced that good crops could be grown in this district on well-worked fallow.

Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S. (Superintendent of Agriculture in the South-East) delivered an address in the evening.

KYBYBOLITE (Average annual rainfall, 22·00in.).

November 13th.—Present: eight members and two visitors.

DISEASES OF FRUIT TREES.—Mr. Leishman contributed a paper in which he dealt with various fruit tree pests which he had noticed in the district. Curl leaf of the peach, he said, was an endophytic fungus, the spores of which lodged under the scales of the buds during the winter and germinated when the sap rose in the spring. Preventive treatment consisted of spraying with Burgundy or Bordeaux mixtures as the buds were swelling. If the tree had been badly affected in the previous year it should be sprayed when the buds were dormant and again when they swelled. Shothole fungus of the apricot was controlled by spraying with Bordeaux mixture when the flowers were open, and again when the fruit had formed. Peach aphides wintered on the roots of the trees. These were sucking insects, hence arsenate of lead sprays were useless. They should be suffocated with tobacco wash, resin wash, or kerosine emulsion. The curculio beetle was a chewing insect, which attacked especially the young and tender shoots of the trees. The larvæ evidently developed in the soil, and in the early spring the beetles attacked the trees at night. A misty spray of 1lb. arsenate of lead to 8galls. of water, or dusting the trees with 1oz. Paris green mixed with 50ozs. flour when they were wet with dew was effective. Poultry would also effectively destroy the pest. The codlin moth was also a chewing insect. During the winter it rested as a white caterpillar in a watertight cocoon. The moth emerged about the time of the flowering of the fruit. The females deposited eggs on the fruit and leaves. Young caterpillars emerged from these within about a week, and crawled to the calyx of the fruit. These caterpillars were fully developed by the time the fruit was about quarter grown. They produced a second brood of moths in the course of a few weeks, and these deposited their eggs on the almost fully grown fruit. Treatment consisted of spraying with arsenate of lead. The first application should be made just after the petals of the flower had fallen, the spray being directed into the calyx cups. The second spraying should be given in from seven to 10 days, a third at the expiration of a fortnight, and others at intervals of four or five weeks. Later ripening varieties of pears and apples should be sprayed as late as February to destroy the second brood of caterpillars. Bandage traps should be examined once a week.

MILLICENT (Average annual rainfall, 29·25in.).

November 11th.—Present: five members.

Fallowing.—In a discussion on this subject Mr. Mitchell thought it paid to fallow land on the Millicent Flats. The grass destroyed was of considerable value, but the increased return in crop compensated for it. Where the land was suitable, however, a summer fodder crop, such as rape, should be sown. Mr. Searle commenced ploughing as soon as possible after harvest, and continued to work the land till seeding time. He had obtained good crops for many years by so doing. Mr. Holzgrefe also favored ploughing during the dry weather. He contended that land in this district was too costly to be left out in bare fallow. Clean crops would be secured if sheep were put on the land during the spring. Members agreed that a catch crop on fallow was profitable. Green feed was of considerable value to young sheep during dry seasons.

NARACOORTE (Average annual rainfall, 22·60in.).

November 8th.—Present: 13 members.

Poultry-Farming.—A lengthy paper was contributed by Mr. F. A. Holmes. He dealt with the importance and prospects of the industry, and emphasized the necessity for perseverance and patience in order to make the business pay. The best stock from proved laying strains should be procured. Chicks should be hatched about September, and in no case after November. The White Leghorn was the best egg-producing breed, other good varieties being Black and Buff Orpingtons, Minorcas, and Andalusians. The Silver Wyandottes and Black Orpingtons were good dual purpose fowls. The essential, however, was to secure a good strain. Generally, a hen over two years old did not lay more than sufficient to pay for her food. Two or three cockerels were enough to fertilise all the eggs the average farmer would need to hatch. Crossbred fowls he thought did not lay as many eggs as the pure bred. When possible a site for the pens should be selected on a slope of dry, sandy, porous soil. Breeding pens could be made 10ft. wide and 40ft. or 50ft. long. These would accommodate eight or 10 hens each. The houses should face the morning sun, be open in front, and contain perches about 18in. from the ground. Fowls roosting in trees and exposed to cold winds and frosts required more feed to keep up the bodily heat; consequently their egg-production fell away. Shade was necessary in summer. The best layers should be mated with a young, vigorous cockerel. The system of feeding recommended was—for cold mornings, a crumbly mash of two parts pollard and one of bran mixed with boiling water, and meat meal added, about 25ozs. being fed to each pen of six birds. At midday green feed should be given, and at night a good handful of grain—principally wheat—per bird. Epsom salts could with advantage be mixed with the mash in hot weather. Rabbit made an excellent substitute for meat meal. Broken china, glass, or flint grit should always be available to the hens. A few Condy's crystals added to the drinking water made an excellent preventive of disease. He preferred setting hens to the incubator for hatching chicks. The hens should not be interfered with during incubation. In the winter the nests should be made in a box, but in the spring holes could be scooped in the ground, and soft straw or grass placed in these. England imported £8,500,000 worth of eggs last year, he said, and Australia should participate in this. A lengthy discussion followed. Mr. W. H. Smith preferred hatching chicks under hens, but Mr. J. M. Wray favored the incubator. Mr. Loller thought cleaner and healthier chickens were secured by the latter method.

WIRREGA (Average annual rainfall, 19in. to 20in.).

Fruit-Growing on the Farm.—Mr. W. Fairweather read a paper, from which the following is taken :—"For a site for the home fruit garden I recommend sandy land with a slight slope towards the east; 2ft. depth of sand is the best. The land should be cropped with a cereal previously, as this sweetens the surface and destroys many fibrous roots, leaving the ground cleaner for planting. For a home garden the septuple system is best, as one gets in more trees than on the square system. The septuple system consists of laying the trees out in regular equilateral triangles, with a tree at each point. A big advantage with this is that one can cultivate between the trees in three different directions, thus reducing the hand labors to a minimum. The holes for the trees should be about 3ft. square, and the clay at the bottom broken up and left, and then mixed with some well-rotted stable manure. Procure the trees from a good nursery. I prefer small trees, as the larger are often forced in the nursery, and when transferred to our poorer soils the check is so great that their subsequent growth is spindly and weak. When planting be careful to put the tree in the same depth as it was in the nursery, and at the same time trim off any bruised or dead roots. Fill in the hole and tramp firmly round the tree. In our soils 16ft. is ample distance between the trees. I strongly advise planting the bulk of the garden in apples and pears, as they have proved by far the best, all making strong growth, besides standing adverse conditions of weather. Half an acre planted on the equilateral triangle system will carry 97 trees; on the square system only 85 trees could be planted. On this area I would put in 30 pears, 50 apples, five peach, five apricot, two quinces, two figs, three plums. The apples should constitute the bulk of the garden, as they keep well and can be dried very easily if the crop is too heavy. Have early, late, and midseason fruits, and not all ripening together. I strongly recommend spraying the peach trees with Bordeaux mixture, which consists of 6lbs. bluestone, 4lbs. lime, 25galls. water, just before the buds burst. This will prevent curl leaf, which I have noticed is thick on nearly all newly-planted peaches in this district. It is most important to cut the tree well back at planting. Do not be sparing with the pruning shears, because the fewer the buds left the greater will be the vitality of the shoots therefrom. A tree left with a lot of wood makes spindly growth, as the shoots draw too heavily on the root system before the tree is established. Remember that a good start to the tree means everything."

GLENCOE.—November 10th.—Eggs.—Mr. P. Clifford read a paper on this subject. Eggs intended for preserving, he said, should be absolutely fresh, clean, and free from cracks. If they were bought they should be carefully tested or "candled" before being put down. The receptacle in which they were stored should be earthen or wooden for preference, and scrupulously clean. Lime water solution for pickling was made by dissolving 1qt. of lime in 15qts. of water. This should be poured over the eggs, which should have been placed in layers with the small ends downward. About 3in. or 4in. of solution should cover the top layer of eggs, and light should be excluded. Lime and salt solution was prepared by thoroughly mixing 1lb. salt and 2lbs. quicklime with 8qts. of water, previously boiled. After the lime had slacked and settled the clear liquid should be poured over the eggs, packed as before mentioned. A 10 per cent. water glass solution was perhaps the best method. The dry methods of preserving were not recommended where it was desirable to keep the eggs for more than a few months. These consisted of packing in salt, dry wood ashes, wheat, bran, oats, &c.

Dairying.—At a previous meeting Mr. J. Riddoch, jun., read a short paper. He preferred the Shorthorn crossed with the Jersey for dairying purposes. Heifers should not be stinted until they were 2 years old. The bull should be kept in a small paddock, into which the cows could be turned as they came into season. Sheds and yards should be well kept, and washed after every milking. Warm milk should on no account be mixed with the cold. Oats fed green with the natural grasses provided the best fodder. Lucerne was hard to establish in this district.

Sheep.—This subject was dealt with by Mr. H. A. Cameron in a paper read at a previous meeting. If wool were the objective, he said, early autumn lambs should be bred, but care should be taken not to overstock, and the ewes should have been previously dipped when fat lambs were desired; the lambing should take place in the early spring; the lambs should be ready for market at about four months old. The best market lamb was the progeny of the Shrop. ram and the first cross or Lincoln ewe. A quick-maturing lamb was the result.

Minister of Agriculture

POINTS FOR PRODUCERS.

Country Conferences.

Farmers' Conferences under the auspices of the Agricultural Bureau, will be held at Orroroo (Upper North Branches) on March 20th, and at Millicent (South-East Branches) on March 25th. The Minister of Agriculture (Hon. T. Pascoe, M.L.C.) will open the Conferences, and officers of the Department of Agriculture will deliver addresses. The Director (Professor Lowrie) and the Superintendent of Agriculture in the South-East (Mr. W. J. Colebatch) will speak at Millicent. Papers will also be submitted by members of local Branches, and these, with the addresses by officers, will be open for discussion and comment. Members of the Bureau may secure rail tickets at excursion fares by applying to the Secretary Advisory Board of Agriculture for the necessary certificate.

South Australian Wheat Crop.

As a result of later investigations the Government Statist (Mr. L. H. Sholl, C.M.G.) issued on Tuesday, February 3rd, a bulletin reducing his estimate of the wheat yield for 1913-14 from 19,491,585bush., average per [illegible] 9·39bush. (forecasted on November 30th, 1913), to 16,805,945bush., average per acre 8·18bush. The previous estimate, Mr. Sholl states, "was based on information contained in reports dated up to November 19th, and undoubtedly was amply justified. Unfortunately, however, immediately after the issue of the forecast the wheat districts were visited by hot winds, and in the absence of sufficient moisture in the soil a considerable decrease in the anticipated yield has resulted in practically every district in the State. To ascertain the extent of this loss all the reports were returned to the collectors early in January for revision, and nearly 300 of these have again been received and analysed. An allowance has been made for the few minor districts outstanding. As a result of the January revision, the area stripped for grain has been reduced by 21,700 acres, owing to the cutting for hay of rust-affected crops. The yield is expected to reach 16,805,945bush., and to average 8·18bush. per acre. The area for hay has been increased to the extent of 21,700 acres, making the total area 471,658 acres, with a yield of 515,331 tons, or 1·09tons to the acre." The November and January estimates of the averages per acre of the various divisions are respectively as follow:—Central 10·41bush., 9·31bush.; Lower North, 13·14bush., 11·78bush.; Upper North, 3·92bush., 3·65bush.; South-Eastern, 9·39bush., 7·56bush; Western, 6·20bush., 4·84bush.

Shop Window Displays in England.

The Trade Commissioner, in his report dated London, December 12th, states :—" From the Adelaide papers I notice that it was stated in the House of Assembly that Canada had been carrying out a propaganda of show displays for the last five years, but I would point out that such is not the case. Canada is not even to-day carrying out advertising methods in the same manner as we are doing. Their one object all along has been emigration, and not with a view of introducing the products of the country. Though Canada has not been doing it in the past, you may be interested to learn that certain of their States intend following our lead. Only this month I have had a call from a special commissioner from the British Columbian Government, who requested me to let him know the principles upon which I was working, as the British Columbian Government proposed appointing a Trade Commissioner, and from what he had heard he did not consider he could do better than follow out our principles. The South African Government also from time to time have communicated with me with a view of getting ideas as to what we are doing."

Market for Pea Nuts.

Reporting to the Minister under date London, November 28th, the Trade Commissioner states--" *Pea Nuts.* -There is certainly a considerable trade to be done in this class of goods, particularly in the north of England, but it would be quite impossible for me to give anything definite as regards price at the moment, because necessarily everything will depend upon the sample. At present, however, I may state the market is as follows :—African pea nuts, 20s. to 21s. per cwt. ; Indian, 20s. to 21s. per cwt. ; Japan, 23s. 6d. to 25s. 6d. per cwt. ; China, 23s. to 24s. per cwt. . Valencia, 15s. to 20s. per cwt. It is only fair, however, to state that these prices are rather above the normal, as stocks at the moment are short."

Newmarket Livestock Sales.

The most wonderful bloodstock sales ever held came to a close at Newmarket on December 5th, says the *Agricultural Gazette.* When at length the hammer fell on the last lot it was found that in the course of the five days 713 lots had realised 308,658 guineas. Last year 659 lots made 240,547 guineas, so that that total, which has stood as a world's record until this week, has been surpassed by 68,111 guineas. These are staggering figures. Altogether Mr. Mantascheff, the Russian enthusiast, secured 25 lots for 47,510 guineas, or just under £50,000. Last year he bought 17 lots for a little over 20,000 guineas. He is the owner of about 180 brood mares, and he has 120 horses in training.

Upkeep of Roads.

Roads of an aggregate length of 100,594 miles were maintained by the 655 rural district councils in England and Wales in 1911-12. The average cost of repairs per mile was—Main roads, £83 10s.; other highways, £24 11s.; the total cost of upkeep being £2,791,498 out of an aggregate expenditure of £4,859,402.—*Agricultural Gazette.*

Dried Yeast as a Food for Stock.

In a recent issue of the Bulletin of Agricultural Intelligence and Plant Diseases, Dr. F. Hayduck, Berlin, gives an account of the development of the dried yeast industry in Germany, and points out the value which this by-product possesses as a food for all classes of farm stock. Fresh yeast has been fed to cattle and pigs with excellent results on farms in the immediate neighborhood of breweries, but since the drying process has been introduced dried yeast can now be procured by all farmers. Dry yeast is described as one of the richest concentrated foods, 55 per cent. of the dry matter being protein. It is very palatable and easily assimilated by all kinds of livestock, and is especially suitable for fattening purposes. It possesses special dietetic properties, and its real value is therefore higher than its calculated food value. Experiments conducted at the above institute resulted in furnishing the following data:—(1) When fed to milch cows the butter-fat content of the milk was increased. (2) The health, appearance, and performance of horses were maintained when more than half of their grain ration was replaced by a corresponding quantity of nutritive substance in the form of dried yeast and dried potatoes. (3) Sheep utilised 94 per cent. of the organic matter, 88 per cent. of the crude protein, and upwards of 100 per cent of the nitrogen-free extract of the dried yeast, which was found to have a higher nutritive value than cottonseed meal. (4) Young pigs fattened readily on a mixture of dried potatoes, dried yeast, and barley, without any dairy by-products. (5) As a food for the fattening of geese, the production of eggs and good quality flesh, dried yeast was equal to meat meal.

Physiology of Sex Determination.

In a paper on the above subject, read before the Section of Physiology of the British Association, Dr. C. Doncaster suggested that all individuals, both of animals and plants, are potential hermaphrodites, the determination of sex being due to the alternative presence or absence of a Mendelian factor.

Hints on Milking.

Mr. R. W. Haydon, of the University of Leeds and Yorkshire College of Agricultural Education, in a recent lecture said that to get the most milk it was necessary to have good milkers. Some farmers erroneously thought it was a good thing to change the milkers. He contended that so far as possible they should have the same milker for a particular cow day after day, as the cow became accustomed to the particular individual, and put itself into the best milk-yielding attitude, which it would not with a stranger. In his younger days there were more women engaged in milking, and he was absolutely sure they were better milkers than men, if they had sufficient strength in their arms. The main reason was, a woman was more conscientious, she had a greater fear of not doing her duty properly. He had often seen cows turn their noses to women, but never to men. The good milking cow had a good bag, with teats about 8in. apart, and a bag covered with a thin skin which stretched. They would get more milk by milking a cow three times a day than twice, as when the bag was empty there was more secretion of milk from the blood. How much milk a cow made depended upon how much blood passed through the udder. They wanted a well-developed family gland and udder, nourished by a large quantity of blood. The nervous system affected the flow of blood to the udder, and if the milker was upon good terms with the cow and the latter felt friendly towards him, the flow of blood was increased and the more milk produced. If the milker was a stranger, or excited nervous feelings, it had the opposite effect.—*Agricultural Gazette.*

Relationship of Bovine to Human Tuberculosis.

In the course of a provincial meeting of the Royal Sanitary Institute, held at Newcastle, Mr. H. J. Hutchens, D.S.O., M.A. (Professor of Comparative Pathology and Bacteriology at Durham University), dealt with "Some Points in the Relationship of Bovine to Human Tuberculosis." Mr. Hutchens, says the *Mark Lane Express,* held that while the tuberculosis of the cow and of the human being is not exactly the same, a child infected with the cow's tubercle is liable to develop the disease in later life, the disease having been latent during a period of transmission from one species of tuberculosis to another. He inclined to the belief that adults are but little susceptible to the tubercle from cattle, and dealt with the methods to be adopted in stamping out the disease in cows, and preventing children from taking the infection. The latest order of the Board of Agriculture as to the examination of cow's milk, might tend, he suggested, to increase rather than diminish the number of tuberculous cows in the country, as it prescribed microscopical examination, which was a very inefficient method. It therefore behoved private individuals to take steps to protect children. The only way to make sure that a child shall not become infected with bovine bacillus was to insist on its not being fed with cow's milk unless the latter be boiled, and that no child at whatever age be allowed to have raw cow's milk. The reason why so many people in the present day were able to drink uncooked cow's milk with immunity was that they had acquired immunity in early days of life by swallowing small doses of living tubercle bacilli. Could the immunising dose of living virulent bovine be determined for each individual, there would be an invaluable means of preventing the disease. Experiments in immunisation were being pursued, and no doubt some day it would be possible to immunise man against tuberculosis as effectually as against smallpox or enteric fever. The paper concluded with a warning against pasteurised milk, the process of pasteurisation being described as worse than useless.

Imports and Export of Fruits, Plants, Etc.

During the month of December, 1913, 12,846bush. of fresh fruits, 450 bags of potatoes, 128 bags of onions, and 36pkgs. of plants, seeds, and bulbs, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Of these, 162bush. of bananas (over-ripe) and 5pkgs. of plants (no declaration) were destroyed. Under the Federal Commerce Act 20 cases of fresh fruits, 26pkgs. of dried fruit, and 94pkgs. of preserved fruit, and 1pkg. of honey were exported to oversea markets during the same period. These were distributed as follows :—For London, 1pkg. of dried fruit; for Germany, 1pkg. of honey; for India, 94pkgs. of preserved fruit; for New Zealand, 20 cases of cherries; for South Africa, 25pkgs. of dried fruit. Under the Federal Quarantine Act, 1,381pkgs. of plants, seeds, bulbs, nuts, &c., were examined and admitted from oversea markets. During the month of January, 1914, 242bush. of fresh fruits, 8,802bush. of bananas, 464 bags of potatoes, and 77 packages of seeds, plants, and bulbs, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910; 4bush. of mangoes (fruit fly), four packages of plants (no declaration), and 186bush. of bananas (over-ripe) were destroyed. Under the Federal Commerce Act 934 cases of apples and 1,450 packages of dried apricots were exported to oversea markets during the same period. These were distributed as follows :—For London, 1,450 packages of dried apricots; for India and the East, 934 cases of apples. Under the Federal Quarantine Act 1,239 packages of plants, bulbs, seeds, nuts, &c., were examined and admitted from oversea markets

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

" J. H. F." seeks advice in regard to the following :- -(1) A three-year-old colt had strangles 12 months ago with result that face, neck, and jaw were badly swollen. After about a month the abscess broke. (2) A mare worked in wagon all day apparently in good health, but about 9 o'clock was found shivering and breathing heavily, though not in acute pain. A 3oz. dose of Epsom salts gave relief, and she was nearly recovered following morning.

Reply—(1) The colt has chronic pyæmic abscess. Clean wound with Condy solution, and give on the tongue daily ½ dram iodide of potassium for three weeks, or if hair falls off before stop. Treatment not likely to be of much benefit. (2) The mare was apparently affected by weather, but the symptoms described are too vague to venture opinion on.

" A. C.," Telowie, had two horses sick for 10 days, supposed caused by worms. Treated for these, giving aloes, oil, and salts. The horses were scoured, and pawed, scraped, and at first passed thick water, but subsequent use of catheter had no effect. They both died, and *post mortem* on one revealed no signs of worms, and very little sand. There was an abscess on large gut, with surrounding inflammation.

Reply—The trouble was pyæmia or blood poisoning, commonly called influenza. Purgative physic was just the wrong treatment, and probably induced the inflammation. In a similar case, stop work at once, give bran mashes only, 10 drops tr. aconite three times a day for three days, and things will probably go better.

" H. P.," Coomandook, has three horses which became hot and trembling. This was followed by swellings on shoulders, neck, belly, and chest. The swellings break and discharge, leaving hollow under skin. The horses have gone lame.

Reply—These are the symptoms of what is commonly called influenza or, technically, lymphadenitis, and show that the blood is invaded by parasites which produce the symptoms. Treatment—Stop work and give bran mashes or green food, 1oz. Epsom salts three times a day in food or, better, 1oz. hyposulphite of soda in food three times a day, and as recovery sets in 1 dram of sulphate of iron and 4 drams sulphur twice a day in food. Wash discharges with Condy's crystals, as much as will lie on a threepenny piece to a pint of warm water, and use with boracic acid after. The lameness may be muscular, for which the above treatment suits. If, however, laminitis sets in, then the feet must be well soaked in hot water or poultices applied as well.

"J. J.," Cleve, has a mare suffering from a heavy cold, with copious discharge from nose. The trouble appears to be mostly in her throat; she half chokes and roars, and the food comes through her nose.

Reply—From the symptoms the mare has a very severe sore throat, probably due to strangles. Feed on sloppy mashes and good sweet hay steamed. DO NOT ATTEMPT TO DRENCH. Steam head well several times daily with a few drops of turpentine or eucalyptus oil on the steamer. Give 10 drops of veterinary tinct. belladonna in a little sugar on the tongue twice a day, and alternate with a similar quantity of arsenicum twice a day. Feed and water from the ground and keep head low when steaming.

"P. R. P.," Clare, asks for treatment for two-year-old filly affected by number of warts round nose and mouth. The filly is in low condition, but appears to eat well.

Reply—These are not contagious, and will probably disappear if you rub the nose with castor oil one day and vinegar the next for a few days. If this does not answer, tr. thuya, 1oz. to 1 pint water, a little applied daily, will move them. As the filly appears low in condition it would be well to let her have once a day a powder consisting of arsenic 1gr., nux vomica 20grs., sugar to hide taste; or veterinary arsenicum, 10 drops morning and evening on the tongue for 10 days.

"Inquirer," Manoora, seeks advice regarding treatment for foal suffering from scrotal hernia.

Reply—Treatment depends on extent of rupture. If severe, probably best to have castrated by covered method; if not larger than an orange, wait and see, as it may reduce naturally; but it must be remembered when the time comes for castration.

The Crystal Brook Branch Agricultural Bureau asks for remedy for fly nuisance in stables.

Reply—Flies breed in horse dung, therefore do not leave it about. Put down tins containing milk and water, with a tablespoonful of formalin and a bit of crust for the flies to settle on. Do this when horses are out. Hang up bunches of gum leaves, and in evening slip a paper bag over each when the flies have settled; screw it up and burn. Do this every night, away from stable. Smear horses legs with refuse machine oil.

"H. S.," Crystal Brook, has a mare with mange on shoulders. He inquires treatment.

Reply—Bring the animal out into the sun; wash well all over with carbolic soft soap; dress with train oil and sulphur, ½lb. to gallon, over affected parts. Repeat every week till cured, and then every three weeks.

"A. J. H.," Mount Gambier writes that he has two cows suffering from what is commony termed redwater. Both animals have had natural grasses only and are in good condition.

Reply—There are different forms of redwater, such as Queensland tick fever, which, fortunately, has not spread as far south as South Australia. Another form is due to constitutional disturbance after calving, but the more common is a form carried from animal to animal by means of biting flies, which inject into the system tiny animal germs, which break down the red blood cells, the coloring matter of which is passed off in the urine. *Post mortem*, the liver will be found to be large, soft, and light in color, and the spleen will also be enlarged. If you could get someone to make blood smears and send them for examination it would be a help. Treatment varies. Often a pound of Epsom salts is followed by a cure, but probably you will be better satisfied by giving a pint or two of yeast. Move the cattle from the place where the disease occurs to higher, drier ground. The disease is not immediately contagious, but an affected beast becomes a source of danger because the poison is obtained from it for the infection of others.

WOOL.

The Booleroo Centre Agricultural Bureau asks—Will sheep that have produced dark, heavy wool, and those that produced hard, greasy wool, clip the same kind of wool each year?

Reply—Mr. Henshaw Jackson, the Wool Expert, states in reply—"It is quite likely that the sheep mentioned will go on producing the same kind of wool, so far as color and condition of yolk is concerned, each year. The quantity of yolk will, of course, vary with the seasons and feed; but color and quantity, apart from seasonal variations, are constitutional. I have had individual sheep that year after year came to the shearing with much heavier and darker wool, so far as yolk is concerned, than others running with them under exactly similar conditions, and at time of replying have a couple of sheep in a small flock of 10 which showed this peculiarity when shorn last year, and bid fair to produce it again next shearing."

ASH FROM GRAPE STEMMINGS.

Two samples of ash were submitted to the Agricultural Department for analysis by the Renmark Agricultural Bureau. The following is the result:—

	Per cent.
Sample No. 1.—	
Insoluble matter (silica, &c.)	45·96
Total phosphoric acid (P_2O_5)	2·26
Total lime (CaO)	9·54
Total potash (K_2O)	12·00
Water soluble potash (K_2O)	10·80
Sodium chloride (*i.e.*, chlorine expressed as sodium chloride)	2·39
Sample No. 2 (ash more granulated)—	
Insoluble matter (silica, &c.)	31·47
Total phosphoric acid (P_2O_5)	4·45
Total lime (CaO)	13·53
Total potash (K_2O)	22·47
Water soluble potash (K_2O)	19·31
Sodium chloride (*i.e.*, chlorine expressed as sodium chloride)	3·36

These analyses show that this ash though produced in small quantities is well worth husbanding carefully. If the analyses be compared with that of kainite as put on the market, guaranteed 12 per cent. or 12½ per cent. of potash, it will be noted that in the first sample the percentage of potash approximates to the percentage of potash in kainite, while in the second sample there is more than one and a half times the potash present in kainite. Kainite is quoted in England at £2 10s. to £2 12s. 6d. per ton in bags, and in Australia at £4 per ton or over. But this ash as a mineral manure has considerable commercial value additional to its potash content in that it contains 2·26 per cent. phosphoric acid in the first sample and 4·45 per cent. in the second, equivalent to 4·9 per cent. and 9·7 per cent. phosphate of lime respectively. Further, the percentage of lime present would increase the value of this ash as a mineral manure.

As the potash, phosphates, and lime in such ash are present in forms particularly readily available for plant life, it will be recognised that there is here a valuable manurial substance worth, if the quality could be maintained, from say £3 to £5 10s. per ton or over, according to market rates for manures. Small though the quantity produced be, it should therefore be carefully saved for application to the land.

SOME PARASITES AFFECTING FARM ANIMALS.

By F. MURRAY-JONES, L.V.Sc., Veterinary Department.

(*Continued from page* 653.)

TREMATODA LIVER FLUKE (*DISTOMA HEPATICUM*).

This variety belongs to order of Trematoides. They are found in sheep, cattle, and occasionally in horses. They are small and flat like a miniature flat fish. They live singly, and during development pass through a most complicated series of developmental changes. Briefly, these changes are as follows :—First, the ova or egg passes from intestine of sheep with the fæces. In four to six weeks, if weather favorable, they develop into embryos with a hairy skin and a borer in front. These in turn bore into the body of the freshwater snail (*Linnæus truncatulus*). The distribution of this snail corresponds to that of the fluke. They are very small, and live on land as well as in water. In 14 days (summer), three to four weeks (winter), they develop into a germinal bag (sporocyst) with germinal cells. By a system of stretching of these cells we get tubes of immature flukes (*Rediæ*), and from these are directly produced the true brood called *Cercariæ*. These little chaps, so small as to be only discernible under a microscope, are like tadpoles, and live freely in water. An idea of the number produced can be obtained by remembering that one egg is capable of producing 1,000. These little swimmers attach themselves to grass blades and become encysted. They lose their swimming tail and develop a tough mantle, which protects them during their waiting period.

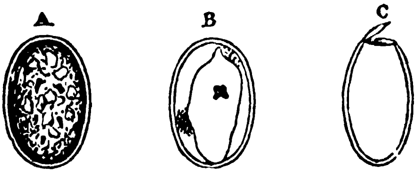

FIG. III.—OVA OR EGG OF FLUKE (*Distoma hepaticum*).
A. Ovum from the bile duct of sheep.
B. Ovum containing developed embryo.
C. Ovum after hatching, showing lid.

Later on, sheep grazing ingest the grass, and with the grass also these little encysted bodies. Infection may also take place by swallowing snails, or even drinking water in which the *Cercariæ* are swimming.

Reaching the sheep's stomach, the gastric juice dissolves the hard covering, and the young flukes are liberated. They pass on into the small intestine, and crawl up the bile duct and finally reach the liver. Here they remain and develop into the adult fluke, reproduce their eggs, which escape down the track of the bile duct, and reach the intestine. Here they are finally discharged with the fæces, and are ready to again travel the cycle of above development.

THE EFFECT OF FLUKE ON SHEEP.

An animal may be infected for some time and apparently little disturbed by their presence, even in some cases distinctly putting on flesh. Wasting generally takes place during the end of second stage of the disease, and then it is generally rapid. The parasites which have been drawing on the animal's blood for so long produce a condition of anæmia and some infection of the bile duct. This generally produces a state of icterus or jaundice; hence one may see on examining the eyes that tingeing of greenish-yellow due to bile. This discoloration is often so pronounced that although we have not a condition of wasting, the tissues are so discolored that it (the carcass) becomes unfit for human food. The third stage is accompanied by general wasting. If you should examine the liver of an animal destroyed or dead from this disease, you would find the liver enlarged, harder than normal, and a thickening of the bile duct, together with the presence of a gritty or calcareous

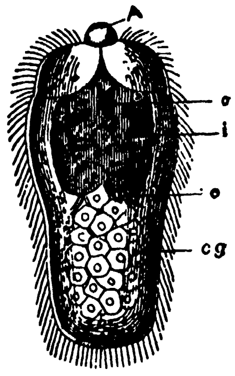

FIG. V. THE SAME CONTRACTED.
i. Digestive canal.
cg. Germinative cells.

substance. Heavy losses occur in different parts of Australia as the result of these parasites, particularly with sheep. They occur generally in low-lying, swampy ground.

TREATMENT.

This consists above all in exercising preventive measures. Pastures get more dangerous as winter sets in. Wet ground should be drained and sprinkled with lime and salt. Rock salt should be supplied to sheep as licks. Salt destroys the young, immature parasites in the stomach of an animal. A good lick for sheep is 1lb. sulphate of iron, 2lbs. salt, 8ozs. sulphur, 4ozs. gentian. Dose—2ozs. per head per day for 10 days, in food.

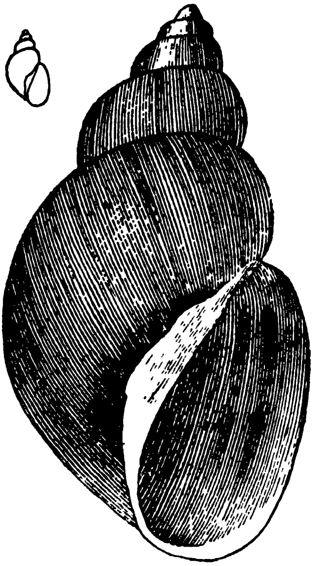

FIG. VI.—FRESHWATER SNAIL (*Limnæ truncatula*). This harbors the fluke embryo. The smaller one, natural size.

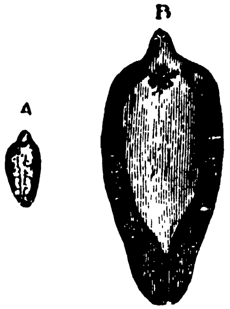

FIG. VII.—THE FLUKE (*Distoma hepaticum*).

B. The adult }

NEMATODES.

The most important order in this group is the *Ascarides*. The *Ascarides* are round worms, and several varieties are found in our different domestic animals, *i.e.*—

1. *Ascaris megalocephalus*, found in intestine of horse.
2. *Ascaris marginata*, found in intestine of dog.
3. *Ascaris mystax*, found in intestine of cat.
4. *Ascaris lumbricoides*, found in intestine of man, cattle, pigs.
5. *Ascaris suillæ*, found in intestine of pig.

The *A. megalocephalus* presents the general features of this order as follows:— It resembles the earthworm in shape. It is yellowish-white in color, stiff and elastic, 6in. to 14in. long, and generally resides in small intestine. Sometimes it travels forward to stomach. They gain entrance to animal's body with drinking water and damp forage. The eggs of the worm are never hatched in the body, but are expelled with the dung. As a rule they cause little or no trouble beyond perhaps absorbing food fluids stolen from the host. If a horse is badly infested, he falls away in condition, coat gets rough and staring, becomes "pot bellied," colicky, and perhaps slight diarrhœa due to irritation. If the animal is affected, one or two worms at least will be found in the dung. They have been known to perforate the bowel.

Life History.

The history of the *Ascaridus* is not very clear. The present opinion held is that an intermediate host is not necessary for completion of the life cycle, and infection generally takes place by the animal swallowing the egg derived from an infected animal.

Treatment.

Tartar emetic, ½ dram; sulphate of iron, 2 drams; to be given as powder three times a week; follow up with a pint of raw linseed oil at end of week. During treatment keep animal on short ration with liberal supply of bran. Tartar emetic has a specific action on the worm, and does not depress the horse. Repeat above treatment after 14 days if necessary. Follow up with 1 dram of sulphate of iron once daily in feed for 14 days. Turpentine may be given, 1oz. to 2ozs. in pint of raw linseed oil. Care should be taken with turpentine, as it has a stimulating effect on kidneys.

STRONGYLES.

Several members of this family are responsible for great losses amongst our sheep and cattle. Their special place of abode is found to be the bronchial and lung tissues.

Strongylus micrurus is found in the lungs of cattle, and may give rise to bronchitis, and even induce a state of mechanical pneumonia.

Strongylus filaria.—This one is found in sheep and camels, and is often spoken of as the husk worm. At times great losses in sheep occur as a result of its presence. This worm is a white thread-like worm, and is found only in the bronchial tubes; whereas the *S. rufescens,* or the red worm, is found in the lung tissues.

Strongylus rufescens.—This worm, as already stated, is found in the substance of the lung, and gives rise to formation of nodules in lung. These two preceding ones produce a condition of bronchitis, and spoken of as husk.

In parasitic bronchitis great numbers of eggs and embryos are expelled from mouth and nostrils by the continual coughing induced by the irritation of their presence. The female worm is capable of discharging several million of embryos, and these find their way to soil; but these require an

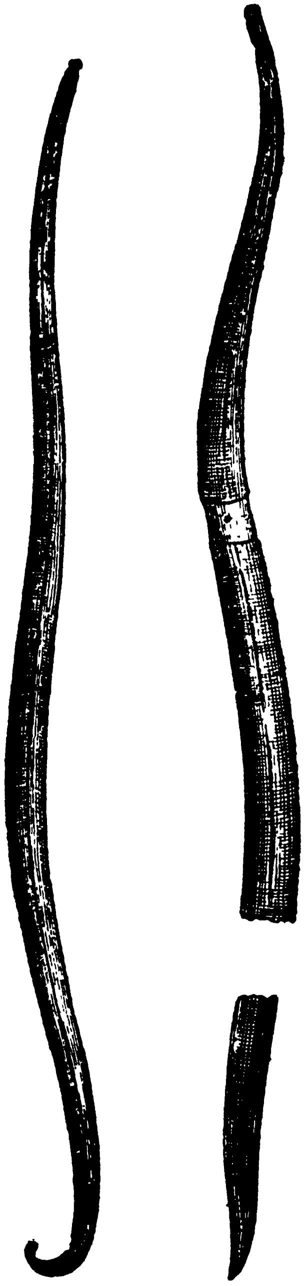

FIG. VIII.—THE COMMON ROUND WORM (*Ascaris lumbricoides*). Male and Female.

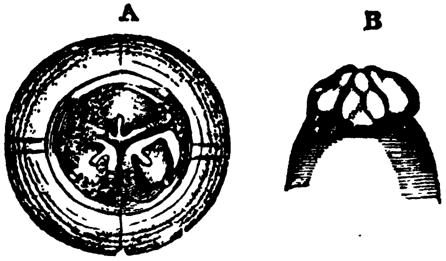

FIG. IX.—HEAD OF COMMON WORM. A. Front view. B. Dorsal view.

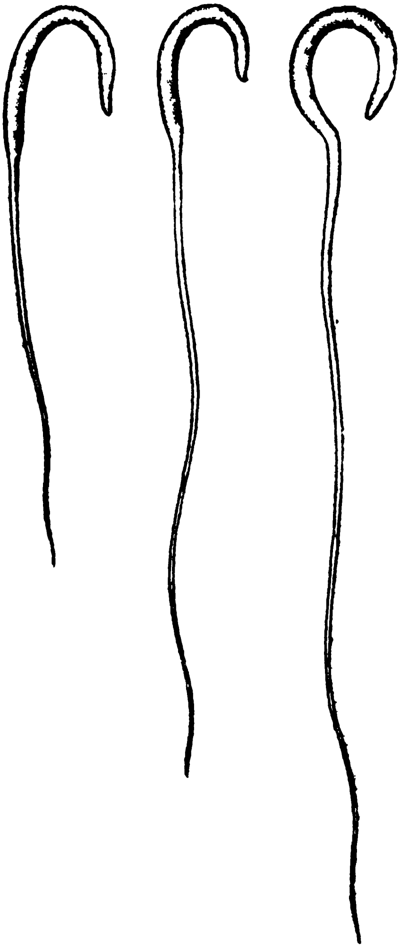

FIG. X.—PIN WORMS (*Oxyuridæ*). Natural size.

intermediate host before infecting sheep or cattle. It is thought that the intermediate host is the earthworm. After passing through the body of the earthworm it again reaches soil, so that infection follows the ingestion of food or water contaminated with their presence.

PREDISPOSING CONDITION.

Over-stocking; reduced vitality of animals through insufficient or innutritious food; low-lying, swampy ground, and infected and stagnant water supply.

PREVENTIVE MEASURES.

Same as recommended for flukes. Liberal feeding, sulphur and salt licks, draining soil, fencing stagnant water, avoiding swampy ground, top-dressing land occupied with sick animals with salt and lime.

OXYURIDÆ—THREAD WORMS.

Oxyuris curvula.—This worm is about 1in. to ¾in. long when fully grown; its tail is thin and whip-like. The front end is thicker and the tail ends in a curve. These worms generally affect the animal more as an inconvenience than one productive of any special harm. The animal is irritated about the dock, and may be seen rubbing the tail vigorously against a door, fence, or vehicle, sometimes so much as to wear the hair off the dock. Around the fundament will be found a collection of mossy-like substance and a light-yellow material containing the eggs of the parasite. Thread worms, like the round wo ms, frequently come away in the dung.

TREATMENT.

Clear out back passage and then inject an enema of warm, salt water. Follow this up with an injection of linseed oil, to which has been added 1½ozs. of turpentine. A solution of tannic acid may also be used in the same way. Should a couple of attempts in the above way be non-successful, probably the worms are too far forward to be reached by this method. Resort to methods already advised for large round worm.

(To be continued.)

LADS FOR SOUTH AUSTRALIAN FARMS.

In the January issue of the *Journal* there appeared an article written by Mr. T. E. Sedgwick, an English gentleman who is keenly interested in junior migration from the United Kingdom to the Oversea Dominions of the Empire.

As indicated by Mr. Sedgwick, the South Australian Government have now decided to act under the provisions of the Immigration Act Amendment Act of 1913, and preliminary arrangements are being made for a party of 50 lads to arrive in South Australia in May next for apprenticeship to farmers. The Commissioner of Crown Lands and Immigration has given instructions to the Immigration Department to issue a circular, of which a copy is published below, to farmers and other producers inviting applications for boys. As the first party will probably be over applied for, early application will be necessary to secure one of them.

The circular issued by the department is as follows :—

IMMIGRATION DEPARTMENT.—BOYS FROM GREAT BRITAIN TO BE APPRENTICED TO FARMERS AND OTHER PRODUCERS.

The Government desire to bring under the notice of farmers and other producers the Immigration Act Amendment Act of 1913, and the regulations thereunder, which provide for the introduction from the United Kingdom of boys between the ages of 15 and 19 years who are physically capable of and wish to take up farm, garden, or station work.

APPRENTICESHIP.

Every boy coming to the State under the provisions of the Act will be placed out or apprenticed for a period of not less than one year nor more than three years. (The first party will probably be apprenticed for three years.) The form of agreement to be signed by the boy and the employer is prescribed by the regulations, and a copy is forwarded herewith. The fact that the boys will be apprenticed is expected to appeal strongly to employers, as they will be able to obtain the benefit of the training they have given the boys, and will not feel that by taking extra trouble in teaching them they are likely to lose their services in the immediate future. The Act provides for a penalty not exceeding £20 against any person who counsels or induces any boy to break his agreement or abscond from his employer.

WAGES.

Employers are asked to state in the appended form of application the minimum rates of wages (in addition to board and lodging) which they are prepared to offer. It will be observed that the form provides for the rates offered being increased during the period of the apprenticeship, and in a pamphlet distributed in the United Kingdom the boys have been informed that it is anticipated that the minimum rates will be as follows :—

First four months ...	8s. to 10s. per week with board and lodging.
Balance first year ...	10s. to 15s. per week with board and lodging.
Second year	12s. 6d. to 17s. 6d. per week with board and lodging.
Third year	15s. to 20s. per week with board and lodging.

With double the rates mentioned in each case during the harvesting period.

Saving Wages.

The agreement provides that each boy will be paid out of his wages 2s. 6d. per week as pocket-money, and the balance of the wages earned by him will be paid by the farmer to the Government and placed to the boy's credit in the Treasury, being retained there at 4 per cent. interest per annum until the boy attains the age of 21 years, when the amount to his credit will be paid to him.

This provision for compulsory saving is considered to be an excellent one, as it will not only train the boy in thrift, but on attaining the age of 21 years he should have from £70 to £100 to his credit in the Treasury, and by transferring the amount to a Savings Bank account and adding to it from wages subsequently earned he would soon be in a position to attain his object in coming to the State, viz., to take up and work land on his own account (engaging in share-farming first), and in many cases, no doubt, he will be assisted in achieving this object by his original employer, who, having trained the boy, will take a life-long interest in him.

Clothing, Etc.

The Minister will have power to debit the boy's account in the Treasury with amounts due by him in connection with his passage to the State and outfit, and with the cost of clothing and other necessaries purchased by the boy with the approval of the Minister. All of the boys introduced will bring with them a complete outfit, and when any of the articles has to be replaced the boy will apply to his employer, who will forward a list for the approval of the Minister. Purchase from the storekeeper recommended in the application will then be authorised by the Minister, who will pay the account when rendered, debiting the boy's account in the Treasury with the amount. This arrangement will, it is considered, be more satisfactory than the original proposal that the clothes should be provided by the employer.

Control of Minister.

During the period of apprenticeship the Minister will have the care, control, and management of the boy. will see that he is properly treated, and that the wages are fair. On the other hand, he will have power to fine the boy for absconding or wilful negligence of his duties, and provision will be made for dismissing the boy if he is guilty of such misconduct as would justify a master in dismissing a servant.

Selection.

The Chief Immigration Agent in London has been instructed to exercise the greatest care in selection, so as to send only boys of good character, who will be capable of adapting themselves to work on the land. Only those who have indicated sterling worth and whose physique is beyond question will be brought out. The experience gained with the 91 lads who were introduced by the Government last year, and of whom only one has been reported as unsatisfactory, makes the department confident that good boys can be secured. They have shown that the British boy is quick, active, receptive, and hard-working.

THE FIRST PARTY.

It is desired that the first party of boys under this scheme should come to the State in the s.s. *Irishman*, which is expected to arrive at the Outer Harbor early in May next. It is unlikely that this party will comprise more than 50 boys, so it is important that farmers and producers desirous of securing them should, to avoid disappointment, apply at once.

As the Government wish the movement to become widely known, farmers and others receiving this circular are asked to discuss the subject with their neighbors, to whom circulars and forms can be forwarded on application.

ED. J. FIELD, Immigration Officer.

Crown Lands and Immigration Office,
Adelaide, January 27th, 1914.

Following is a copy of the form of agreement which the employer and the boy will be required to sign :—

Apprenticeship Agreement.

Memorandum of agreement made this................day of................19....., in pursuance of the Immigration Act Amendment Act, 1913, between ...., Commissioner of Crown Lands and Immigration for the State of South Australia on behalf of His Majesty the King (hereinafter called the ' Minister ") of the first part ....lately arrived in the State of South Australia (hereinafter called the " employé ") of the second part, and................of.................. (hereinafter called the " employer ") of the third part, whereby it is agreed by and between the parties as follows, that is to say :—

1. In consideration of the agreements hereinafter contained on the part of the Minister and the employé, the employer hereby agrees with the Minister and with the employé that he will employ the employé upon his ....situated at............for the term of...........years from the date of these presents at a wage of............shillings per week during the first four months, and ....shillings per week during the remaining eight months of the first year; ....shillings per week during the second year, and..............shillings per week during the third year: Provided that in respect of the period of harvest (any dispute as to the duration of which shall be determined by the Minister) the rate of wages shall be doubled. The wages shall be payable as follows :—The sum of two shillings and sixpence per week shall be paid to the employé for pocket-money, and the balance shall be paid monthly to the Minister or his appointee upon trust for the purposes hereinafter mentioned.

2. The employer, for the consideration aforesaid, hereby further agrees with the Minister and with the employé that he will during the said term teach the employé the business of................and maintain him with proper food, nourishment, and lodging, and treat him with consideration and humanity, and shall grant the employé reasonable facilities at least once on every Sunday to attend some place of divine worship according to the tenets of the religious persuasion in which the employé has been brought up, or which he professes, if there is any such place within three miles from the residence of the employer.

3. In consideration of the above agreement on the part of the employer and the agreement hereinafter contained on the part of the Minister, the employé hereby agrees with the Minister and with the employer that he, the employé, shall and will truly and faithfully serve the employer during the said term and conform to all his lawful and reasonable orders, and shall and will be honest, upright, and diligent in the discharge of his duties; and that during the said term the employer may pay all wages earned by the employé (with the exception of the sum of two shillings and sixpence per week hereinbefore mentioned) to

the Minister or his appointee; and that such wages (with the interest thereon) shall be held by the Minister or his appointee, and be applied firstly in the payment of the amount of ....which is hereby acknowledged to be due by the employé to the Minister in respect of moneys advanced and expenses incurred by the State on the employé's behalf before and (or) during his passage to the State and (or) after his arrival in the State: Secondly, in repaying any money advanced by any person, society, or association in the State or elsewhere towards the passage money of the boy, and (or) expended in providing him with an outfit for the purposes of his coming to the State: Thirdly, for the benefit of the employé when and in such manner as the Minister from time to time deems advisable; any balance (subject as hereinafter provided) to be paid to the employé upon his attaining the age of 21 years.

4. It is hereby further agreed that the employer shall, with the consent in writing of the Minister first had and obtained, have the right at any time during the said term, if the employé is guilty of such misconduct as would justify a master in dismissing a servant, or for any other reason which appears good and sufficient to the Minister, to dismiss the employé.

5. The employé hereby agrees to abstain from smoking cigarettes during the term of his apprenticeship.

6. The employé hereby further agrees that if the Minister is satisfied that the employé has been guilty of misbehaviour, or of wilful neglect of duty, it shall be lawful for the Minister, by writing under his hand, to forfeit any moneys held by the Minister on behalf of the employé, or any part of such moneys, and to apply all moneys so forfeited in manner provided by section 15 of the Immigration Act Amendment Act, 1913.

7. The employer hereby further agrees that he will not assign or transfer the employé or make over to any other person the services or care of the employé, without the consent in writing of the Minister first had and obtained.

8. It is hereby further agreed between the parties hereto that the Minister shall have power to appoint from time to time some person or persons who shall have authority to visit the employé at all reasonable times and to inquire as to whether he is being well treated, and as to whether the employer is abiding by the provisions of this agreement, and to report to the Minister thereon, and the employer shall not in any way interfere with any such person in the exercise of such authority, but shall allow him every facility necessary for the exercise thereof.

9. If at any time during the said term the employer fails to abide by the provisions of this agreement, or any of them, or is not properly treating the employé, or in any other case provided by the said Act, it shall be lawful for the Minister to terminate this agreement and to withdraw the employé from the service of the employer, and the employer shall have no redress or remedy whatever for such withdrawal or loss of service, and if the agreement is so terminated or otherwise becomes of no effect, the Minister may, by order in writing signed by him, require the employé forthwith to return to any place or institution to be named in the order, and the Minister may, by the same or a separate order, require the employer forthwith to deliver the employé to some person therein named.

10. The employer and the employé hereby severally further agree to abide by all the provisions of the Immigration Act Amendment Act, 1913, and of all regulations thereunder.

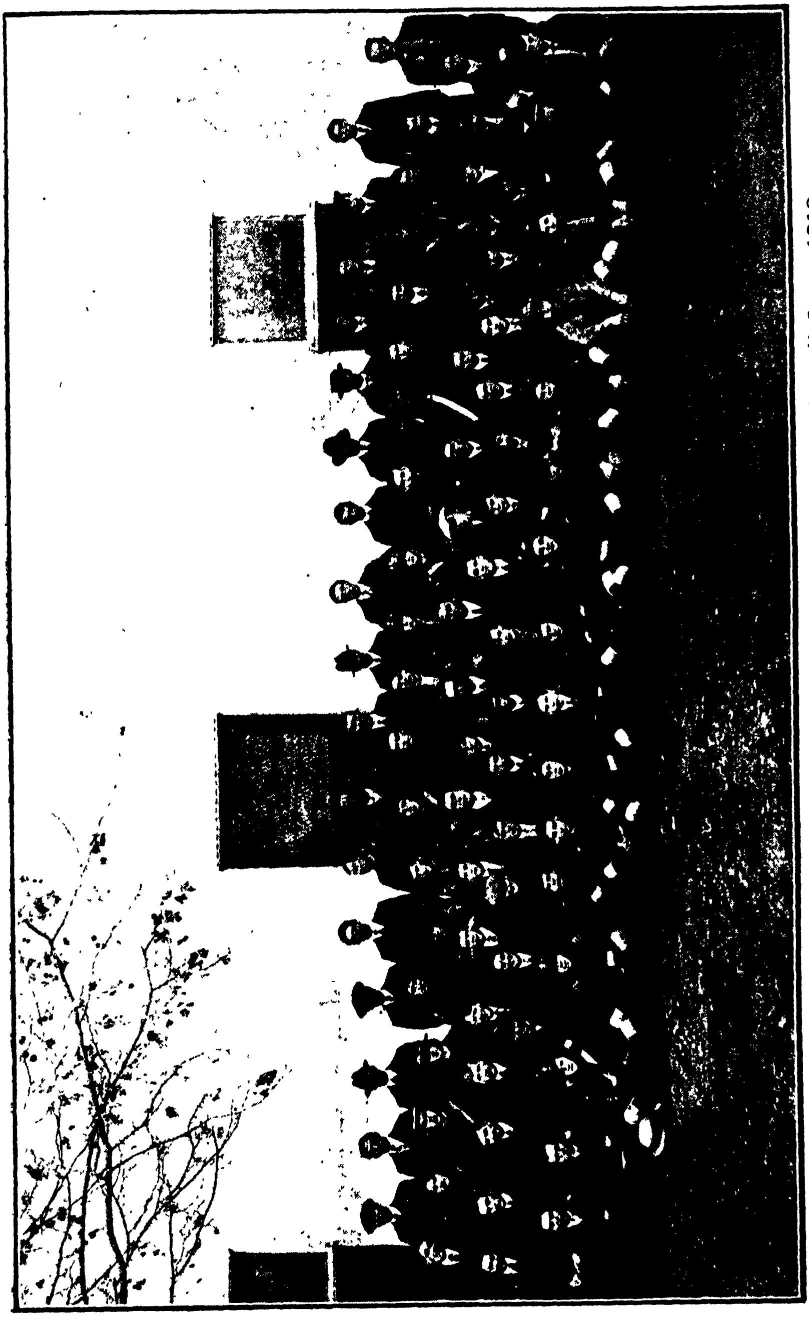
In witness whereof the parties hereto have hereunto subscribed their names on the day and year first above written.

Signed by the said..............on behalf of His Majesty the King, in the presence of } ....

Signed by the said ....in the presence of } ....

Signed by the said ....in the presence of } ....

Below will be found extracts from letters received by the Immigration Department from some of the employers, and also some of the 81 British lads who arrived in June last and were placed with farmers without apprenticeship. Nearly all the farmers add remarks testifying to the willingness of the lads and the satisfactory nature of their progress, especially in view of



Party of British Lads. Arrived South Australia per s.s. "Beltana," June, 1913.

their general ignorance of rural work on arrival. The boys correspond regularly with the department, and their letters show that British lads soon adapt themselves to the conditions of farm life.

EXTRACTS FROM FARM[illegible] TERS.

"The youth is proving a very useful lad."

"The youth seems to be a very good class of boy, and ought to do well here."

"I find the boy quick at learning, well behaved, and disciplined beyond the average boy of his age."

"He takes an interest in all his work."

"I can do with another of the same sort at any time."

"He is well mannered."

"He is a real good lad. He is well brought up, and is well liked by all my household and everyone around him."

"He is exceptionally keen and bright, and has proved himself quite capable of managing large teams. Moreover, he is well bred, and is a thorough gentleman. If the half-dozen young fellows around this locality are any indication of the rural youths available, they will be of great advantage to the country, and will do well themselves."

EXTRACTS FROM BOYS' LETTERS.

"I am quite satisfied with my work and prospects, and I hope that my fellow emigrants have as good masters as I myself have."

"I could not wish for a better place. I like the country very much, and I could not wish to be treated better than I am treated here."

"My employer is a perfect gentleman, and is quite willing to teach me as much as he can. So far he has treated me more like a brother than a hired laborer, which spirit is typical of the South Australians, as many as I have met."

"Mr. ——— is a very good master, and I have no fault to find with him, and anybody ought to be able to get on with him."

"The people are very kind to me, and treat me with every respect; not only that, I have all my meals with them, which I didn't think I should. I am in a comfortable place, and there is nothing to stop me from getting on and becoming a farmer within a few years—seven or eight. I am so glad I came out here, as I can see I am better off than I was in England. I hope all the other lads are as satisfied as I am. I mean to stick here as long as I can. I am getting on great with my governor and all."

"I am very satisfied with the work, and like the farming life very much. There is every chance of getting on in life if a lad is willing to work hard."

"I have been made exceedingly comfortable, and the people are very homely."

"I ask nothing better than to stop here until I am in a position to become my own master."

"I could not be with better people than who I am with. I am treated as if I was one of their own. Where they go I go with them, and what they have I have also. Although this is a dry year it does not make my governor cross towards me."

"I am very pleased indeed with my master and my work, and I have every prospect before me, owing to his kind words and great encouragement he is giving me, of bettering myself immensely."

"I have got a good home here, and the people I like very much, and I will try all I can to stop with them as long as my employer has got work for me."

"I am treated with proper care, and am very thankful to the Immigration Officer for putting me in such a decent place."

"In my first month's work I learned to ride and harness a horse, drive and milk cows Mr. ———— is a jolly nice man and has got patience with anyone, so it gives me encouragement to strive on, put my mind into my work, and make it a success."

"What I am learning about farming I like very much, and the life makes you strong and healthy. I have heard from my other two friends, and they say they have good people to work for, and they also like the work."

* * *

Haymaking.

FURTHER INVESTIGATIONS INTO FACTORS AFFECTING THE HANDLING OF WHEATEN HAY, INCLUDING A STUDY OF ITS DIGESTIBILITY.

By ARTHUR J. PERKINS, Principal Roseworthy Agricultural College; J. H. PHILLIPS, B.Sc., Agricultural Chemist; W. J. SPAFFORD, Assistant Experimentalist; and N. S. MAY, Assistant Analyst.

Last year we published the results of certain investigations into the nature and quality of wheaten hay, cut in various stages of development. These investigations, however, which were conducted during the 1911-12 season, were imperfect, to the extent that they were not conclusively closed by direct digestion tests on animals consuming the various samples of hay cut. Hence it was thought advisable to enlarge their scope in the season that followed. The provisional conclusions of the 1911-12 experiments may be summarised as follows :—

1. Maximum hay yields may be anticipated when the grain begins to enter upon the dough stage.
2. Hay cut in this stage of development is generally very dry and bleached, and carries an abnormal proportion of grain. We inferred for hay of this type a certain degree of indigestibility, although we had no experimental data to put forward in support of these impressions.
3. From the dough stage onwards a marked and progressively increasing reduction in the hay yield is very noticeable.
4. Hay of the highest feeding quality is secured when the crop is cut down with the grain at full size but in the milky stage.
5. The usual commercial standards for quality in wheaten hay—green color and shrivelled grain—were in our opinion amply justified.

THE 1912-13 EXPERIMENTS.

In the 1912-13 season we determined to repeat the earlier tests, and to complete them by direct digestion tests on horses. The 1911-12 experiments were limited to individual areas of one-hundredth of an acre, convenient because of the evenness in growth of the several cuts that came in for examination, but altogether inadequate if digestion tests were to follow at a later date. Hence, with a view to securing amply sufficient hay for the feeding of four horses over a period of 10 to 12 days, in 1912-13 the individual area of each cut of hay was raised approximately to half an acre. And although we carefully selected as evenly-grown a portion of a hay field as could be found, the larger areas that we were compelled to use have given rise in some instances to a certain degree of irregularity in yields which will be duly noted in the course of this report.

THE 1912-13 CUTS OF HAY.

At regular weekly intervals, seven successive cuts of hay were taken from a well-grown field of King's White wheat, starting with the field in full bloom, and closing with the grain practically ripe. Full details concerning these several cuts and their respective yields are shown below in Table I.

TABLE I.—*Showing Details of Seven Cuts of Hay taken between Full Bloom and Ripeness.*

No.	Area Cut.	Date Cut.	Remarks.	Quantity Cut.	Yield per Acre.	Moisture.
	Acres.			lbs.	Tons cwts. lbs.	%
A	0·5525	Oct. 10 .	One day after full bloom	2337	1 17 86	11·31
B	0·5400	Oct. 16 .	Grain ¼ to ⅓ of full size	2551	2 2 20	10·27
C	0·5300	Oct. 23 .	Grain nearly full size ; milky	2949·5	2 9 77	10·71
D	0·5375	Oct. 30 .	Grain full size ; still milky	3220	2 13 55	9·95
E	0·5762	Nov. 6 .	Crop just turning yellow ; grain in dough stage	3166·5	2 9 7	8·27
F	0·5112	Nov. 13	Grain firming ; very little green in crop	2910·5	2 10 93	7·53
G	0·5175	Nov. 20.	Crop white ; grain almost dry ripe	2816·5	2 8 67	7·20

It will be noted from the figures in Table I., which have been given graphic illustration in Fig. 1, that in the 1912-13 experiments the heaviest cut of hay was taken at the fourth cut, 20 days after full bloom, and at a time when the grain was still in the milky stage (Cut No. D). In 1911-12, on the other hand, the heaviest hay yield was taken at the fifth cut (Cut No. E), about 29 days after full bloom, and with the grain in the full dough stage. We have reason to believe that in normal conditions the 1911-12 results would have been repeated in 1912-13, and that for reasons that escape us, connected probably with some irregularity in growth, Cut No. E was abnormal in 1912-13. We assume, therefore, that in ordinary circumstances the graphic curve shown in Fig 1 would have followed the direction of the dotted, and not that of the full, line.

The last column in Table I. shows that hay cut rather on the green side retains on drying appreciably more moisture than hay cut on the ripe side.

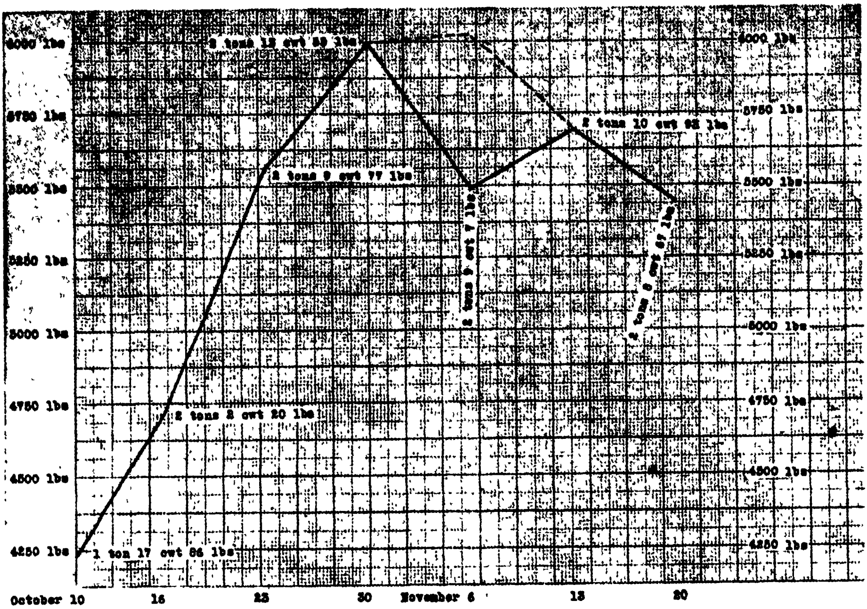


Fig 1 - Curve illustrating Table I and showing progressive rise and fall of Hay Yield as the Crop passes from Full Bloom to Ripeness of the Grain

EXTERNAL CHARACTERISTICS AND APPARENT QUALITY OF HAY CUT IN VARIOUS STAGES OF MATURITY.

In Table II. we have summarised a few notes on the general appearance and character of the several cuts of hay when they were found to be in condition for stacking. We have also indicated the loss of weight on drying for each cut.

TABLE II.—*Showing Character of each Cut of Hay when fit for Stacking, together with Loss of Weight on Drying.*

No.	Loss of Weight on Drying.	Descriptive Notes.
	%	
A	71·33	Very green in the straw; heads all bleached; empty shells in lieu of grain
B	61·32	Very green in color throughout; grain no more than skins
C	53·11	Good green color throughout; grain still no more than skins
D	47·37	Very attractive hay; green color throughout; grain almost full size but very much pinched
E	49·15	Pale-green in color; lower third of straw white; grain full size but pinched
F	33·63	Hay almost white, only traces of green being perceptible; grain good and fully developed
G	24·00	Hay brittle and white; grain good seeding sample

With reference to Table II., we wish merely to draw attention to the fact that although throughout the period under consideration—from full bloom to ripeness—the loss of weight of the hay on drying was on a progressively descending scale. There is an apparent anomaly in the case of Cut No. E, in which the loss of weight was greater than in Cut No. D immediately preceding it. This fact serves to confirm our impression that there was something abnormal in Cut No. E which at the time escaped our notice.

On the Relation between the Ears on the one hand, and the Culms and Flag on the other, in the Successive Cuts of Progressively Ripening Wheaten Hay.

In our earlier paper we succeeded in showing that the gradually increasing weight of the ears of ripening corn was gained very largely at the expense of the weight of the culms and flag. This implies that the material stored up in the ears is taken from the culms and flag, which are to that extent impoverished and reduced in value as feeding material. In other words overripe hay is ill-balanced hay, in which the valuable food materials are very unevenly distributed. This experiment was repeated in the course of the 1912-13 tests on the following lines :—From each cut of hay two typical sheaves were taken when the hay was judged to have reached stacking condition. These two sheaves were carefully weighed ; the ears were then carefully separated from the culms and weighed. The results of these data are summarised below in Table III. It should be stated that for the sake of comparison in Table III. all figures have been calculated on a basis of a hay going 10 per cent. of moisture throughout. In the earlier paper we adopted 15 per cent. of moisture as a standard. As the result of more numerous analyses, however, we are satisfied that normal hay under our conditions retains, as a rule, no more than 10 per cent. of moisture.

Table III.—*Showing Proportions respectively of Ears on the one hand, and Culms and Flag on the other, in several Cuts of Wheaten Hay cut in Varying Stages of Maturity, and calculated to a Uniform* 10 *per cent. Moisture Contents.*

No.	Culms and Flag.		Ears.		Percentage of Ears.
	In Two Sheaves.	Per Acre.	In Two Sheaves.	Per Acre.	
	lbs.	lbs.	lbs.	lbs.	%
A	11·618	3,657	1·623	511	12·26
B	11·188	3,995	2·000	714	15·17
C	11·028	4,468	2·600	1,053	19·08
D	15·056	4.515	4·933	1,479	24·68
E	14·134	3.665	7·463	1,936	34·56
F	12·767	3,680	7·527	2.169	37·09
G	12·709	3,400	8·268	2,212	39·41

The following conclusions may be derived from the results set out in Table III. :—

1. That for a period of 20 days after full bloom there is a perceptible increase in the total weight per acre of culms and flag ; and that the maximum increase at the fourth cut is close on 23½ per cent. of the original weight at full bloom.

2. That after 20 days there is a gradual decrease in the total weight of culms and flag, and that when the grain is ripe the weight of culms and flag is actually less than was the case when the plants were in full bloom. The fall of the flag is no doubt partly accountable for these results. There are, however, other factors to be taken into consideration, as we shall have occasion to see later on.

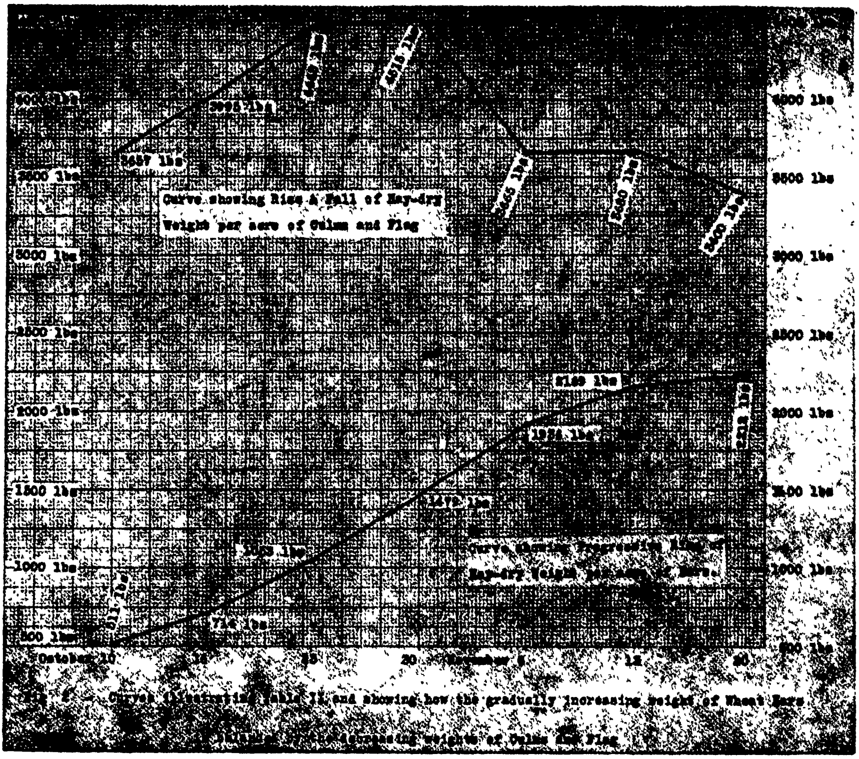

Fig. 2. — Curves illustrating Table II. and showing how the gradually increasing weight of Wheat Ears [illegible] decreasing weights of Culms and Flag.

3. That the increase in weight per acre of the ears is, on the other hand, on a progressively rising scale from full bloom to ripeness of the grain, and that throughout this period this increase in weight is always in excess of that of the culms and flag, as is indicated in the last column of Table III. by the gradually increasing percentage which the weight of the ears bears to that of the total hay in each successive cut. Thus, whilst in hay cut at full bloom the proportion of ears was about 12¼ per cent, this proportion had attained

to close on 25 per cent. 20 days after, and to close on 40 per cent. when the grain was ripe. These facts have been given graphic illustration in Fig. 2.

We may note in this connection that here again the anomalous character of Cut No. E is brought into relief. In this cut the weight of culms and flag per acre is less than that of Cut No. F, immediately following it, whereas the weight of ears is apparently normal. This would have the effect of rendering the percentage of ears in the fifth cut rather too high. We must infer, therefore that the abnormal features in this cut are probably connected with the average height of its culms, or with the proportion of flag which it carried.

CHEMICAL COMPOSITION OF WHEATEN HAY CUT IN VARIOUS STAGES OF MATURITY.

Within certain limits it is possible, by means of chemical analysis, to pronounce on the probable value of any given foodstuff ; and in this connection it is customary to separate the various constituents of the foodstuff under several headings. In the first place the water contents are ascertained, and this gives us water on the one hand and dry matter on the other. Thus a ton of hay going 10 per cent. of moisture would contain 2,016lbs. of dry matter, the balance being water. The dry matter itself may in the first instance be split up into mineral matter, or ash, on the one hand, and into organic matter, or combustible matter, on the other. Mineral matter may on the whole be considered of secondary importance in most foodstuffs, although it is naturally essential to the building up of the bony skeleton of young and growing animals. At the same time an excess of mineral matter such as is met with in immature vegetable growth is apt to lead to scouring and digestive troubles.

In all foodstuffs, on the other hand, the quality and composition of the organic matter must be looked upon as of the greatest importance. This organic matter it is customary to split up on the following lines :—(1) Proteins, or nitrogenous organic matter, regarded as the chief flesh-building material of the foodstuff ; (2) fat ; (3) carbohydrates ; and (4) fibre ; all of which, to the extent that they are actually digestible—a point which we shall have to consider later on—provide the fuel which keep the animal's vital functions going and contribute towards the building up of reserves of animal fat.

The chemical analysis of the several cuts of hay on these lines are indicated below in Table IV. It will be noted that in these figures separate data have been given for ears on the one hand, and for culms and flag on the other. This has been done in order to bring out more clearly the gradual enriching of the former at the expense of the latter.

G	1·10	1·10	71·34	48·12	13·02	42·07

We may draw the following inferences from the results in Table IV. :—(1) There is practically no difference between the percentages of mineral matter, and consequently between the percentage of organic matter also, in the ears on the one hand, and in the culms and flag on the other. (2) In both there is a gradual decrease in the percentage of mineral matter and a corresponding increase in the percentage of organic matter as maturity progresses, although there is an apparent increase in mineral matter in culms and flag in the last fortnight, which may be attributed to the wasting away of the flag. (3) The percentage of proteins in the ears is from three to four times that present in the culms and flag. (4) The percentage of protein, in both ears on the one hand and in culms and flag on the other, ascends gradually until 20 to 15 days after full bloom; thereafter it shows a perceptible decrease. (5) The fat percentages are fairly stationary, and generally higher in the ears than in the culms and flag. (6) In the ears the carbohydrates, as might be expected in the starchy grain, rise steadily from full bloom to ripeness. At full bloom they are represented by about 50 per cent. of the weight of the dry matter in the ears, and by close on 72 per cent. when the grain is ripe. (7) In the culms and flag the carbohydrates increase slightly in the first fortnight after full bloom; thereafter they are more or less stationary until the last fortnight in the ripening stage, when a distinct decline is noticeable. (8) In the ears the proportion of fibre declines steadily from full bloom to ripeness. It is represented by 30 per cent. at full bloom time and declines to 13 per cent. when the grain is ripe. (9) Conversely, in culms and flag there is a steady increase in fibre from full bloom to ripeness. The proportion is about 32 per cent. of the dry matter at full bloom and 42 per cent. when the grain is ripe.

Distribution to the Acre of Constituent Parts of Wheaten Hay cut in Various Stages of Maturity.

In order to follow out more closely the changes which advancing maturity gradually brings about in wheaten hay, we shall consider next, for each cut, the distribution to the acre of the several constituent parts. These figures have been summarised below in Table V. :—

Table V.—*Showing Distribution per Acre of Constituent Parts of Wheaten Hay cut in Various Stages of Maturity.*

No.	Mineral Matter.	Organic Matter.	Proteins.	Fat.	Carbo-hydrates.	Fibre.
	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
A	292·69	3458·71	204·62	26·39	1209·28	2018·20
B	301·35	3937·65	234·60	43·29	1319·62	2340·14
C	320·62	4648·28	281·59	46·62	1528·02	2792·07
D	368·50	5026·10	326·55	51·50	1618·40	3029·64
E	287·51	4753·39	214·71	40·51	1426·68	3071·50
F	347·50	4916·60	235·18	42·52	1536·56	3102·33
G	292·92	4757·88	263·05	55·56	1546·63	2892·65

In examining the results tabulated in Table V. we must set aside those having reference to Cut No. E, which, as has already been pointed out, is more or less abnormal. If we bear this in mind, we shall notice as we pass from one cut to another that there is a steady increase per acre at every stage all along the line down to Cut D inclusively, *i.e.*, for a period of 20 days after full bloom. This general increase should in all probability have extended to Cut No. E, taken 26 days after full bloom. In the last fortnight of ripening, however, there is an evident decrease in all the constituents ; a loss, in fact, of dry matter to which we drew attention last year, and which we propose considering in detail in the light of the new figures now supplied.

LOSS OF DRY MATTER IN THE LAST STAGES OF THE RIPENING OF THE GRAIN.

We now propose discussing the causes of the loss of dry matter observed in the last fortnight of the development of the wheat plant. The total quantity of dry matter was represented on October 30th by 5,394·6lbs. to the acre (Cut No. D); and we have reason to suppose that this apparent maximum should have been exceeded in the next cut (Cut No. E). This cut, as has already been repeatedly stated, was abnormal, and showed instead an unexpected decrease of total dry matter, which must tend to hamper our calculations in this connection. On November 20th, with the grain practically ripe, we find the total dry matter represented by 5,050·8lbs. to the acre (Cut No. G)—an appreciable falling away from the results of Cut No. D, which, in the circumstances, we are compelled to take as the maximum cut of the series. [illegible] position may therefore be set out as follows:—

	lbs.
No. D (apparently maximum cut)	5,394·6
No. G (grain ripe)...............	5,050·8
Loss of dry matter per acre	343·8 or 6·41 per cent.

This loss—6·41 per cent. of maximum quantity of dry matter noted—is considerably below that noted in 1911-12, which amounted to 22·9 per cent. In the latter case, however, Cut No. E was normal and yielded a heavier quantity of dry matter than Cut No. D.

This loss of dry material, which characterises the ripening off of the wheat crop, must be set down to several factors, the chief of which would appear to be the fall of the exhausted flag. In our earlier paper we pointed out as additional contributing causes the shaking out of grain and other accidental losses, the weakening or suspension of assimilation, which would lead to the burning up of reserve organic material in the respiratory function without the compensation, or with only inadequate compensation, of new supplies; and occasionally the leaching action of rain on the dry porous material. We also pointed out that if these were to be considered the sole factors responsible for the disappearance of dry matter in the ripening process, then the loss of organic matter should be greater, or at all events not less than that of mineral matter. Our 1911-12 results showed that such was not the case, and our 1912-13 results support them. Thus, in 1912-13—

	lbs.
Total loss of dry matter	344·00 or 6·41 per cent.
Loss of organic matter	268·42 or 5·34 per cent.
Loss of mineral matter	75·58 or 20·51 per cent.

Thus, then, the proportional loss of mineral matter is considerably greater than that of organic matter. From another point of view: If we suppose the whole loss—344lbs.—to be represented by the fall of the flag, and take the average mineral composition of the latter to be 6·36 per cent. of the dry matter—the average of the last three cuts—the total loss of mineral matter should have been represented by 21·88lbs. instead of 75·58lbs. as indicated above. The inference, therefore, appears irresistible that as maturity progresses there must be a distinct migration of the mineral matter from the culms and flag to the roots. This is the solution that appeared to us to arise from our 1911-12 results; and we see it confirmed in the 1912-13 results.

ON THE LOSS OF DRY MATTER THAT TAKES PLACE DURING THE CURING PROCESS OF WHEATEN HAY.

When a more or less green crop of wheaten hay is cut and thrown into stooks it gradually dries, losing weight the while to an extent that varies with the stage of ripeness which the crop has attained to. Below, in Table VI., we have indicated what were the losses in weight of hay cut in various stages of maturity between full bloom and ripeness.

TABLE VI.—*Showing Loss of Weight on Drying of Wheaten Hay cut in Various Stages of Growth.*

No.	Weight of 40 Sheaves.		Loss of Weight on Drying.	
	Fresh Cut.	Hay-dry.	Total.	Percentage.
	lbs.	lbs.	lbs	%
A	835·96	238·96	597·0	71·41
B	643·96	248·46	395·5	61·42
C	633·46	296·46	337·0	53·20
D	740·96	389·46	351·5	47·44
E	766·96	389·46	377·5	49·22
F	609·96	404·46	205·5	33·69
G	521·96	396·46	125·5	24·04

It will be noted, therefore, that whilst very green hay, cut at full bloom time, will lose on drying close on three-quarters of its original weight, wheat with the grain ripe does not lose more than about one-quarter of its original weight. Average wheaten hay of good quality, on the other hand, cut between a fortnight and three weeks after full bloom, will on drying lose about one-half of its original weight.

These losses in weight correspond no doubt, for the most part, to losses of water, given off from the slowly-drying plant tissues. There is, however, a loss of another order to be taken into consideration (less striking, perhaps, than that of water, but of importance nevertheless from the point of view of the quality of the hay) and that is the loss of organic matter which always accompanies the slow death of living matter from which the water necessary to its continued existence is being gradually withdrawn. It is, perhaps, unnecessary to point out that when the sheaf is cut and bound its green tissues consist of an agglomeration of living cells, each independent one of the other, and each continuing to breathe normally so long as a sufficiency of moisture continues within its reach. In this breathing process, or respiration, organic matter is burnt up and expelled from the plant tissues in the form of water and carbon dioxide. Hence in the drying and curing process of hay there must be waste and loss of organic matter, which represents so much fuel burnt up and not replaced by new material supplied by the energies of the normally growing plant. Chemical changes, too, of another order also accompany what may be termed the dying agonies of the living matter. It may be said that the violent changes so characteristic of the ensilage pit, in which the drying-off process is practically inhibited, are repeated on a smaller and less conspicuous scale in the hay field; and they represent essentially what is known as the curing of the hay, a process which is generally supposed to enhance its feeding value. We thought that it would be interesting to ascertain the extent of these changes under our special conditions of climate. And although our experiments in this direction are far from conclusive, and on the whole elementary in character, we give them for what they are worth, with the statement that we intend investigating this question far more fully as soon as circumstances permit.

We indicate below in Table VII. the difference in chemical composition of the same sample of hay (Cut No. C) in the one instance oven-dried and analysed immediately after cutting, and in the other analysed after the usual field-drying process.

TABLE VII.—*Showing Chemical Composition of* (1) *Wheaten Hay Oven-dried immediately after cutting, and of* (2) *Wheaten Hay analysed after ordinary Field-drying Process.*

	Oven-Dried Sample. %	Field-Dried Sample. %		Oven-Dried Sample %	Field-Dried Sample. %
Mineral matter	6·63	6·91	Fibre	28·02	28·36
Organic matter	93·37	93·09	Carbohydrates	58·42	57·84
Proteins	6·13	6·13	Moisture	58·95	11·99
Fat	0·80	0·76			

In the above table all figures are expressed in terms of oven-dried material, and are therefore strictly comparable one with the other. It will be observed in the first place that there is an apparent increase in the mineral matter of the field-dried sample, and a corresponding decrease in organic matter. These facts are in accord with what might have been expected, *i.e.*, that there should have been a certain amount of waste of organic matter during the slow field-drying process. The figures in Table VII., however, do not convey an accurate idea of the amount of waste that has taken place, since on the one hand we have the analysis of material in which no waste has taken place, and on the other the analysis of material which is known to have undergone waste. We submit provisionally that the actual waste may be determined by the following considerations, a fact which we hope to verify as soon as circumstances permit.

We base our determinations on the fact that whilst in the field-drying process there must be loss of organic matter there can be no less of mineral matter so long as the weather continues dry. The mineral matter, therefore, remaining constant, must show an apparent increase in the analysis of material which has undergone waste of organic matter in the field-drying process. If, then, 6·63lbs. represents the quantity of mineral matter originally present in 100lbs. of the dry matter of the freshly-cut hay, and 6·91lbs. the quantity of mineral matter in 100lbs. of the dry matter of the same hay after field drying, and x the loss of organic matter per 100lbs. of dry matter originally present, then the following ratio is true, and from it we may determine the loss of organic matter that took place during the field drying, together with its distribution among the component parts of the hay :—

6·91 : 100 :: 6·63 : 100—x.

The working out of this ratio gives a value of 4·05 per cent. to the loss of dry matter arising during the course of field drying, or of 1·66 per cent. of the original green hay containing 58·95 per cent. of moisture. In Table VIII. we have indicated what is the distribution of this loss, basing the results on the data set out above in Table VII.

TABLE VIII.—*Showing the Calculated Distribution of the Loss of Organic Matter accompanying ordinary Field-Drying of Wheaten Hay.*

	Composition of Green Hay at the Time of Cutting.		Calculated Composition of Green Hay from Analysis of Field-Dried Sample.		Loss of Dry Matter in Field-Drying Process.	
	Per Ton. lbs.	Per cent.	Per Ton. lbs.	Per cent.	Per Ton. lbs.	Per cent.
Moisture	1320·48	58·95	1320·48	58·95	—	—
Dry matter.....	919·52	41·05	882·28	39·39	37·24	1·66
Mineral matter .	60·96	2·72	60·96	2·72	—	—
Organic matter .	858·56	38·33	821·32	36·37	37·24	1·66
Proteins	56·37	2·52	54·08	2·41	2·29	0·11
Fat	7·36	0·33	6·71	0·30	0·65	0·03
Fibre	257·65	11·50	250·22	11·17	7·43	0·33
Carbohydrates .	537·18	23·98	510·31	22·78	26·87	1·20

Thus, then, it will be seen, if our premises are granted, that 1 ton of green hay loses in field-drying, over and above moisture evaporated, 37¼lbs. of dry matter, or 1·66 per cent. of its original weight. Over seven-tenths of this loss is represented by carbohydrates, the balance being distributed among fibre, proteins, and fat, in order of importance.

We are quite aware that these data are based on an indirect treatment of the question, and that as such it calls for experimental confirmation, which we propose giving to it in the near future. The direct method, on the other hand, presents in our experience almost insuperable difficulties, unless confined to extremely small quantities of material. The chief difficulty is connected with the exact moisture determination of the sample at the time of bulk field-weighing. Under our conditions of climate, losses of moisture from plants recently cut is exceedingly rapid in the field, and it is almost impossible to guarantee that the moisture contents in the laboratory sample corresponds exactly to that of the bulk field sample at the time of weighing. Another difficulty is the prevalence of dust storms during the drying process of the hay, with the result that the field weight of the dried hay is generally in excess of what it should be. It may be added that all our last season's attempts at a direct determination of the problem failed for these and other reasons. We do not quote the results, as they were purely negative in character. At a later date we hope to be in a position to bring up more satisfactory results.

ON THE DIGESTIBILITY OF WHEATEN HAY.

It will be evident that the value of wheaten hay as a foodstuff will depend very largely on its relative digestibility, *i.e.*, on the extent to which animals consuming it would be able to make use of it in building up their tissues and giving effect to their various vital functions. This digestibility, it appeared to us, would probably vary with the state of ripeness attained to by the crop when the hay was cut; and to these variations should correspond similar variations in the commercial value of the hay. We determined, therefore, to attempt the solution of this problem on the seven cuts of hay that have been occupying our attention.

Definition of "Digestibility."

In principle the digestible portion of a foodstuff is that portion of it which passes into the animal economy, taking the form of reserve tissues, or else reappearing in the form of urine, sweat, breath, &c., whilst the undigested portion of the foodstuff is that portion of it which is voided from the body in the form of solid excreta. In order, therefore, to determine the digestibility of any foodstuff, one must compare the foodstuff itself, both quantitatively and qualitatively, with the solid excreta voided. The difference between the two represents material digested.

Mode of Procedure.

We shall first describe our mode of procedure, which was repeated seven times in experiments extending between February 10th and April 23rd.

We selected for the purpose four draught horses, two of which were three-year-old fillies, and two geldings five years old They were known respectively by the following names, which we shall make use of in connection with the data collected:—Fillies—Katrine and Lomond; geldings—Laird and Kyby.

Each one of these seven tests, during the course of which chaffed wheaten hay of varying degrees of maturity was fed to the four horses, extended over six complete days of 24 hours, starting from 7 a.m. of the first day and closing at 7 a.m. of the seventh day. Each test, too, was separated from the one immediately preceding it by an interval of four days, during which the horses were fed exclusively on the type of chaff to be experimented upon in the following six days. In other words the horses were fed on each of the seven types of chaff for successive periods of 10 days, the last six of which were availed of for direct digestion experiments. During the course of these experiments the horses were confined to open loose boxes, provided with impermeable sloping brick floors, and specially built mangers, from which the chaff supplied could not be nosed out by the animals. These boxes were built under an ordinary open shed, facing the south-west, and were therefore amply ventilated.

The horses were fed six times in the 24 hours with quantities of chaff which varied with their individual abilities to clean up the mangers. A sample of chaff was kept back for analysis from each feed supplied. Once in 24 hours feeding residues were swept out of the mangers, weighed, and sampled for analysis. The analysis of these residues for moisture is always essential, since their moisture contents are always greater than that of the chaff supplied, and their apparent weight, therefore, in excess of their true chaff weight. An attendant was on duty watching the horses day and night. It was his immediate duty carefully to sweep up the solid excreta as soon as they were voided. These excreta were kept in closed tins, and weighed and sampled for analysis every 12 hours. Every precaution was taken to avoid contamination by urine. The floors were carefully hosed down every time urine was passed by the animals.

The horses were led to water four times in the 24 hours, and weighed over the weighbridge once daily. They were groomed twice daily, but in the circumstances of the experiment could not be provided with bedding. In each period of six days the horses were without exercise beyond the daily stroll to the weighbridge, and no doubt they felt the lack of it. This, however, was without appreciable influence on their general health, and throughout the experimental periods they showed a tendency to put on flesh. During the four days' intervals that separated each test, the horses were securely muzzled and allowed to roam over a bare field, returning to their boxes for feeding purposes.

GENERAL HEALTH OF THE HORSES DURING THE EXPERIMENTS.

Throughout these experiments the horses were under the immediate supervision of Mr. F. E. Place, B.V.Sc., M.R.C.V.S., who, *inter alia*, reports that all four were in normal health and condition throughout the 70 days covered by the experiments. He adds that pulse, temperature, and excretory functions were normal, with the one exception of the gelding Laird, who was taken with an attack of colic during the digestion test bearing on hay sample No. B. The symptoms were those of impaction of the cæcum, and in Mr. Place's opinion the colic was attributable to the presence of sclerotomata, and not to the character of the food supplied. On the whole this slight accident to one horse, which did not go beyond a single day, is in our opinion without material influence on our results.

In the fourth experimental period (hay sample No. D) all four horses discharged a certain number of worms which Mr. Place identified as *Ascaris megalocephala* and *Oxyuris curvula.* These continued to appear spasmodically, and to a less degree in later feedings. Mr. Place attributes the discharge of these worms to the generally improving tone and condition of the horses.

GENERAL BEHAVIOUR OF THE HORSES DURING THE EXPERIMENTS.

On the whole, from the point of view of these experiments, the general behaviour of all four horses was good. The gelding Laird was very quiet and contented throughout. The gelding Kyby, on the other hand, was very fidgety and nervous, being constantly on the move, and often refusing to lie down at night. According to Mr. Place he probably missed his bedding. This did not, however, interfere with his feeding capacities, which were considerable. The filly Lomond was generally quiet and contented. The filly Katrine was rather restless in the earlier periods covering hay samples Nos. G, F, and E, but settled down in the later periods affecting hay samples D, C, B, and A. Both geldings were voracious feeders. The fillies, less used to confinement, perhaps, were smaller eaters and more difficult in their tastes.

We append below in tabular form a statement showing the average length of time each horse lay down during the 42 days they were under observation.

TABLE IX.—*Showing Average Length of Time the Horses lay down at Night during the course of the Experiments.*

Hay. Sample No.	Average of Six Nights.			
	Laird.	Kyby.	Lomond.	Katrine.
A	1 hour 47mins.	1 hour 7mins.	4 hours 41mins.	4 hours 54mins.
B	1 " 9 "	0 " 51 "	5 " 2 "	5 " 22 "
C	1 " 5 "	0 " 51 "	5 " 5 "	4 " 33 "
D	0 " 54 "	0 " 21 "	4 " 36 "	4 " 29 "
E	0 " 49 "	0 " 4 "	4 " 42 "	4 " 19 "
F	0 " 30 "	0 " 24 "	4 " 54 "	5 " 35 "
G	0 " 27 "	0 " 20 "	5 " 56 "	5 " 12 "
Means for 42 days	0 " 57 "	0 " 34 "	4 " 59 "	4 " 55 "

It will be noted that whilst the fillies took a moderate amount of rest, the two geldings lay down only to a very limited extent during the 42 days of the experiments.

EXPERIMENT I.—THE DIGESTIBILITY OF WHEATEN HAY CUT IN FULL BLOOM (OCTOBER 10TH). HAY SAMPLE NO. A.

It should be stated that in these digestion tests, which extended from February 10th to April 23rd, we started with the ripest hay (sample No. G) and closed with the greenest one (sample No. A), the one at present under consideration. We thought it advisable to follow this course, lest the greener hay should have had a scouring influence on the animals, which might have influenced the results of later feeding operations with maturer hays. In submitting the data, however, we have thought it better to proceed from the greenest to the ripest hay.

In Table X. below, we indicate in the first instance the general analysis of the early-cut hay consumed, together with that of the solid excreta of the four horses fed on it exclusively for a period of 10 days. The analysis of the excreta, however, refers to excreta voided in the last six days only of the experiment.

TABLE X.—*Showing General Analysis of Wheaten Hay cut at Full Bloom, and of the Solid Excreta of Four Horses fed exclusively thereon. Results expressed in terms of Oven-dried Material.*

	Moisture.	Mineral Matter.	Organic Matter.	Proteins.	Fibre.	Carbohydrates and Fat.
	%	%	%	%	%	%
Hay	10·32	7·14	92·85	7·35	30·62	54·89
Solid excreta—						
Laird	79·05	11·50	88·50	6·39	36·00	46·11
Kyby........	80·10	11·99	88·01	6·21	35·52	46·28
Lomond	83·14	12·14	87·86	6·56	35·69	45·61
Katrine	80·85	11·77	88·23	6·56	34·89	46·78

It will be noted that in the above table we have grouped together carbohydrates and fat. We were driven to this arrangement by the large proportion of substances other than fat—chiefly digestive secretions—that enter into the ether extract of the excreta. So great, indeed, was the proportion of these foreign bodies that it completely masked the digestibility of the small proportions of fat usually present in wheaten hay. On the whole, however, the quantity of digestible fat is so small in wheaten hay that the arrangement adopted will not interfere materially with our results.

We append below in Table XI. the quantitative distribution of the constituents indicated by analysis in both the hay consumed and in the excreta voided in a period of six days. We have also indicated the quantities actually digested by the horses over the same period of time.

TABLE XI.—*Showing Quantitative Distribution of Constituents in Wheaten Hay cut at Full Bloom, and Consumed by Four Horses in six days, and those of Excreta derived therefrom, together with Digestibility of these Constituents.*

Albumenoid ratio.................... 1 : 10·9

In the above table attention should be concentrated on the coefficients of digestibility indicated in its last section. We may note that in hay cut at full bloom 54·32 per cent. of the total dry matter is digestible, 24·22 per cent. of the mineral matter, 56·64 per cent. of the organic matter, 60·10 per cent. of the proteins, 46·99 per cent. of the fibre, and 62·21 per cent. of the combined carbohydrates and fat. And if we assume a general moisture percentage of 10 for the hay, it means that, independently of the water, 48·89 per cent. of the weight of the hay consumed by horses is digested by them.

The albumenoid ratio is the ratio found to exist in any foodstuff between the digestible proteins on the one hand and the balance of the digestible non-nitrogenous organic matter on the other. In wheaten hay cut at full bloom we find this ratio to be 1 : 10·9, or what may be termed a fairly wide ratio. In reality this ratio should be slightly higher than the figures we have given, because of our inability to separate digestible fat from digestible carbohydrates, and to give to the former in the calculation of the ratio its true nutritive value. The proportion of fat present is so small, however, that the difference involved is not likely to be of much consequence.

For purposes of later comparison with the results of tests with maturer hays, we summarise below in Table XII. both the total and digestible constituents of hay cut in full bloom, per cent. and per ton, on the assumption that the hay in question retains 10 per cent. of moisture. This percentage of moisture in hay naturally varies with a variety of circumstances. In our experience, however, 10 per cent. represents fairly closely the general condition of good local hay.

TABLE XII.—*Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Wheaten Hay, cut in Full Bloom, and Retaining* 10 *per cent. of Moisture.*

	PER CENT.		PER TON.	
	Total.	Digestible.	Total	Digestible.
	%	%	lbs.	lbs.
Moisture	10·00	—	224·00	—
Dry matter	90·00	48·89	2016·00	1095·14
Mineral matter	6·43	1·56	144·03	34·94
Organic matter	83·57	47·34	1871·97	1060·42
Proteins	6·61	3·98	148·06	89·15
Fibre	27·56	12·95	617·34	290·08
Carbohydrates and fat	49·40	30·41	1106·56	681·18

Thus, then, in 1 ton of this description of hay digestible matter will be represented by about 1,095lbs., more than three-fifths of which is represented by carbohydrates and fat, and more than a quarter of which is fibre, and less than one-tenth protein.

APPARENT PALATABILITY OF HAY CUT IN FULL BLOOM.

As far as could be seen the horses did not appear to relish this hay. The mangers were cleared up less readily than was the case with any of the other types of hay.

EXPERIMENT II.—THE DIGESTIBILITY OF WHEATEN HAY CUT SIX DAYS AFTER FULL BLOOM (OCTOBER 16TH). HAY SAMPLE NO. B.

When this hay was cut the grain was already formed, and between one-quarter to one-third of the normal size. The hay dried very green, and the grain was reduced to mere skins.

The general analysis of this hay, together with that of excreta derived from it, is indicated below in Table XIII.

TABLE XIII.—*Showing General Analysis of Wheaten Hay cut Six Days after Full Bloom, and of the Solid Excreta of Four Horses exclusively fed thereon. Results expressed in terms of Oven-dried Material.*

Albumenoid ratio...................... 1 : 9·5

We see, then, from Table XIV. that in wheat cut six days after full bloom there is a falling off in the digestibility of the dry matter of nearly 2½ per cent. when compared with that of wheat cut in full bloom; a falling off of over 2½ per cent. in the digestibility of the fibre; a falling off of nearly 5¼ per cent. in the digestibility of the carbohydrates and fat combined; but an increase of 1¾ per cent. in the digestibility of the proteins; and an unaccountable increase of 18 per cent. in the digestibility of the mineral matter.

Increase in the digestibility of the proteins and decrease in the digestibility of the carbohydrates and fat, has led to a slight narrowing in the albumenoid ration, which for wheat cut six days after full bloom becomes 1 : 9·5.

Below, in Table XV., we have, as for the preceding cut of hay, summarised the total and digestible constituents of hay cut six days after full bloom, in terms of hay retaining 10 per cent. of moisture, both as parts of 100 and parts of 1 ton.

TABLE XV. —*Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Hay cut Six Days after Full Bloom, and Retaining* 10 *per cent. of Moisture.*

PALATABILITY OF HAY.

With the exception of Laird, who was taken with colic, the horses appeared to take this hay very well.

EXPERIMENT III.—THE DIGESTIBILITY OF WHEATEN HAY CUT 13 DAYS AFTER FULL BLOOM (OCTOBER 23RD). HAY SAMPLE C.

When this hay was cut the grain was almost full size, and very milky. It dried out a good green color throughout, with the dried grains little more than skins. The general analysis of this hay, together with that of the excreta derived from it, it shown below in Table XVI,

TABLE XVI.—*Showing General Analysis of Wheaten Hay cut* 13 *Days after Full Bloom, together with that of the Solid Excreta of Four Horses exclusively fed thereon. Results expressed in terms of Oven-dried Material.*

Albumenoid ratio.................... 1 : 11·5

Table XVII. shows that the digestibility of the dry matter of hay cut 13 days after full bloom does not differ much from that of hay cut six days after full bloom. The most salient differences are (1) a decrease in the digestibility of proteins, (2) an increase in the digestibility of carbohydrates, and (3) a marked decrease in the digestibility of fibre--a decrease of over 10 per cent. This decrease in the digestibility of proteins, accompanied by an increase in the digestibility of the carbohydrates, has led to the widening of the albumenoid ratio.

We show below in Table XVIII. the distribution of both total and digestible constituents in hay cut 13 days after full bloom, and retaining 10 per cent. of moisture.

TABLE XVIII. *Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Hay cut* 13 *days after Full Bloom, and retaining* 10 *per cent. of Moisture.*

APPARENT PALATABILITY OF THE HAY.

All four horses ate this hay very readily. It is perhaps worth noting that of all the seven samples under experiment, this is the only one from which absolutely no feeding residues were collected.

EXPERIMENT IV.--THE DIGESTIBILITY OF WHEATEN HAY CUT 20 DAYS AFTER FULL BLOOM (OCTOBER 30TH). HAY SAMPLE NO. D.

When this hay was cut the grain was fully developed, but still in the milky stage. On drying it formed very attractive looking hay, and green throughout. The grain was full size, but very much pinched.

The general analysis of this hay, together with that of the solid excreta derived from it, is shown below in Table XIX.

TABLE XIX.—*Showing General Analysis of Wheaten Hay cut 20 Days after Full Bloom, together with that of the Solid Excreta of Four Horses exclusively fed thereon. Results expressed in terms of Oven-dried Material.*

Albumenoid ratio.................... 1 : 15·25

Table XX. clearly indicates the influence of advancing maturity on the digestibility of hay. The digestibility of total dry matter remains sensibly the same as that observed for hay cut seven days earlier. The digestibility of the mineral matter, however, is reduced by about 4 per cent., that of the proteins by 6·20 per cent., and that of the fibre by about 1½ per cent. The digestibility of carbohydrates and fat combined shows an increase of about 1¼ per cent. The general result of these changes is that the albumenoid ratio is now 1 : 15·25, a very wide ratio, pointing to a considerable reduction in the general value of the hay as a foodstuff.

Finally, in Table XXI., we show the total and digestible constituents of hay cut 20 days after full bloom in terms of hay retaining 10 per cent. of moisture.

TABLE XXI. *Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Hay cut* 20 *Days after Full Bloom, and retaining* 10 *per cent. of Moisture.*

APPARENT PALATABILITY OF THE HAY.

All four horses ate this sample of hay very readily.

EXPERIMENT V. -THE DIGESTIBILITY OF WHEATEN HAY CUT 27 DAYS AFTER FULL BLOOM (NOVEMBER 6TH). HAY SAMPLE NO. E.

When this hay was cut the crop was just beginning to yellow off, the grain being very distinctly in the dough stage. Later on, at stacking time, the general color of the dry hay was pale-green, the lower third of the culms, however, being more or less white; the grain was pinched.

The general analysis of this hay, together with that of the excreta derived therefrom is shown below in Table XXII.

TABLE XXII.—*Showing General Analysis of Wheaten Hay cut 27 Days after Full Bloom, together with that of the Excreta of Four Horses, exclusively fed thereon. Results expressed in terms of Oven-dried Material.*

Albumenoid ratio.................... 1 : 15·2

Relatively to hay cut a week earlier, hay cut 27 days after full bloom shows a reduction of 1 per cent. in the total dry matter digested. Appreciable decreases in the digestibility of both fibre and carbohydrates is also to be noted, as also a very marked decrease in the digestibility of the mineral matter. On the other hand the digestibility of the proteins appear to be higher. The albumenoid ratio undergoes no change.

In Table XXIV. we have summarised data showing both total and digestible constituents in wheaten hay cut 27 days after full bloom, and retaining 10 per cent. of moisture.

TABLE XXIV.—*Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Hay cut 27 Days after Full Bloom, and Retaining 10 per cent. of Moisture.*

APPARENT PALATABILITY OF HAY.

The two geldings ate this hay readily enough, whilst the fillies took to it fairly well.

EXPERIMENT VI.—THE DIGESTIBILITY OF WHEATEN HAY CUT 34 DAYS AFTER FULL BLOOM (NOVEMBER 13TH). HAY SAMPLE NO. F.

When the hay was cut in this stage the crop showed only slight traces of green, whilst the grain was beginning to firm. The hay dried out almost white in color, with the merest traces of green, nor was the grain to any extent shrivelled.

The general analysis of this hay, together with that of the excreta derived therefrom, is shown below in Table XXV.

TABLE XXV.—*Showing General Analysis of Wheaten Hay cut 34 Days after Full Bloom, together with that of the Excreta of Four Horses exclusively fed thereon. Results expressed in terms of Oven-dried Material.*

Albumenoid ratio.................... 1 : 12·24

From Table XXVI. we see that wheaten hay cut 34 days after full bloom relatively to similar hay cut a week earlier, shows a reduction in the digestibility of the dry matter represented by over 3 per cent. ; of over 7 per cent. in the mineral matter ; of over 6 per cent. in the fibre ; and of 2 per cent. in the carbohydrates and fat combined. On the other hand there was an apparent increase in the digestibility of the proteins, which, combined with the decreases in other lines, has led to the narrowing of the albumenoid ratio.

In Table XXVII. below we have summarised both the total and digestible constituents, per cent. and per ton, for wheaten hay cut 34 days after full bloom and retaining 10 per cent. of moisture.

TABLE XXVII.—*Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Wheaten Hay cut* 34 *Days after Full Bloom, and retaining* 10 *per cent. of Moisture.*

APPARENT PALATABILITY OF THE HAY.

Here again, whilst the two geldings ate this hay readily enough, the two fillies were inclined to play with it.

EXPERIMENT VII.—THE DIGESTIBILITY OF WHEATEN HAY CUT 41 DAYS AFTER FULL BLOOM, WHEN THE GRAIN WAS PRACTICALLY RIPE (NOVEMBER 20TH). HAY SAMPLE NO. G.

This hay, when cut, had of course reached a stage not met with in ordinary practice. We wished, however, for the sake of completeness, to push these tests to the ripening of the corn. When the crop was cut down it was quite white, and the grain almost dry. Later on, at stacking time, the hay showed on examination very white and brittle, whilst the grain could be described as a good seeding sample.

The general analysis of this hay, together with that of the excreta derived therefrom, is shown below in Table XXVIII.

TABLE XXVIII.—*Showing General Analysis of Wheaten Hay cut with the Grain ripe, together with that of the Excreta of Four Horses exclusively fed thereon. Results expressed in terms of Oven-dried Material.*

Albumenoid ratio,,,,,,,,,,,,,,,,,,,, 1 ; 12·24

A comparison between Tables XXVI. and XXIX. will show that there is not much difference between the digestibility of wheaten hay cut one week before the ripening of the grain and wheaten hay cut with the grain ripe. The most striking difference in the two tables has reference to the apparent digestibility of the fibre, which is over 5 per cent. higher for the riper of the two hays—a fact which to us appears abnormal, but for which we are unable to account. The albumenoid ratio remains the same in the two hays.

We summarise below, in Table XXX., both the total and digestive constituents, per cent. and per ton, for wheaten hay cut with the grain ripe, and retaining 10 per cent. of moisture.

Table XXX.—*Showing Per Cent. and Per Ton Distribution of Total and Digestible Constituents of Wheaten Hay cut with the Grain Ripe, and retaining* 10 *per cent. of Moisture.*

Table XXXI. has been given graphic illustration in Fig. 3.

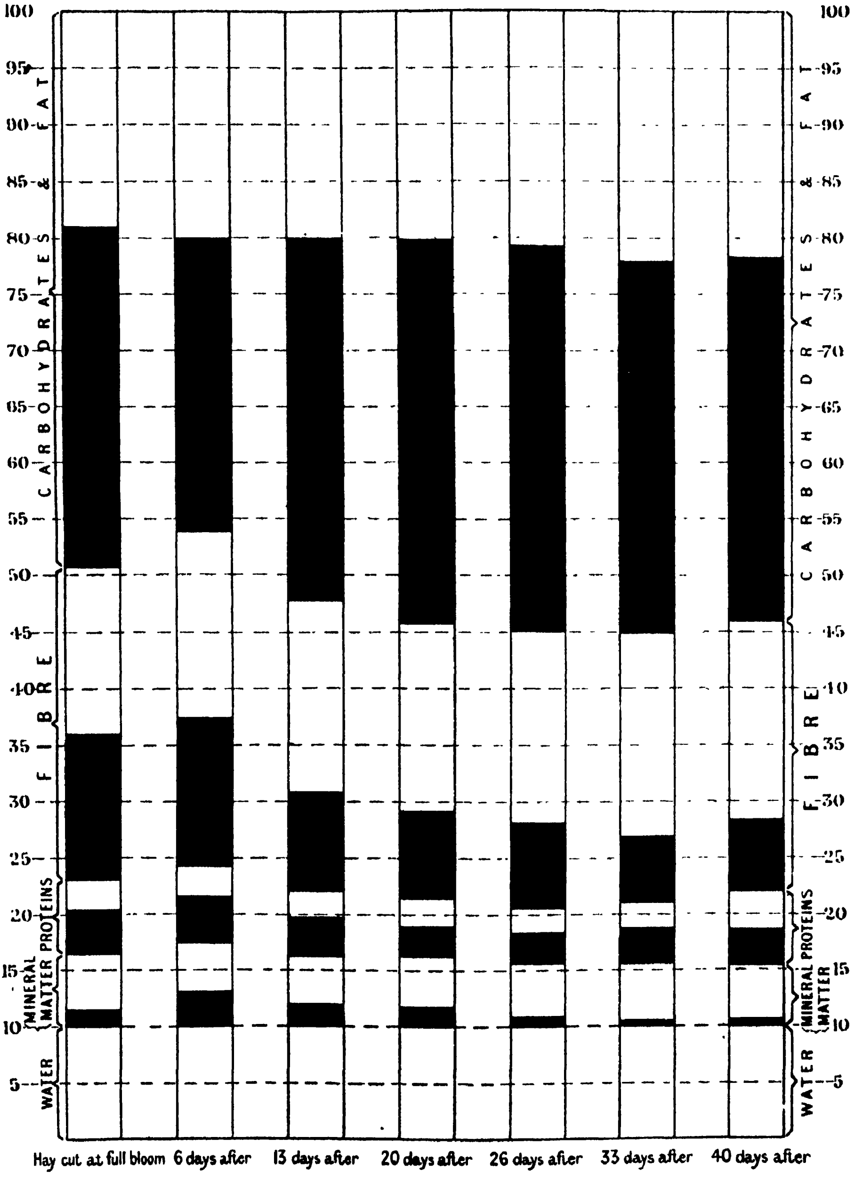
It will be noted in the first place that the digestibility of the total dry matter declines steadily from hay that is cut at full bloom to hay cut when the grain is ripe. So much is this the case that, if we were to value hay on this basis alone, we might say that the feeding value of 1 ton of hay cut at full bloom is equivalent to the feeding value of—

1 ton 0cwt. 106lbs. of hay cut six days after full bloom.
1 ton 1cwt. 2lbs. of hay cut 13 days after full bloom.
1 ton 0cwt. 108lbs. of hay cut 20 days after full bloom.
1 ton 1cwt. 51lbs. of hay cut 27 days after full bloom.
1 ton 2cwts. 84lbs. of hay cut 34 days after full bloom.
1 ton 2cwts. 28lbs. of hay cut with the grain ripe.

Figure 3 - Illustrating Table 31

And showing relative proportions of Digestible and Undigested Material in constituents of Wheaten Hay cut in various stages of development.

Within each bracket the dark portion of the column represents Digestible Material



This decrease in the digestibility of rapidly ripening hay appears to be most marked and regular in the matter of fibre and mineral matter. A decrease in the digestibility of other constituents is also perceptible, as a rule, but is less marked and less regular. It must be recognised, however, that this difference in digestibility is not as great as might, perhaps, have been anticipated.

Of greater importance, perhaps, is the gradual widening of the albumenoid ratio, which is another feature of advancing maturity. For the sake of comparison we summarise these results below.

TABLE XXXII.—*Showing Albumenoid Ratios for Wheats cut in Various Stages of Maturity.*

At full bloom time	1 : 10·9
Six days after full bloom	1 : 9·5
Thirteen days after full bloom	1 : 11·5
Twenty days after full bloom	1 : 15·25
Twenty-seven days after full bloom	1 : 15·2
Thirty-four days after full bloom	1 : 12·24
With grain ripe	1 : 12·24

AVERAGE QUANTITIES OF SOLID EXCRETA VOIDED IN 24 HOURS BY HORSES FED ON WHEATEN HAY CHAFF.

In these experiments we had four horses fed exclusively on wheaten hay chaff for a period of 70 days, and during 42 of these the solid excreta were carefully collected and weighed. We are therefore in a position to state accurately what are, in these conditions of feeding, the average quantities of solid excreta voided by horses in a period of 24 hours. For this period we found the mean figures to be 72·66lbs. of solid excreta, of an average moisture contents of 78·57 per cent., in 24 hours. The average quantity of chaff fed during this period was 35·10lbs., of an average moisture contents of 9·58 per cent.; whilst the average weight of the horses over this period was 1,419lbs.

It might be pointed out here how necessary it is that horses maintained on a dry diet should have easy access to an ample supply of drinking water for the healthy action of the digestive functions. The moisture in the mean quantity of solid excreta voided in 24 hours is represented by 57·09lbs., whilst the moisture present in the food consumed was only 3·36lbs. This leaves 53·75lbs. or over 2½galls., to be supplied from drinking water, over and above the liquid voided in the form of urine, or given off from the body in evaporation.

GENERAL CONCLUSIONS.

It remains for us to summarise what appear to be the general conclusions that may be drawn from these two years' experiments.

1. The yield of a crop of wheat cut down for hay will vary considerably according to the stage of development which the crop has attained to.

2. If we combine the results of the two seasons' experiments we find the average increase in yield above that of a crop cut in the full bloom stage to be—

20·31	per cent.	in the case of	hay cut	6	days	after full bloom.
24·02	"	"	"	13	"	"
36·04	"	"	"	21	"	"
32·62	"	"	"	28	"	"
21·90	"	"	"	35	"	"
14·24	"	"	"	42*	"	"

* Grain ripe.

It follows, therefore, that maximum yields will be secured from cuts taken about three weeks after full bloom, at a time when the grain is just about to leave the milky stage. In this connection it should be recollected that these three weeks have reference to an early wheat grown under conditions of climate such that there elapses a period of six weeks between full bloom and the ripeness of the grain. In a general way it is perhaps better to state that maximum hay yields may be expected from cuts taken when the grain is about to leave the milky stage and enter upon the dough stage.

3. We note that in the three weeks that follow full bloom time total increase in hay yield is distributed between ears on the one hand, and culms and flag on the other, but in uneven proportion, the ears increasing in weight at a far more accelerated ratio than the culms and flag. From the third week after full bloom down to complete grain ripeness the ears continue steadily to gain weight. Culms and flag, on the other hand, lose weight correspondingly in the same period, until, in the last fortnight of the grain development they actually contain less dry matter than was the case at full bloom time.

If we combine the results of the two seasons the following figures will serve to indicate the nature of the increases gained respectively by ears on the one hand, and by culms and flag on the other, over and above their original weight at full bloom.

TABLE XXXIII.—*Showing Mean Percentage Increases* (1911 *and* 1912) *of Ears on the one hand, and Culms and Flag on the other, above Original Weights at Full Bloom Time.*

	Ears.	Culms & Flag.
At full bloom time	100·00	100·00
Six days after	137·77	118·28
Thirteen days after	153·10	119·98
Twenty-one days after	246·75	120·48
Twenty-eight days after	321·05	106·70
Thirty-five days after	337·00	92·54
Forty-two days after (grain ripe)	340·40	83·33

We conclude, therefore, that when the grain begins to leave the milky stage there is not only a great disproportion between the relative weights of ears on the one hand, and culms and flag on the other, but relatively to the period of full bloom, a loss of weight in the latter, which although at first compensated for by a corresponding increase in the weight of the ears, becomes in the end an actual loss of what might have been good feeding material had the crop been cut earlier. In other words, hay cut after the milky stage of the grain tends more and more to become ill-balanced hay, in which the culms and flag rapidly lose their feeding value ; whilst if the hay is not cut at least a fortnight earlier than the ripening of the grain there arises to the grower an actual loss of hay.

4. In the matter of the chemical composition the chief differences between hay cut at full bloom and later cuts are as follows :—(1) Progressive decrease in the percentage of mineral matter and corresponding increase in that of organic matter characterises the gradual ripening off of the crop. (2) The percentage of proteins shows a tendency to rise during the first three weeks ; thereafter it steadily declines to the ripeness of the grain. (3) The percentage of fat appears to remain more or less stationary throughout the whole period. (4) The percentage of carbohydrates rises regularly and steadily in the ears throughout the six weeks. It is balanced by a corresponding regular decrease in culms and flag. (5) Conversely, whilst the percentage of fibre steadily rises in culms and flag, it equally steadily declines in the ears.

5. We note a heavy loss of dry matter in the last two or three weeks of the development of the wheat crop, a loss which attained to 22·9 per cent. of the maximum cut in 1911, and 6·41 per cent. of the maximum cut in 1912. This loss, no doubt, must be attributed chiefly to the fall of the exhausted flag, and to a less degree to occasional shaking out of grain and other accidental causes ; to the weakening or suspension of the assimilation function ; and to the occasional leaching action of rain on a dry, porous tissue. In each year, however, we found that the proportional loss of mineral matter was considerably greater than that of organic matter, and we infer therefrom that as maturity advances there must be some sort of migration of the mineral matter towards the root system.

6. The loss of weight on drying of a wheaten hay crop becomes gradually less and less as the ripening of the grain is approached. It is represented by close on three-quarters of the green weight of the crop in the full bloom stage, and by less than one-quarter of the green weight when the grain is ripe.

7. The percentage of moisture retained by wheaten hay varies slightly with the conditions under which the hay was dried. Generally speaking, however, early-cut hay retains slightly more moisture than late-cut hay. We submit, however, that in round figures 10 per cent. represents the average moisture contents of South Australian wheaten hay.

8. When a crop of hay is left to dry in a field, the loss of weight observed is not exclusively the result of the evaporation of water. Intimate chemical reactions set up in the drying cells of the plants, the ultimate result of which is the destruction of more or less organic matter. We submit tentatively that for wheaten hay losses in this direction may attain to slightly over 1½ per cent. of the original green weight, and that it is connected chiefly in the breaking down of carbohydrates.

9. Direct digestion experiments show that hay cut at full bloom is more highly digestible than any hay cut at later periods, and that in general the digestibility of wheaten hay decreases by regular steps as the period of complete ripeness is approached. In this connection there is a difference of over 12 per cent. between the digestibility of hay cut at full bloom and that of hay cut a week before the ripening of the grain.

10. This superior digestibility of wheaten hay cut at full bloom holds good all along the line, with the exception, perhaps, of the doubtful case of the mineral matter. The regular decline in the digestibility of hays cut at later periods is most marked in the case of proteins and fibre. Carbohydrates are, on the whole, rather erratic in their behaviour, and perhaps on the whole they may be considered more or less stationary in their direct digestibility.

11. The albumenoid ratio is narrower and more favorable in character in the earlier cut hays than in those in more advanced stages of development. This arises from the more highly digestible condition of the proteins in the less mature cuts of hay, and the overwhelming preponderance of carbohydrates in the later cuts.

12. We note that the average weight of solid excreta voided in 24 hours by draught horses of an average weight of 1,420lbs., and consuming 35lbs. of wheaten chaff, is represented by 72·66lbs.

13. It appears to us that there is nothing to be gained, and much to be lost, in deferring the cutting of wheaten hay until the grain begins to enter upon the dough stage. It involves, as a rule, both a reduction in total yields of hay and a reduction in quality represented by a reduced digestibility and a wider albumenoid ratio. Assuming that hay-cutting operations can be completed within a week to 10 days, we are of the opinion that these operations should be put in hand not later than a fortnight after full bloom.

14. These experiments of ours amply confirm the value of the usual commercial standard by which hay is judged, viz., color. It may be taken for granted that any hay that is not of a good bright green color is of inferior quality for feeding purposes, although it might make excellent litter.

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

To Promote Feathering.

Many people, especially those who breed some of the heavier sorts of fowls, complain that the chickens do not feather well, but remain bare. During the next few months moulting will be general, and unless the food supplies the necessary material the system cannot elaborate the feather-forming compounds. Feathers are largely built up of a protein material called keratin, which contains a large percentage of sulphur. The white of an egg also contains sulphur. To give crude sulphur to poultry is not always advisable, and even when it is care is necessary to give only a proper quantity. An old-fashioned method of administering sulphur is still the best, viz., as sulphuret of lime (calcii sulphurati). It is made as follows :—Procure a large iron saucepan—an old one will do. Place in the saucepan four lumps of quicklime each as large as a duck's egg. Slake the lime with boiling water, and then stir in 6ozs. of flowers of sulphur and add 2qrts. of boiling water, stirring gently. Boil this mixture for an hour and then let it cool and settle. Pour off and bottle the clear liquid. Keep this out of the dwelling-house, as the fumes given off are most disagreeable. Of this liquid for every eight hens or 12 chickens add to the water used for mixing the daily mash one teaspoonful.

Another very good mixture is as follows :—Take half a pound of linseed (flax seed), place in a large saucepan and boil to a jelly ; stir in half an ounce of each flowers of sulphur and common salt. Do not keep this in a dwelling-house. For each fowl add one teaspoonful to the daily mash.

Proper Sulphur Ointment.—This is very useful for applying to places denuded of feathers. It is also excellent for parrots, cage birds, &c. It may be made in ounces or pounds according to the following formula :—Flowers of sulphur, 1 ; glycerine, 1 ; lard, 10 ; white wax, 4. Melt the glycerine, lard, and white wax in an iron pan, and while cooling stir in the sulphur.

Cooling Medicines.

Green foods are rich in minerals and salts, and should be freely used. Sometimes it is necessary to supplement, or make good the want of, sufficient green food. Epsom salts are generally recommended, and they are excellent for fowls, but not so good for ducks and turkeys. Epsom salts are magnesium sulphate. Glauber salts, which are sodium sulphate, are dearer, but are more suitable, and are, in fact, invaluable for laying hens. For their proper administration a stock solution should be kept in a bottle. Dissolve in a pint of hot water 4ozs. of Glauber salts, and of this add one tablespoonful to each pint of drinking water; or it may be added in the same proportion to the water used for the mash. The action on the liver and bile ducts is excellent. As a tonic for the oviduct and as a precaution against protusion and other troubles this salt is excellent. For fowls the two salts—Epsom and Glauber—may be used in combination, viz., 2ozs. of Epsom to 1oz. of Glauber, and made into the stock solution.

To Destroy Red Mites, Etc., in Poultry Houses.

Obtain powdered napthaline and dissolve half a pound in a gallon of kerosine. apply freely to perches, cracks, crevices, and all haunts of this pest. This odorous mixture is deadly to such pests as red mites, ticks, &c.

Autumn Breeding.

Get your most forward old hens ready for breeding next month. Those that have not started to moult and are still laying will do; others may have finished moulting at the end of February, and will lay in March. Mate these with vigorous cockerels, and you will have strongly fertile eggs. Those breeders who have adopted autumn breeding find it extremely profitable.

Heavy Breeds at the March Show.

Visitors to the R.A. & H. Society's March Show in Adelaide are especially invited to visit the section allotted to the General Purpose Poultry Society, which was recently formed to carry out a series of competitions to demonstrate all the points of various breeds of poultry. There will be 28 competitors who will exhibit six pullets, three cockerels, and a dozen eggs representing Gold, Silver, and White Wyandottes; Barred and White Rocks; Black, Buff, and White Orpingtons; Rhode Island Reds, Langshans, Indian and Old English Game. The six pullets of each entry will, after the show, be sent to Parafield, where they will form Section 4 of the laying competitions. On the second day of the show the three cockerels of each breed which were exhibited alive the first day will be killed and dressed and exhibited as table birds, and should make a fine display.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1913-14.

[Started April 1st, 1913, to terminate March 31st, 1914.]

SECTION 1.—LIGHT BREEDS.

White Leghorns.

Competitor.	Eggs Laid for Month ended Jan. 31st.	Total Eggs Laid from April 1st, 1913, to January 31st, 1914.

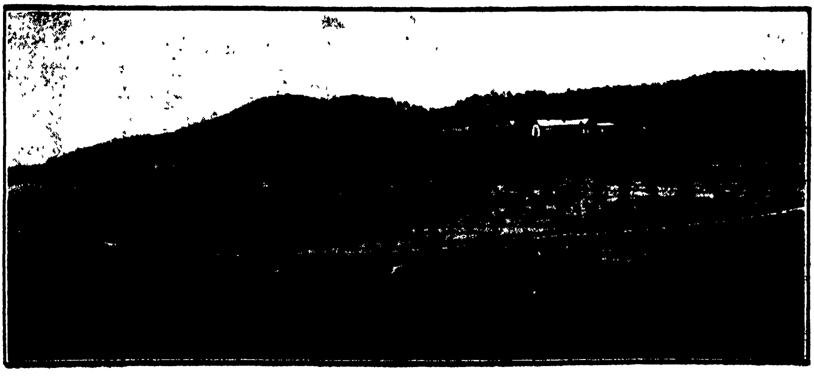
D. F. LAURIE, Poultry Expert.



Orchard, Near Clare.

PARAFIELD EGG-LAYING COMPETITION.

MONTHLY REPORT.

Health of Birds.

The general health of the birds has been good. There were 10 deaths—four in Section 1, one in Section 2, and five in Section 3; causes various. One bird developed an ovarian cyst, and had to be replaced. There are now five pens which are one bird short, viz., pens 16, 36, 41, 143, and 149. Pen 148 is two birds short. There have been no replacements by owners, and thus their scores are small.

Moulting.

The birds are now showing signs of a general moult.

Egg Production.

The seasonable falling off due to the moult and other causes is affecting the egg yield. In last month's report reference was made to a new nine month's record. This should have been in reference to previous records at Roseworthy. Last year Messrs. Moritz Bros'. score was 1,170 at Kybybolite as against McKenzie's 1,164 this year.

The weather has been seasonable; generally mild, with warm days; 57 points of rain fell. The score for the leading pen, Section 1, E. McKenzie, Victoria, was 1,287; Section 2, D. Kenway, New South Wales, 1,098; Section 3, C. Sampson, South Australia, 1,161.

The averages are still maintained, and show a satisfactory advance on last year's figures. It is useless attempting any forecast, but appearances point to satisfactory final results.

D. F. LAURIE, Poultry Expert and Lecturer.

Camel Team, Oodnadatta.

THE WHEAT MARKET.

Advices received from Europe indicated that for practically the whole of January the wheat market was quiet and little trading done. Locally the market was steady, with growers not much inclined to operate.

Under date London, January 2nd, *Beerbohm's Evening Corn Trade List* states :- -The latest information received points to a shortage in the exports from Argentina and India this year of about 8,000,000qrs. compared with 1913, but the surplus remaining in Russia and Roumania, although nothing definite is known, is generally believed to be considerably larger than at this time last year. Australia has a surplus of about 2,000,000qrs. more than in 1913, whilst Canada and the United States have still large quantities left, over and above the home requirements, the last two crops having been very large ones ; but whether America will be a free seller at present prices remains to be seen. In this connection much will depend, especially a little later in the year, on the prospects of the next winter wheat crop. The present outlook is an exceptionally favorable one, on a record area, but, of course, much may happen between now and harvest time. In Europe the present condition of the autumn sown crops is a satisfactory one. There has been more disposition shown, during the past few weeks, to offer native wheat freely in most European countries, and, if the official estimates of the yields were correct, farmers must hold a larger proportion of their crops than usual.

The preliminary official estimate of the Argentine wheat crop has been cabled over this week, and shows the crop to be a very disappointing one, the yield of 16,500,000qrs. being quite as small, if not smaller, than the lowest private estimates pointed to. The home consumption is about 8,000,000qrs., and on this basis there would only be about 8,500,000qrs. for export, against 13,400,000qrs. exported in the 12 months ended yesterday. This year's shipments from the Argentine from January to April will probably be less than half last year's exceptionally big total, partly owing to the crop being a very small one, and partly because there is much more wheat available from Russia, Roumania, and Australia than was the case last year.

The preliminary official estimates of the area sown to wheat in India have now been received for all districts except Hyderabad and Rajputana, and show a decrease in the acreage of about 13 per cent. compared with the preliminary estimate last year, but of no less than 20 per cent. compared with last year's final figures. It is quite probable that these two districts will also show a decrease, but it is also probable that the final figures for the Punjab, Bombay, and Central India will be appreciably larger than the preliminary figures. It is impossible to estimate the probable yield, but, according to private reports received by firms engaged in the Indian trade, the exports next season are not expected to exceed 3,000,000qrs., or less than half the present season's total.

Sailer Freights.—From South Australia to United Kingdom-Continent, 26s. 3d. per ton (8⅖d. per bushel), new crop ; South Africa, 23s. 9d. per ton (7⅗d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on February 2nd—

BUTTER FACTORY.

The supply of cream to hand during the month compared very favorably with that received in the corresponding period of last year, and the demand for butter has been very consistent. There has been a slight drop in prices during the month, the present quotations being superfine 1s 2¼d per lb., and pure creamery 1s. 0½d. per lb.

A. W. Sandford & Co., Limited, reported on February 1st—

BUTTER.—The month of January was on the whole cool, with one or two short spells of heat. Values in butters maintained the advance recorded last month, and have throughout January been practically stationary in top grades, though poorer qualities and heat affected lots have met a more dragging sale. Best factory and creamery, fresh in prints, realised 1s. to 1s. 2½d. per pound; choice separators and dairies, 10d. to 1s.; store and collectors', 7½d. to 8d.

EGGS.—Supplies have held up very well with very slight fluctuation, though during the closing days of the month an advance set in owing to a marked cut-off in quantities coming forward. Hen are selling at 8½d. per dozen, and duck at 9d.

CHEESE.—Good business was again reported in this line both for local and export trade, without any quotable alteration in rates, which are—Large to loaf, 5d. to 5½d. per pound.

BACON.—Usually business in bacon is slow during January, but this year has been an exception, and although high prices have ruled the steady demand has readily cleared all offering. Best factory-cured sides sold at 10½d. to 11¼d. per lb.; hams, 1s. to 1s. 2d.; nicely cut and cured farm lots, 7d. to 9d.

HONEY.—The new take is coming in more freely and meeting with speedy quittance at 2¾d. per lb. for prime clear extracted. Beeswax, 1s. 2½d.

ALMONDS.—The crop is again late, and very little trade is being recorded in this line. Brandis, 6d.; mixed soft-shells, 5½d.; hard-shells, 3d.; kernels, 1s. 6d.

LIVE POULTRY.—During the month heavy quantities have been marketed, but unfortunately a larger proportion have been poor and light sorts, so that buyers were more critical in their purchasings. Anything of quality commanded good rates, while medium sorts sold accordingly. Good table roosters brought 3s. to 3s. 6d. each; nice conditioned cockerels, 2s. to 2s. 6d.; hens, 1s. 6d. to 2s.; ducks, 1s. 4d. to 2s. 9d.; geese, 3s. to 3s. 6d.; pigeons, 5½d.; turkeys from 8d. to 10d. per lb. live weight for fair to good table birds.

POTATOES AND ONIONS.—The Adelaide market has been fully supplied with potatoes contributed chiefly by growers in the adjacent hills, and prices have fluctuated very slightly. A little business has taken place in early Gambiers, although samples from there were hardly so ripe as could have been desired. This defect, however, may reasonably be expected to disappear as the present month progresses, and no doubt Mount Gambier will now command increased attention from potato buyers. **ONIONS.**—All orders for onions have been met without any alteration in values, and as good crops are now being pulled in the South-East, prices have a downward tendency. Present quotations—Potatoes, £4 2s. 6d. per ton of 2,240lbs. on rail Adelaide or Port Adelaide; 4s. to 5s. per cwt. in the market. Onions.—£8 per ton of 2,240lbs. on rail Adelaide or Port Adelaide, 7s. to 8s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of January, 1914, also the average precipitation to the end of January, and the average annual rainfall.

⁂

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

March 11th and April 8th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

TARCOWIE (Average annual rainfall, about 15½in.).

December 20th.—Present: 12 members.

Harvesting Machinery.—Mr. J. Burgess read a short paper. He drew attention to several defects in the machinery at present used for harvesting grain, both the stripper and the harvester "hanging off," and there was difficulty in keeping up the speed of the latter when going up hill. The lowering of the combs with the main axle as a pivot resulted in the loss of wheat over the combs, and when they were raised for a high crop the straw did not get back under the beaters. The harvester did not turn out a good marketable sample of wheat Messrs. Symons and Miller contended that the harvester did good work in capable hands. Mr. Walter favored the use of the stripper and motor winnower.

Demonstration Plots.—A committee, consisting of Messrs. J. P. Smith, J. Symons, and H. Dempster was appointed to supervise demonstration and experimental tests to be conducted under the direction of the Branch.

WILMINGTON (Average annual rainfall, 18·26in.)

January 14th.—Present: 15 members and one visitor.

Farmers' Wool Clips.—Mr. Farrell read a paper, in which he said it was a mistake to divide a small clip into a number of different lots. Merino ewes were generally kept by farmers. The fleeces of these should be skirted lightly, all burrs being removed from around the edges. Those heavy in grease should be kept apart from the bright, light, and attractive looking fleeces. If the flock were not large enough to warrant the use of separate bales for pieces, bellies, and locks, they should be put into sacks. Skirting should be carried out on a table made for the purpose. If the wool were only burry about the breech it would pay to remove the burrs, but this was largely a matter of discretion. Where the clip was sufficiently large it was advisable to sort the pieces into two classes. Baling and branding should be done neatly. In reply to questions, the writer of the paper said fleeces should be rolled from the head to the breech. The wool on the back should be hidden as much as possible.

WIRRABARA (Average annual rainfall, 18·91in.)

January 10th.—Present: 21 members.

Water Conservation.—Mr. H. Jericho read a paper on this subject. Dams, he said, constituted the cheapest and simplest method of conserving water where good clay holding ground was available. For household purposes the stone underground tank was best, but was expensive, and considerable difficulty was encountered if it cracked or leaked. Two 3,000gall. galvanized iron tanks would provide a cheaper substitute. Water for irrigation was best secured from subterranean flows by being tapped by a bore, The difficulty was to locate the water, He had no faith in the divining rod, COOMOOROO, January 17th.—MARKETING WHEAT.—Mr. G. B. Lillicrapp delivered an address on this subject. He strongly recommended the system of marketing the grain in bulk, as he considered that as a result the sample of grain sold would be improved. Mr. W. Robertson said bagged wheat sold at 3s. per quarter more than grain in bulk. In any case it would be necessary to bag the wheat in order to take it from the farm to the station. He favored grading. Mr. Cooke thought farmers should be encouraged to market a good clean sample.

CRADOCK, January 10th.—Members discussed the merits of the divining rod, and expressed the opinion that it had been of considerable service in this district.

ORROROO, December 13th.—FLOORS.—Mr. T. H. P. Tapscott described a cheap and easy method of constructing floors for outhouses, verandahs, &c. After levelling the surface, a layer of 2in. of soil, preferably limey, should be put through a coarse sieve, mixed in the manner that concrete was mixed, and then rammed down well. A further layer of soil, 1in. deep, and put through a finer sieve, should be added and treated similarly. Coal tar, brought nearly to boiling point, should be applied with a whitewash brush, and dry ashes sieved on top of this. A cracked flag floor could be improved by the application of tar and fine sand mixed to a thick paste to the cracks, ashes being spread on the tar. Tar with ashes on brick or concrete made a splendid floor.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

MOUNT BRYAN EAST (Average annual rainfall, 16in.).

December 6th.—Present: eight members and one visitor.

HAYMAKING.—Mr. E. S. Wilks read a paper on this subject. Hay for feeding should be cut a little on the green side, he said. When required for sale it should be more matured. Oats, if cut too green, became bitter to the taste. This fodder should always be chaffed. The best hay wheats for the district were Dart's Imperial, Yandilla King, and King's Red. The long-strawed wheats, such as Le Huguenot and Baroota Wonder, required a heavier rainfall and better soil conditions than those prevailing in this district. Good sized sheaves, tightly tied, were preferable, and stooking should be done directly after the binder. Round, upright, and fairly large stooks kept the rain out well, but if the hay were damp at the time of stooking they should be made in the shape of a pyramid. The hay should be carted in cool weather, ten days or more after it had been put into the stooks. The stack should be built fairly high, the heads of the sheaves being outwards after the first layer; every sheaf on the outside should be "kneed." A good sloping roof, with heads out, should be built. If two rails were placed on top, one each side of the centre, and weights hung from these on wires, the stack would not suffer from the effects of the wind until the time it could be thatched.

NORTH BUNDALEER.

December 10th.—Present: 12 members and one visitor.

HARVESTING.—Mr. G. Lambert read a paper on this subject. The harvester, he said, should be well oiled, and if the belts were inclined to slip on the pulleys it was a good plan to have them covered with leather. The machine should be put in gear before being started, and if the belt were given a pull back a sudden jerk would be obviated. If the offside horse were inclined to eat the wheat it should be muzzled. The machine should be cleaned well after each variety was taken off. It was necessary to regulate the blast. If the horses were going slowly more wind was necessary to keep the machine clear. A choke-cutter was very useful. If the belts were thrown off the flywheel each night they would not stretch.

CROSS FERTILISATION OF WHEAT.—This subject was dealt with in a paper by Mr. W. Shadforth. The following is extracted:—"The average man with a knowledge of the natural laws of breeding can safely experiment in crossbreeding wheat, and a more interesting subject to men that are engaged in wheat-growing I cannot think of. It is not necessary at first to carry this out on an extensive plan, but simply to deal with a couple of heads of, say, two different varieties. The idea of cross fertilisation is to establish—(1) A wheat that will produce the greatest average yield per acre; (2) to cross one variety that is of a weak-strawed nature with an equally good yielder with a heavier straw;

(3) to establish wheats that will prove rust resistant. There are, of course, besides these a great many more objects in view, such as producing wheats with a chaff that will thresh readily with machines and yet that will not shake out in the field ; to establish beardless varieties, early varieties, &c. The Government institutions of the different States, and a great many private men, such as Mr. Petatz (of Caltowie), the late Mr. King (of Georgetown), Mr. Coleman (of Saddleworth), and others have done a good deal towards helping the farmers to obtain better varieties. The flower of the wheat plant is made up of the following:—The ovary (immature grain), on top of which is a feathery stigma (this remains on the matured grain as the ' brush '), forming the female part of the flower ; and three anthers (pollen sacs) or filaments (stalks) forming the male part. These two parts are enclosed in glumes, commonly known as chaff. The flowers are arranged in clumps of three to five and are known as spikelets, and these spikelets are arranged alternately on a central stalk to form the head. The anthers burst and scatter the pollen on to the stigma whilst still inside the chaff. As soon as this has happened the filaments grow and force the empty (or nearly so) pollen sacs out of the sheath. This is what is seen on the heads soon after they have left the sheath (or flag). Then one can be quite positive about the flowering inside of the chaff. This accounts for the fact that one seldom gets a naturally cross fertilised wheat, and also admits of growing varieties close to one another, at the same time keeping them pure. Cross fertilising or hybridising consists in removing anthers from a head of the plant being retained as a female and replacing them with pollen from the ' male ' plant. The female plant should have the anthers slightly yellow and the stigma spread out like a feather. In flowers that are too green the stigma is all clotted together like a small paint brush. The anthers from the male plant should have just burst, or be on the point of doing so. When they are near the bursting point they are very yellow and have a full and rounded appearance, and when too green they are pointed and more or less pinched. The middle spikelets on a head of wheat nearly always flower first, and when these are fit to fertilise the bottom ones are always too green and the top ones usually so. This being the case, pull off the bottom two spikelets on each side of the head. To get good results one must hurry, as under good weather conditions (bright, warm mornings) the handling rapidly brings these flowers to maturity. Avoid bursting the flowers in the heads. Utilise only one flower in each spikelet, making sure to pull the others off. This should leave the inside glume (chaff) facing the operator. Both sides treated in this manner means 14 to 20 flowers in each head, and it is so much easier and quicker to do 30 to 40 in two heads than the same number in a single head. *Method of Operation.*—Catch the edge of the ' inner ' glume with forceps and then pull it just far enough for it to remain open. Extract three anthers ; put a recently burst anther from a male plant in the flower and close the glumes together. It is then necessary to have this head wrapped up to keep the glumes closed until all parts have flowered, and the easiest and quickest way to do this is with ordinary darning wool, wrapping up the whole head and leaving it in this state until the heads are picked. It is extremely difficult to fix new varieties."

REDHILL (Average annual rainfall, 16·79in.)

January 13th.—Present : 15 members and two visitors.

Bulk Handling of Wheat.—In initiating a discussion on this subject, Mr. McAvaney said he preferred bulk handling to the present system. He did not think farmers would obtain a better price for bagged wheat as was often stated. At all large shipping centres in England elevators were installed and the bags were ripped open in such a manner as to render them useless in the holds of the ships for convenience in handling. He also commented on the unsatisfactory results of weighing wheat with scales, and mentioned that many farmers were continually complaining of receiving a shortage in weight. Mr. Coffey had examined scales at a certain wheat-buying centre and they had shown a deficiency of 7lbs. He thought a travelling expert should be appointed to inspect scales, instead of the local clerk of council. Members were in favor of bulk handling of wheat.

Early Fodder Crops.—Mr. McAvaney recommended sowing barley, oats, peas, or an early variety of wheat for early feed. This would not only be of great value for fattening stock and lamb-raising, but would improve the condition of the soil. Great loss had been sustained this season through deep drilling. In the majority of cases light drilling gave the best results. Mr. Stone did not think it advisable to sow oats as early feed, as stock did not like this crop in the early stage of its growth. He recommended sowing early wheat, and also peas, as they considerably enhanced the yields from the following crops of wheat. Mr. F. A. Wheaton thought barley best for feed.

WHYTE-YARCOWIE (Average annual rainfall, 13·91in.)

January 12th.—Present: 12 members and one visitor.

Irrigation and Fodder Crops.—Mr. van Senden read a paper on this subject. Lucerne, kale, rape, and chou moellier could be successfully grown under irrigation on fairly rich flats. Silver beet was an excellent fodder for fattening sheep and topping off lambs. In New Zealand a 12 months yield of fodder of this crop weighed 218 tons per acre. It required good soil and plenty of moisture. The best method of watering in this district was to erect a large tank at the windmill, well, or dam, conducting the water through 1¼in. pipes by gravitation to the plots. Standard pipes and taps should be 1in. Shortages of feed just about lambing time could be overcome by the provision of straw stacks, which could be fed with molasses. Small grass paddocks were advisable. Mr. Wittwer said silver beet as a fodder crop was quite new to him. He had tried lucerne, and although the grasshoppers stripped it bare in the early part of the summer there was green picking again now. He strongly believed in conserving fodder in the shape of straw and wheaten chaff. He had been informed on good authority that sprinklers were going out of use in America, in favor of a system of pipes, in which small holes were drilled at intervals. These were laid at a depth of 6in. or so from the surface; in this way evaporation was reduced to a minimum. Mr. McGregor said that, while doubtless it would pay to give attention to these secondary sources of income, it paid better while land was plentiful and labor scarce to give the whole attention to the larger matters. Mr. Hunt doubted if under our conditions silver beet could be grown successfully. Straw and chaff, with molasses, constituted a very useful fodder. Mr. McLeod several years ago had sown lucerne seed with his wheat crop, and there was still a number of plants which provided green picking for stock when it was most needed. The President (Mr. G. F. Jenkins) had found silver beet a very good vegetable, and under garden conditions it grew readily here, and it was not injured by brackish water or cutting. He had had no experience of it as a fodder, but thought farmers often went far afield in their efforts to find a fodder plant suited to local conditions and neglected the one close at hand. The buck-bush (*Salsola kali*), for instance, grew readily, and was undoubtedly suited to the district; if more attention were given to it a large amount of fodder might result.

BURRA, December 19th.—Co-operation.—Mr. F. G. Scholtz read a paper, in which he urged the necessity for farmers to co-operate. Three or four branches of the Bureau, he said, could unite in the purchase of such requirements as cornsacks, woolpacks, twine, super, machine oil, petrol, &c., and by this means effect a considerable saving.

PORT BROUGHTON.—Super. and Wheat.—Mr. Pattingale had tested the relative values of high and low grade super. He applied 20 per cent. more of the latter, and whilst there was no appreciable difference in the wheat crop, the subsequent grazing value of the land was enhanced. Thomas's super., he found, resulted in good heads and little straw. Members discussed the effect of the climate on the wheat. The further north, in good wheat land, the crop was grown, the stronger was the flour produced. Gluyas yielded well in this district, and the sample of grain was superior to that of German Wonder, Marshall's, and other varieties.

Caterpillars.—Mr. Pattingale recommended a mixture of bran, sugar (preferably brown), and Paris green, for destroying caterpillars on tomatoes.

SPALDING, November 21st.—Co-operation Amongst Farmers.—Mr. Hennessy contributed a paper, in which he urged producers to co-operate. Requirements could be then ordered in bulk lots direct from the manufacturers. He commended the practice of farming communities in Germany which issued bonds to the public when members desired to secure loans.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16·46in.)

January 17th.—Present: 20 members and three visitors.

Experimental Plots.—The Hon. Secretary (Mr. W. O. Eime) supplied the following table of the results of the experimental plots carried out on Messrs. Eime Bros'. holding :—

VARIETY TEST.

Variety.	Sown.	Area of Plot. Acres.	Seed per Acre. lbs.	Super. per Acre. cwts.	Average Yield per Acre. bush.	lbs.
Bayah	May 28	5	66	1	14	16
Federation..............	"	2½	66	1	12	31
Firbank	"	2½	66	1	13	39
Crossbred 28	"	2½	66	1	14	38

Figures of a manure test were also given. Mr. Eime remarked that the season had not been good for testing. The wheats used were all early varieties. The Bayah seemed to stand the dry weather right through better than the other varieties. It grew quickly from the start and kept up with King's Early which was sown around the tracks. It ripened later than the King's Early, but about the same time as Federation. The Firbank and Crossbred 28 ripened at the same time as King's Early. These plots were all practically together. The remainder of the paddock (91 acres) was sown with Federation, and averaged 16½bush., sown with the same amount of seed and super. The Yandilla King, with which other paddocks were sown, had 76lbs. seed and 1cwt. super. This, on the cultivated fallow, averaged from 22bush., and the ordinary ploughed fallow yielded 14½bush. to 17bush. per acre. The first sown was the best. In a late-sown paddock there was a plot of 8½ acres of Yandilla King, the seed of which had been secured from Turretfield; 66lbs. seed and 1cwt. special wheat manure, 40 per cent. soluble, were sown, but it yielded only 12bush. All the seed from Turretfield yielded considerably lower than their own, their idea being that Turretfield seed was not so well acclimatised. Mr. A. L. McEwin thought Correll's No. 7 good for hay. It grew very tall, but he favored the Yandilla King, and considered it the best wheat for this district. He generally found the early-sown wheat the best. Mr. J. J. Clarke considered the Yandilla King the best, but he found the late-sown wheat best. Mr. W. Pratt had had King's Early go 10bush., Bunyip 7½bush., Silver Prince 14bush., Yandilla King 12bush., and Marshall's No. 3 10bush. He found the Silver Prince a good early wheat, which grew to a good height, stood up well, and never shook out. He considered it good for hay, and thought the best variety for grain for scrub lands was Yandilla King, but found that out on the plain of Mount Templeton Federation yielded double that of any other wheat. Mr. M. Coleman had found Marshall's No. 3 best for last season. So far as he was concerned it had yielded 3bush. more per acre than other wheats. Mr. T. Roberts also found Marshall's No. 3 best. Mr. C. H. Zweck stated that he found the Yandilla King by far the best.

CLARE (Average annual rainfall, 24·30in.)

December 12th.—Present: 15 members.

EXPLOSIVES.—Mr. E. L. Elliott contributed a paper on the use of explosives. Dynamite, he said, was exploded by a detonator and fuse. The detonator should be made water-tight in order to protect the fulminate of mercury, of which it was composed. In dry places blasting powder could be used. Continuing, the paper read—"This does not require a detonator; simply place about 75 per cent. of the charge in the hole, insert the fuse, then the remainder of the charge, and tamp as tightly as possible. Charges of from half a plug to four or five or up to 100 plugs of dynamite are used, and powder is used in charges from 1oz. to 5lb., 10lb., or 25lbs. I recommend the use of powder in quarrying and log-splitting. When preparing a charge it is advisable to cut the fuse on the slant and crimp the casing with crimping nippers or with a pocket knife. Do not crimp the cap with the teeth; do not use hard fracteur; do not use other than Nobel's explosives and safety fuse, as they are inferior; do not carry dynamite in the pockets; do not allow people who do not understand their use and danger to handle explosives."

HOMESTEAD MEETING.—On December 20th members visited the homestead of Mr. W. Pattullo to inspect the results of the pruning match carried out under the auspices of the Branch during the winter.

FRIEDRICHSWALDE (Average annual rainfall, 18in. to 19in.).

December 13th.—Present: nine members and three visitors.

FENCING.—Mr. G. Grope read a short paper on this subject He thought red gum the best material for posts. They should be not less than 6in. x 5in. on top, and 5ft. 4in. in length. Strainers should be 7ft. long and placed 3ft. 6in. in the ground, being well strutted with a substantial rail placed between the two top wires. Strainers in the fence line need not be put more than 2ft. 6in. or 3ft. in the ground, but should be at intervals of not more than 96yds. Ordinary posts should be 14ft. apart. A cheaper fence could be erected by putting three T iron standards and then one wooden post, at intervals of not more than 12ft. Five plain wires with a barbed wire on top were necessary for a boundary fence. The barbed wire should be fastened to the posts with wire instead of staples. The first wire should be 6in. from the ground, the second 11in., the third 17in. (these being No. 10 gauge), the fourth 23in., and fifth 30in. (being No. 8 gauge), and the barbed wire 39in. from the ground. A space should be cleared around wooden posts to protect them from fire.

FRIEDRICHSWALDE (Average annual rainfall, 18in. to 19in.)

January 10th.—Present: six members.

Engines.—Mr. J. Heintze read a short paper. An engine attached to a winnower, he said, would cost per day 2s. for benzine and 6d. for oil, and thus would save the labor of one hand at 8s. per day. Saving was effected and considerable advantage secured also by attaching an engine to the harvester. When this was done two men could clean and bag ready for market 100 bags of wheat per day.

RIVERTON (Average annual rainfall, 20·48in.)

November.—Present: 17 members and three visitors.

Dairying.—Mr. M. F. Phillips contributed a paper. The average conditions under which dairying was carried on in the Lower North, he said, were not fair to the industry. The cows kept were generally inferior, and they received scant feed and attention. It was a mistake to purchase milch cows from the market without a knowledge of their breeding. He advised farmers to sow a few acres of barley annually for feed for the cows. Two or three animals of good quality, fed and cared for properly, would be found much more profitable than a number of underfed, illcared-for beasts.

STOCKPORT, January 9th.—**Crops in District.**—In pursuance of the Branch's decision to record the results of the harvest during successive years on a particular section, section 225 H.A. was selected as being typical of the land in the district. This was sown on April 20th with Marshall's No. 3 wheat. Small patches of less than a quarter acre in area germinated promptly, but the balance did not come up until the beginning of August. The average yield was about 15bush. per acre.

WATERVALE, November 10th.—**Farm Horses.**—In a paper on "The Care and Management of Farm Horses," Mr. A. S. Davis advised the provision of stables with stone walls and a thatched roof. This should be divided into stalls. Water should be provided in the yard, so that the horses could drink when they desired. Each animal should have a well-fitting collar. The collar of a horse which was susceptible to sore shoulders should be stuffed and lined. The horses should be worked in the same place in the team regularly, and it was advisable to always brush them well.

WATERVALE, December 8th.—**Lucerne.**—Members generally were of the opinion that lucerne could not be grown in this district without irrigation. The ground was liable to crack in the summer. Mr. Holder had sown an acre to this fodder and it appeared to be a failure. The following year he ploughed the land and planted fruit trees, since when he had been troubled to get rid of the lucerne.

Manuring Vineyards.—The Chairman mentioned that as very little rubbish was permitted to grow in the vineyards, the vines did not receive the benefit they formerly secured from the ploughing in of the weeds, consequently he recommended the application of manure

---

YORKE PENINSULA DISTRICT.

(TO BUTE.)

MINLATON (Average annual rainfall, 17·41in.).

December 11th.—Present: eight members.

Marketing Wheat.—Mr. J. Boundy read a paper on this subject. He urged the necessity for farmers to thoroughly clean their wheat. A small quantity of foreign matter in each single bag constituted a considerable amount of rubbish when the production of the State was taken into consideration. The combined harvester was the cheapest method of handling the crop, but the sample secured was not as good as that stripped and put through the motor winnower. Well-cleaned wheat, oats, and barley, put into good bags, would secure the best prices. The Hon. Secretary (Mr. J. McKenzie) thought the system of marketing adopted in this State unsuitable to the conditions. Mr. Evans put his grain through the winnower twice. He thought wheat should be sold in two or three grades, according to sample.

KADINA, January 10th.—Samples of wheat grown during the year were tabled by different members. Mr. Correll tabled Late Gluyas and Yandilla King; Mr. Malcolm, Silver King, one portion of which on fallow yielded 30bush. per acre, another 18bush. per acre, and portion on land not fallowed 12bush. per acre; Late Gluyas, on fallow, returned 15bush. to 18bush., and on land not fallowed, 10bush.; John Brown, 12bush. and 9bush. per acre respectively. Mr. Pedlar had secured results as follows:—Lutz, 15½bush.; Late Gluyas, 14bush.; Yandilla King, 14½bush.; Federation, 10bush. Mr. Wiedenbach—King's Early, 12bush.; Late Gluyas, 15bush.; Marshall's No. 3, on stubble, 7bush. Mr. Paterson tabled a sample of oats 6ft. 3in. in height.

YORKETOWN, December 13th.—CARE OF HARNESS.—A paper on this subject was contributed by Mr. R. F. Venning.

WESTERN DISTRICT.

COORABIE (Average annual rainfall, 11in. to 12in.).

December 13th.—Present: 20 members and two visitors.

DEMONSTRATION PLOTS.—Members decided that arrangements should be made to inaugurate three series of experimental plots—one each in Wookata, Coorabie, and Kooringabie—to test two different quantities of superphosphate and two varieties of wheat on fallow and stubble land.

HOME REMEDIES FOR STOCK.—Members discussed at length remedies for different diseases in stock. One member reported the occurrence of a hard lump about the size of a cricket ball half-way up the shoulder of a horse. Mr. Stretton advised painting the swelling with iodine daily for a week. [The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) commenting on the above, stated that the growth was fibrous, and should be cut out if the iodine failed.] Mr. Riddle reported that he had a horse suffering from a skin disease. Small lumps about the size of a pea appeared on various parts of the body. These broke and discharged a light pus, after which the hair came off. [Mr. Place attributed this to digestive troubles, and advised giving ½oz. sulphur daily in food for a fortnight. Boracic ointment to be applied to the sores.]

KOPPIO (Average annual rainfall, 22·40in.)

December 11th.—Present: eight members and three visitors.

WOOL AND SHEEP.—The Wool Instructor (Mr. Henshaw Jackson) gave an address and demonstration. He commented on the smallness of frame of the sheep he had seen in the district, and suggested that the introduction of big-framed Northern rams would make an improvement. For the farmer he advocated breeding crossbreds, using long-wool rams on Merino ewes, on account of the wool of that cross being more profitable. Where suitable conditions existed for growing fodder crops fat lamb raising would be found profitable. Mr. Jackson considered much good fodder was wasted on the farm through farmers not making full use of cocky chaff and stubble; 3lbs. of cocky chaff and ½lb. crushed oats would make a cheap and excellent ration for a sheep when feed was scarce. He had himself conducted experiments in the feeding of sheep. He kept 13 sheep in a small enclosure for 220 days on 1lb. chaff and 2ozs. oil, at a cost of ½d. per sheep per day, and at the end of that period they were fat. Mr. Jackson emphasised the fact that it would pay growers to carefully class their wool for market, but they should avoid over-classing. He then gave a demonstration on skirting and rolling. If no bur or seed were present in the fleece, stained pieces and hairy growth round the breech and neck should be taken off. If there were bur or seed it was advisable to skirt in as far as it extended, and take all stained pieces out of the belly. They should carefully pick over the pieces and divide them into two lots—good clean wool, and dirty or stained pieces, branding each bale plainly on the top and front with the grower's brand and description

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

BERRI.

December 13th.—Present: 16 members.

Buildings.—Mr. H. P. Wishart contributed a paper. Frequently, he said, the occupier of an irrigation block selected sites for buildings on any portion of the land unsuited for cultivation purposes, irrespective of whether it constituted the best site for the economic working of the holding. Beauty as well as utility should be considered in connection with the erection of the homestead. Stone or brick was the best material to use. The walls should be high, rooms large, well lighted and ventilated, preferably with a verandah or shelter on every side. Other buildings should be some distance from the dwelling-house. The stables should be large enough to accommodate all the livestock on the farm. Implement, tool, and hay sheds should adjoin. These could be made of concrete consisting of one part lime to two parts sand and three parts rubble, mixed and placed between 12in. boards at the required distance apart. Continuing, the paper read—"A very convenient building or shed for the irrigation blocker is a large roof or covering supported on posts a considerable distance apart, and having at least three sides open; if one is closed it should be the side facing the windy and rainy point. Until such time as the blocker is in the financial position that will allow the construction of a building for each specific purpose this covering or shed could be made to serve as a hayshed, and for implements and tools, including all drying trays, sweat boxes, &c., and could be so fitted for portion to serve temporarily as a stable. The supports and, in fact, the greater portion of timber needed in this shed could be secured locally. The roof should be of galvanized iron. The settler must have some idea of the completed plan of his holding, so that the buildings thereon can be arranged to fit in with all necessary requirements for the most economic and profitable working of his property." Generally, members favored concrete for building, as the material was easily obtainable locally.

RENMARK (Average annual rainfall, 10·93in.).

December 9th.—Present: seven members and five visitors.

Dried Fruits.—Mr. Alfred Odgers read a lengthy and instructive paper on this subject He drew attention to the fact that the consumption of dried fruit in Australia was relatively small, attributing this to the high prices. Prices to the consumer could be lowered if better cultivation were practised. The more general use of gypsum and manure and better pruning were necessary. Labor-saving implements and appliances should be adopted. Continuing, the paper read—"There is yet another great factor that will operate if prices are lower, viz., the export of dried fruits to Europe. Some years ago the representatives of some of the great co-operative societies in England were interviewed whilst in Adelaide, and asked as to the possibility of securing a share of their trade in dried fruits. Because we were unable to supply their yearly requirements, they said there was no hope of doing business. At that time some of them were buying each year from 500 to 800 tons from America and Canada. France and Germany would be large buyers if the prices were right. Both countries would also be large buyers of preserved fruits. For this trade these must be put up in clear white glass jars. The get-up of such commodities has much to do with the demand for them." He recommended special efforts to encourage the consumption of fruit within the Commonwealth by extensive advertising, which could be undertaken by a Commonwealth fruit growers' co-operation. Mr. Muspratt considered one central agency necessary for selling dried fruit, owing to the number of tied stores. Many blocks were planted with trees or vines unsuited to the soil. Returns from the majority of the orchards would be improved with more cultivation and manure. A fair estimate of working expenses was £10 per acre per annum. Mr. Basey thought there were too many grades in grape fruit. Mr. Cuttle said there should be a bulk grade and one other; these should not vary.

WYNARKA (Average annual rainfall, 14in. to 15in.).

December 5th.—Present: six members and two visitors.

Demonstration Plots.—A committee, consisting of Messrs. J. R. Beck, A. Hood, C. B. Wright, J. Boyce, C. Schultz, and C. S. Hall was appointed to superintend demonstration work. Wheat varieties tests were to be undertaken by Mr. Beck, quantities of seed tests by Mr. Thompson, manurial tests by Messrs. Schultz and Boyce, and cultivation tests by Mr. Hall.

COONALPYN, December 12th.—HARNESS.—Mr. R. F. Venning contributed a paper dealing with the care of harness.

SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.)
January 12th.—Present: 18 members.

THE FRUIT CROP.—Mr. Penno grew only Moorpark apricots. For four years he had good crops; the next year the crop was poor owing to the hail knocking the fruit off the trees. The following year the setting was poor, but this year the trees were carrying a very heavy crop. Mr. James reported that his apricot crop was a failure this year. If there were a good quantity of fibrous roots in the surface soil the following crop of apricots would be heavy; if the fibrous roots were absent the crop would be poor—even if the flowering were good the fruits would fall from the trees. Mr. G. W. Summers reported that he had the Duchess, L'Inconnue, Beurre Clairgeau, and Josephine de Malines pears in consecutive rows, and the crop on the Duchess was poor, while the other varieties carried good crops. Mr. Winser said he had two blocks of Jonathans, one of 250 trees and the other of 400, together with a block of 1,000 Cleopatra, all of which set good crops, but a block of 600 Cleopatras opposite the Jonathans did not set so well.

BLACK SPOT ON APPLES.—Mr. W. L. Summers read an extract from a report of spraying tests carried out at Bairnsdale. The district was very favorable to scab, and there were heavy dews at night several times a week right through the late spring and early summer months, causing the leaves to drip as from a shower of rain. The trees in the tests were very large, being up to 30ft. high, and carried dense foliage. The spraying was carried out in September, when a pinkish tinge was showing in the flower buds. The trees that were sprayed were clean, and those left unsprayed were badly affected with fusicladium, both on the foliage and fruit. The mixtures used were Bordeaux mixture 6lbs. bluestone, 4lbs. lime. 40galls. water; Burgundy mixture—6lbs. bluestone, 9lbs. soda, 40galls. water; verdegris, 3lb., to 40galls. water; and a lime-sulphur mixture. The results were all satisfactory, whether one, two, or three sprayings were given. Where verdegris was used the results were most satisfactory. The comparative cost of sprays per 50galls. was Bordeaux 1s. 10d., Burgundy 2s. 8d., verdegris 5s. Verdegris was used very largely in France. Members were agreed that where apple trees were sheltered the fruit was clean, but where exposed the fruit was dirty, and that early spraying was most effective.

CHERRY GARDENS (Average annual rainfall, 35·03in.)
January 6th.—Present: nine members.

FRUIT TREES.—Mr. A. R. Stone read a paper. He preferred young trees that had been budded to those that had been grafted. When planted out, it was advisable to cut the rough ends of roots that had been damaged in transit, and place the tree on a small mound in the centre of the hole to about the same depth as it was formerly. If the ground beneath the trees were dry it could be loosened by means of explosives. The land should be worked well, and the trees placed about 20ft. apart. Continuing, the paper read—"After planting it is necessary to prune off all the surplus wood or limbs, leaving only the number desired to shape the tree, and in most cases cut to an outside bud. In spring, when the shoots are making a growth, it will be necessary to move the surface to retain all the moisture available, otherwise the land will become baked, dry, and hard, the soil beneath being unable to nourish the roots, and the tree will soon be showing the need of care and attention. At intervals a little later on, especially after rain, it will do much good to hoe, or by other methods move the surface again. During the first year or so young trees have a tendency to make too much top, and with the wind will cause a large space around the stem to become hard and smooth, while the tree is not likely to have a good root system. Summer pruning or cutting back part of the young growth will have the desired effect. A stiff, low tree is better than a tall, slender one, as later on it is not so difficult to gather the fruit. Some varities of fruit trees, chiefly apples, form fruit buds during the first year or two, and often, if not picked, these will keep a limb from the position desired to form a good evenly balanced tree. At planting time a few handfuls of bonedust worked or mixed with the soil around and as far as convenient away from the stem of the tree will cause the roots to extend and develop better than if placed directly on them. Most manures have a beneficial effect upon trees. It is best not to manure close to the trunk, but encourage the roots to spread out into open ground."

CLARENDON (Average annual rainfall, 33·67in.)

January 19th.—Present: eight members.

Fertilisers.—The Hon. Secretary (Mr. A. Phelps) read a paper. He considered it necessary that every farmer should ascertain by experiment exactly which manurial dressings gave the best results on his holding. Different crops also required different applications. When due attention was given these points, and the soil was worked intelligently and selected seed sown, satisfactory returns were practically assured.

Feed for Cows.—Mr. C. C. Spencer had been feeding his cows on lucerne and oaten hay for alternate periods. Best results were secured from the latter.

HARTLEY (Average annual rainfall, 15in. to 16in.).

December 10th.—Present: 18 members and one visitor.

Poultry.—Mr. W. Cross read a paper on this subject. He advised farmers to provide a small shed, with a layer of straw on the floor, on which to feed the hens in winter. A flock of 100 hens necessitated two breeding pens. A pure-bred rooster should be mated with 10 of the best hens. About 120 chicks should be reared annually, as early as possible, to keep up the laying flock, and the old hens should be rigidly culled. In addition to the laying strain it was advisable to keep hens of a good sitting breed. When sufficient eggs for sitting purposes were secured the hens should be turned out, but the male birds should still be kept in confinement. Members considered hens required exercise during cold weather, and, therefore, did not approve of shutting them in houses or yards. Some thought more than 10 hens could be advantageously mated with one rooster.

Dairying and Pig-Breeding.—Mr. F. Bruns, in a short paper, said indifference and carelessness in breeding dairy stock was the weak spot in this industry. Unprofitable cows should not be kept. He proferred the Jersey for dairy purposes, but the best dairy animal was not the best for beef. Cleanliness and regular and prompt marketing were essential. The Essex-Berkshire cross was the best class of pig. Breeding sows should not be kept in small sties, as they required plenty of exercise when in farrow. During the summer they should have water in which to bathe. Members thought the Jersey cow good as a creamer only. The Shorthorn was good for the dairy, and for beef could not be beaten.

INMAN VALLEY (Average annual rainfall, 26in. to 27in.)

December 10th.—Present: 16 members.

Dairying.—Mr. D. A. Norsworth read a paper. Agricultural pursuits in this district were not quite as successful as was desirable on account of the wet seasons, he said. Dairying could be carried on to profit on the best of the land, and the second-class areas could well be utilised for growing fodder for the cows. The cow sheds should have bricked or tiled floors, dipping well, to allow of good drainage. Separate bails should be provided for each cow, as stall feeding would be necessary during part of the year. The dual purpose cow was the best suited to the district, *i.e.*, the Milking Shorthorn. Whatever breed was chosen it should be kept true to type. The bull should not be allowed to roam at large with the herd. Regularity of milking was essential, and testing was advisable.

MYPONGA (Average annual rainfall, 33·33in.).

December 22nd.—Present: seven members and four visitors.

Potatoes.—Mr. K. Stephenson read a paper, in which he related conclusions from experiences in potato culture at Mount Jagged. He said—"In potato-growing three factors exercise a large influence on the success or failure of the crop, *i.e.*, preparation of soil, seed selection, and climatic conditions. We have found from experience that deep cultivation is the best. The ground should be well ploughed to a depth of 8in. or 9in., and, if possible, deeper. It should then be worked with the harrows and roller until the top 4in. or 5in. are reduced to as fine tilth as possible. If the ground is dirty disc harrows will be found far superior to ordinary harrows. The selection of the seed is a matter to which too much care cannot be given. Although some growers will use nothing but large seed cut into sets, we have not found much difference between cut and whole seeds, providing the whole sets are from good plants. As soon as the potatoes shoot they should be picked over, all shoots being removed and tubers of doubtful quality thrown out. The seed should be put in a thin layer on a cool floor in a fairly dark shed. Planting may be done in dry ground in August or September. In the swamps and damp soils December is the best time to plant. The ground should be given a second ploughing to a depth of 4in. to 5in., the sets being placed in the bottom of the furrows. It is advisable to manure at the rate of half a ton per acre; bonedust and guano super. being in our experience the best. After planting, the land should be harrowed and, if lumpy, rolled. When the rows can be distinguished the horse-hoe should be put to work to keep weeds in check. When the plants are 8in. or 9in. high they should be banked up, after which they may be safely left until dug." Members condemned the idea of keeping seed in a dark shed. They would rather have it exposed to light, keeping tubers intended for domestic purpose dark. The practice of broadcasting manure had much to recommend it. Whole seed were more liable to produce runouts than cut seed.

The Hon. Secretary (Mr. F. Müller) also read a paper on this subject, in which he said —"The chief points to be considered are good cultivation, good seed of suitable sorts, sufficient manure of the right kind, and the correct season for planting. The land should be cultivated as deeply as strength will allow. Turning up a little clay will not hurt the potatoes. The soil should be well stirred and the clods crushed. It is preferable to work the land well before planting, as I hold that frequent horse-hoeing injures many roots, and consequently the plants. At the second ploughing after the soil has been well pulverised, plant in every third or fourth furrow. Place the sets not less than 12in. apart, 15in. is better, a little more being allowed for Snowflakes. When the rows are showing well, horse hoe, and later on earth up the crop with mouldboards on the ordinary horse hoe. Good seed is necessary. Select it when digging and keep it pure. To ensure strong hardy shoots at the time of planting, expose the seed to light and air, but not necessarily from the time of digging. Autumn potatoes can be kept in bags until about August and then shot under trees or anywhere out of reach of cattle, pigs, or poultry. A better plan is to keep them on racks or trays one or two deep, but this might prove rather expensive for a beginner. The kinds generally grown in this district are Up-to-Date for early crops, and Snowflakes for late. I find that guano super. does best with us, after a careful test of potato manure, bone super., mineral super, and guano super. Half a ton per acre should be broadcasted and harrowed in before the second ploughing. Broadcasting distributes the manure throughout the soil. It is a well-known fact that the roots run right across from one row to the other in their search for food; they are searching in unmanured soil if the common practice of manuring in the furrow with the sets is adopted. After three years' trial I have determined that November and December are the best months for planting. I am so confident that late planting is a success that I intend planting till the end of January this season. It is inadvisable to plant cut sets in dry ground, as they are liable to dry rot; but whole sets will sprout no matter how dry the soil, and once they are up potatoes can hold their own until the autumn rains set in, or in any case they will have cooler weather in which to mature instead of midsummer, as is the case if planted in early spring. This district produces about 10 times as many potatoes now as it did eight years ago, but the industry is capable and deserving of greater expansion, when we consider the immense quantities imported from Victoria annually, and the fact that one city firm handles about 6,000 tons per annum, shows that it can hardly be overdone. I estimate that we can grow this crop to profit at £4 per ton. We expect to average at least five tons per acre. The cost is no more than £11, made up thus—half a ton manure, £2 12s. 6d. delivered; half a ton seed, about £2 10s. to £3; cultivation, including planting, £3; digging five tons at 10s. per ton, £2 10s., leaving £9 per acre over cost, besides the certainty of the land being benefited by the crop."

NARRUNG (Average annual rainfall, 17in. to 18in.)

January 9th.—Present: 13 members.

Colt-Breaking.—An address on this subject was given by Mr. J. W. McNicol. The colt should be caught and handled when it was weaned, and at intervals of a few months thereafter, he said. At two years old it should be roped, and the operator should gently work up to its head. A halter should be put on, and a rope fastened to the noseband of this. The animal should be lunged from side to side until it answered the rope. It should then be flicked under the forelegs with a light whip until it would walk up to the operator, and lead or follow as soon as the arm was raised. A bit should be placed in its mouth and fastened to the halter with a short strap or spring hook. A surcingle with a ring attached to each side should be put on, and a line run through the rings with one end fastened to each of the rings of the bit. A firm pressure should be kept on the lines and the animal driven round and taught to guide and pull up. A bag should then be placed around its neck, and a strong rope tied around this and attached to a strong post. It should be made to pull back; when it realised that it could not get away it would give up the practice for all time. A strap should then be put around the colt's neck and a rein on to the near side of the bit, running back through the strap on the neck. A quiet horse should be mounted and the colt kept up alongside, a whip being used on to its rump. For riding, the animal should first be mounted in a yard. A firm grip should be taken of the ear with the left hand, the near rein being held tight and the off rein somewhat loose. The right hand should grasp the front of the saddle or a monkey strap, and the operator should get lightly into the saddle. After awhile the animal could be ridden into the open. For driving, it should be placed alongside a quiet horse at first. There was no need to hurry the operation, but the animal should be used a little every day for a week. The mouth should be allowed to harden with the bit. Firm, but not rough, treatment was necessary.

STRATHALBYN (Average annual rainfall, 19·28in.)

January 13th.—Present: 15 members.

Rust.—Mr. J. W. C. Fisher read a paper, in which he related experiences with this wheat disease since it first came under his notice in 1850. In some cases crops which stood as high as the fences turned out utter failures. Whilst the wheat failed, however, oats yielded 25bush. to 30bush. per acre, which demonstrated the advisableness of lessening the risk of complete failure of crops by sowing different cereals. Persistent spring rains, with damp, thundery days, appeared to encourage the development of the disease. Soft strawed wheats were more liable to rust than the more solid strawed varieties. His opinion was that certain atmospheric conditions seemed to be responsible for the disease.

Wool.—A lengthy paper on this subject was read by Mr. A. Beviss. Climatic conditions, he said, had a great deal to do with the condition of the wool. Hot winds and glaring heat tended to make the wool dry and harsh. Exposure to cold and bleak conditions destroyed the yolk. Plenty of good clean water should be available to the sheep in summer. He described in detail the points of a sheep. Culling should be carried out when the animals were 12 months old, and again when two years old. Stud stock should be yarded and tabled at least twice a year. The sheep should be shorn when the " bloom " was on the wool. The operation should be performed on a good clean board. Hand shears were preferable to the machine. After the stained parts had been removed the fleece should be rolled. After any portion of the neck that was not fit to be included with the fleeces had been removed the sides could then be rolled to the centre. Tender, stained, and broken fleeces should be kept by themselves.

HARTLEY.—During the month of January the Branch held four meetings, at which the Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) delivered a course of lectures on (1) The Anatomy of the Horse, (2) Diseases of the Horse, (3) the Cow, and (4) the Pig and Sheep. Members expressed their entire satisfaction with the way in which the subjects were treated.

IRONBANK, December 13th.—**Summer Pruning.**—Mr. R. Coats read a paper. When fruit trees were pruned heavily during the winter, he said, they sent out numbers of unnecessary shoots. These should be pinched off to a length of about 3in. It was sometimes necessary to thin the crop, which should be carried out as soon as the fruit had set. Members generally agreed.

LONGWOOD, January 10th.—**Homestead Meeting.**—Members met at the homestead of Mr. E. J. Oinn. A hand chaffcutter, to which two counter weights had been attached, was found to work well. A good supply of water was secured by constructing a reservoir just below several good springs at the base of a hill. Some fine potatoes were noticed.

MEADOWS, December 8th.—**Breeding and Feeding Horses.**—This subject was discussed at length by members. Mr. Brooks thought this State could breed stallions instead of importing them from neighboring States. The Chairman (Mr. G. Ellis) considered that too little feed was given to foals during the cold winter months in the Hills District. Mr. Phillips had found it profitable to feed foals during the winter months.

SOUTH-EAST DISTRICT.

MILLICENT (Average annual rainfall, 29·25in.)

December 9th.—Present: eight members.

Wheat after Oats.—Mr. Edgcumbe stated that wheat crops on land which had during the preceding season carried oats had, in his experience, been highly satisfactory, and there was a noticeable absence of takeall in them. Members agreed that generally a better yield of wheat would be secured after a crop of oats.

Wool Industry.—Mr. H. F. G. Holzgrefe gave an instructive address. He was impressed, he said, with the immense future before graziers who could grow good wool. He regretted that more interest was not taken in the growing of wool in some districts, and also in the care of sheep and the "get-up" of the clips. A comparison of prices obtained in the various markets clearly showed what a large quantity of inferior wool was sold each year. For instance, in Geelong, only the previous week, the record price of 29¼d. per pound had been realised for greasy lambs' wool, and fleece had reached 20¼d., while the pieces and bellies of the same clip had brought 14¾d. and 13d. respectively. Glancing through the catalogue he had noticed several lots of lambs' wool up to 25d., and fleece from 16d. to 20d. It was regrettable to see dipping operations carried out in a haphazard fashion, and sheep driven along dusty roads almost immediately afterwards. He had known cases of the best sheep in the flock being fattened and sold and the inferior stuff kept for wool. Every man needed to study his own country, but the use of cheap and inferior rams was, in many cases, the cause of so much low-priced wool. He emphasised the necessity for keeping the best lambs every year to maintain and improve the flock. The preparation of the clip for market was of the utmost importance. It was no use trying to deceive the buyer. There had been a great improvement in the sheep in the Millicent district of late years. However, there was still room for improvement. The Chairman (Mr. J. J. Mullins) said the class of country on which the sheep were grazed had a big influence on the wool. The animals should not be allowed to remain too long on unhealthy country which would cause a break in the wool.

MOUNT GAMBIER (Average annual rainfall, 32in.)

December 6th.—Present: nine members.

Sheep and Wool.—Mr. J. Botterill delivered an address on this subject. This year, he said, prices ranging up to 29½d. per pound had been secured for wool. There were several factors to which these high prices might be attributed—(1) The increase in population in Australia, and the consequent increase in consumption; (2) the increase in the purchasing power of the people; (3) and finally, and most important of all, the increase in the export trade in sheep and lambs. At the end of the year 1912 Australia showed a shortage of 10,000,000 sheep, and this seemed extraordinary, coming, as it did, at the end of a period of 10 or 12 good years. The only set-backs were in one district in New South Wales, and another in the northern portion of this State; but this was due to a poor lambing. In South Australia to-day there were 500,000 less sheep than they should have. One factor, as he had mentioned, was the increased consumption of mutton. Ten years ago the weekly yarding of sheep in the Adelaide market was about 3,000. To-day the yarding went up to 16,000, and this large total was all absorbed, either for local consumption or for freezers. Anyone who had watched the market closely would see that last year more sheep were taken for freezing than in any previous year. It was common to see exporters take 3,000, and 10 years ago this was reckoned a good total yarding. A glance at the export trade explained this more fully. In 1888 the total number of carcasses of sheep imported into Great Britain was 400. During last year Australia sent to Great Britain 1,450,000 sheep and 1,900,000 lambs, and New Zealand 3,191,000 sheep and 2,360,000 lambs. These amounted to about 10,000,000, or equal to the shortage reported in Australia in the last 12 months. The demand for frozen produce in England was increasing, and, in addition, new markets were being opened up in Germany and America, and these would absorb many millions of carcasses in the future. He did not see how they were going to cope with the demand under present conditions. It was well to consider that, in the production of cereals, Australia had to meet with the competition of the whole world. In a small country like Italy several times more wheat was grown than in all Australia and New Zealand. In the production of sheep and wool Australia had practically no competition to face. South Africa was making great efforts to build up the industry, but there was a tremendous lot of pioneering work for her to do. In the Argentine he doubted whether they had a serious competitor, or that the Argentine ever would be in wool, although she might be in fats. Too much attention could not be paid to the careful selection of ewes, and the purchase of first-class rams for breeding. Even a man with a few hundred sheep would be amply repaid if he bought good rams. For country that would carry one and a halt sheep to the acre there was nothing better than the Merino-Lincoln cross. The sheep at Coola were practically all halfbreeds. They cut a fair clip, the wool brought a good price, and the sheep brought a big price off shears. The Merino would cut more wool, but the carcass was not so good. There was one essential in regard to crossbreds, and that was to get a big frame. But there was some land not strong enough for crossbreds, and then Merinos should be used. They must get weight in crossbred wool, and this was not possible on light country. Merinos, on the other hand, would grow a lot of wool without much condition. It was questionable whether it would not pay better to grow wool and fatten sheep on much of the land instead of cultivating it. He thought the Government should do more to show the small landholder how to keep sheep. The owners of most of the small farms were brought up to agriculture alone, and in sheep-raising they had to get their experience somewhere, and it was costly if they had to buy it. A lengthy and interesting discussion followed.

TINTINARA (Average annual rainfall, 18·78in.)

October 25th.—Present: 19 members.

Fruit Culture.—Mr. Max Scott read a paper under this heading. He advised intending growers to plant the trees in well-worked fallow. Cultivation between and across the rows should be commenced immediately the trees made headway; this would assist in conserving moisture. Many horticulturists adopted the practice of planting the trees on crowns made by throwing two single plough furrows together from opposite directions. The earth was then hilled up and firmly stamped around the butt. These furrows also collected a large amount of water during the wet season. Peas at the rate of 2½bush. per acre, should be sown and ploughed in green before the trees were planted. If the latter were not making satisfactory progress during the first year, half a pound of nitrate of soda could be applied to the base of each, or the same quantity of a mixture consisting of 1cwt. chloride potash, 2cwts. sulphate of ammonia, 5cwts. concentrated super. Stable manure could also be used to advantage, about two wheelbarrow loads being placed at the foot of the hill around each tree and ploughed in during the following year. Stringent steps should be taken to prevent the introduction of codlin moth to the district.

Melilotus.—Mr. A. Koeppen Wendt reported having visited the district of Rye (Victoria) where the cultivation of melilotus was largely carried on. Captain Hill, who went in for this fodder on a considerable scale, he said, "Considers this a splendid pioneer for cleaning the land; but later on other fodders can be grown to better advantage. Mr. Norquay thinks that it cannot be improved upon in that district. I inspected some of Mr. Norquay's melilotus paddocks. The land was originally dense teatree scrub. The soil consists of about 2ft. of black sand on top, under which is yellow sand. It is prolific in phosphates and lime, but deficient in potash. The method of sowing in this district is to burn the standing scrub in February and then to broadcast the seed as soon as possible after the burn. Most of the scrub is killed by one fire, and seedlings are practically the only subsequent growth. These are killed when the melilotus is fired the following year. The seed is sown at the rate of about 15lbs. to 20lbs, per acre, early in February, so that it lies exposed to the sun and heat, thus melting its waxy encasement and leaving it in a fit state for germination with the first rains. The first year the melilotus comes up very thin, but if this is fed off lightly and allowed to seed the crop next year should be thicker. This fodder has splendid fattening properties. At Rye, one paddock was carrying a bullock to two acres. Notwithstanding this the melilotus was about 2ft. high. To get the best results from a paddock of this fodder it should be burnt at least once every two years, as a good burn ensures a good germination the following year. In my opinion melilotus should thrive on these fertile downs. Small plots have been grown by different farmers with great success, but they have not received fair treatment. One of the greatest advantages of this fodder is that it can be sown on land not yet clean, as by burning it every year shoots, &c., are destroyed. It also belongs to the leguminous family, thus supplying nitrogen to the soil and improving the fertility of the land. By grazing it all the organic matter from the droppings is obtained, so that land which had been under melilotus for four or five years should be in tip-top condition and produce excellent crops. The sooner the farms in this district are able to carry stock and are manured through this medium, the sooner will really good crops be grown."

KEITH, January 10th.—DEMONSTRATION PLOTS.—A committee, consisting of Messrs. Redpath, Makin, and Gill, were appointed to superintend the experimental work to be undertaken by Mr. Makin.

HUNDRED OF PENDLETON.—Mention was made of the fact that very fine crops of onions, potatoes, and wheat had been grown in this hundred.

WIRREGA, November 29th.—WHEAT.—Mr. P. Prime read a short paper. The best varieties of wheat for this district, he said, were Dart's Imperial, Lots, Gluyas, and Federation. The latter was rather short, but yielded well. Floor pickled graded seed should be sown, and where a good stubble burn was secured 50lbs. to 60lbs. of manure was sufficient, this being increased to from 75lbs. to 90lbs. in later years. Crops on light land should be rolled.

T. PASCOE,

Minister of Agriculture.

POINTS FOR PRODUCERS.

Farmers' Conferences.

Conferences under the auspices of the Agricultural Bureau will be held at Orroroo (Upper Northern Branches) on March 20th, and at Millicent (South-Eastern Branches) on March 25th. The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), will deliver the opening addresses at both of these conferences. Other speakers will be the Director of Agriculture and the Government Veterinary Lecturer, at Orroroo, the latter dealing with "The Importance of Water in the Diet of Stock"; and at Millicent, the Director, the Superintendent of Agriculture in South-East (Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S.), and the Government Dairy Expert (Mr. P. H. Suter). Professor Lowrie will deal with "The Cultivation of Fodder Crops," Mr. Colebatch will speak on "Lime in Relation to South-Eastern Soils," and Mr. Suter will speak on the "Feeding of Pigs for the Production of Bacon and Pork."

Fruit Export to Java.

The Consul for Netherlands has forwarded to the Department of Agriculture for the information and guidance of fruit exporters to Java an outline of the regulations proposed by the Netherlands Indian Department of Agriculture, etc., governing the importation of plants, fresh fruit, &c., from abroad. In connection with the above, the date of inception of same was February 1st, 1914. All consignments of fruit must be in new cases, and accompanied by a certificate signed by an official expert of the Government of the country of origin, in which is stated that the consignment concerned when shipped from Australia was free from fruit flies and other injurious insects, and diseases. The goods will be inspected on arrival by an official of the Netherlands Indian Department, and if found to be diseased will be rejected and destroyed. Fees will be charged for inspection on arrival, and the usual penalties for any infringement of the regulations are set out. Only certain ports will be "ports of entry" for fruit. The Department of Agriculture has taken steps to obtain copies of the regulations, and when forthcoming the details will be made public.

Agricultural Labor in England.

At the instance of the Dominions Royal Commission, the British Board of Agriculture recently investigated the question of migration from rural districts in England and Wales. The report of the board, which was issued in December last, states, *inter alia*—" It is evident that at the present time considerably more men could find employment on the land than are now available. There certainly appears to be a fairly general deficiency of skilled farm hands. The manual arts of agriculture are being neglected, even by those who still seek employment on the land."

Pollination of Fruit Trees.

At the present time some fruit experts are greatly engaged in relation to the pollination of fruit blossoms. Certain varieties of many kinds of fruit do not bear fully, if at all, when self-pollinated. They require the pollen from another variety to fertilise their blossoms. The work of transferring pollen from one variety to another is mainly done by bees and other insects, but the limit of distance at which this work is done effectively is uncertain. Also unsettled is the question as to the extent to which pollen is carried from one variety to another by wind. The experiments to test these points have been carried out only on a limited scale, and there seems to be more positiveness in asserting the conclusions based upon them than they warrant. It is not certain that the method of testing self-pollination does not in some way tend unduly to negative results, and by far the best test is that of the observation on an extensive scale of the cropping of the several fruits when in large blocks of the same variety, as compared with their cropping when another variety is near them.

Science and the Farmer.

In the course of a recent lecture on " Modern Science and Modern Agriculture," Professor Ainsworth Davis, Principal of the Royal Agricultural College, Cirencester, said that among the results of the scientific study of the soil was the discovery of the bacterial nature of the process of nitrification. On the other hand, denitrifying organisms were also discovered, and the problem was to destroy the latter without detriment to the former. More recently Dr. Russell and his colleagues at Rothamsted had found that partial sterilisation of the soil was followed, after a short interval, by a marked increase in fertility. The theory put forward was that the soil contained microscopic animals which preyed upon the nitrifying bacteria. These animal organisms were destroyed by sterilisation, which at the same time was not sufficient to destroy the bacteria. Notable work had also been done in the production of new varieties of crops. At Cambridge the application of Mendel's theories had borne fruit in Professor Biffen's experiments in the crossing of varieties of wheat, and the production of a wheat that had immunity from rust combined with strength and yield. The next development that agriculturists would look for in Mendelian research would be the production of a good potato free from potato disease.—*Agricultural Gazette.*

Australian Wine in England.

In his report dated London, January 2nd, the Trade Commissioner states :—“ I understand that it is likely that the English Government will consider a suggestion from the Portuguese Government in regard to prohibiting the admission of any wine coming into this country under the name of “ Port ” excepting it comes from Oporto. In consideration of the English Government agreeing to this proposal, the Portuguese Government will put England under their favored nation clause in regard to the admission of woollen goods into Portugal. So far as this particular variety of wine is concerned, this treaty is of little consequence to Australia ; but if this is conceded to Portugal it is probable that France may come along with a similar suggestion in regard to Burgundy, a contingency that would materially affect the sale of our wines in this country, at any rate for a considerable time.”

Of Interest to Sheepowners.

Mr. Henshaw Jackson writes as follows :—

A few ewes of undeniable breeding and correct individual merit are more to be desired than a lot of inferior ones.

It will pay beginners in the sheep and wool business to visit the best breeder within ordinary train distance. Try and have a day or two on his property, and a few hours' personal conversation with the breeder himself. You will probably learn a good deal that is impossible to put on paper.

Small sheepbreeders might do worse than visit each other occasionally. Even if there is nothing to learn, it is interesting to see how others do things, and to compare notes. Such visits would bind interests, unite efforts, and impart benefits from the experience of others.

Plenty of new ideas can be gleaned relating to breeding and feeding. The breeding of livestock is a much greater work than is supposed by those who have never tried it, and there is no royal road to success. Many are called to it, but few are chosen. The sheep-breeding industry needs a bigger number of steady breeders desiring to improve their own flocks and raise the sheep standards of the State. It needs less of those gentry who dash in with a few thousand sheep and hope and expect to make their piles in a couple of seasons.

As a steady line, sheep on the farm are more profitable than any other animal on four legs to-day. When founding a flock don't regard it as a golden hole, to be worked for so long. Rather view it as a life's work, and strive to attain your ideal, even if it takes a long period of years. There's a good living in it while you are striving.

Sheepfarmers should endeavor to have good drafts of fats through the year as well as a good clip. The former have a marked effect on the size of your income.

Poorly-kept sheep don't have prime lambs, or help to make their owners any richer. The best way to improve the prospect for lambing is to give proper attention to the ewes.

If you have a seedy or "off-looking" sheep in your flock, put him into hospital paddock. Find out what ails him if you can; if you can't, look after his skin.

A sheep with dry and pale impoverished skin will never produce a good fleece.

Young sheep are generally the most profitable wool producers. Breed only to first-class rams, and according to your ewes so will you get good, better, and best in the lambs.

A sheep producing a good fleece is also not far out of it in the goodness of the mutton he will kill into.

Fodder that produces good bodily growth also aids in bringing a good fleece to the shearing board.

A good way to mark dogs which prowl round on sheep-killing expeditions is to cut off their tails—close up to their ears!

Shearing.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"H. K.," Fords, asks for advice as to treatment of a foal suffering from navel or umbilical rupture.

Reply—Generally this form of rupture is best left alone till the foal is about 8 months old, when it will often have disappeared ; if not, the foal should be starved over night and tied upon his back, the skin over the rupture drawn tight, and the bowel returned into the belly. Two skewers should be placed crosswise between the belly wall through the skin, and between them and the wall about 3ft. of saddler's waxend should be wound tightly round the intervening skin, which, with the skewers should be left to slough off, during which time nature will have closed the rupture hole with fibrous tissue.

"J. F. S.," forwards portion of fleshy substance cut from under throat of 5-months-old foal which died. A living foal has the same growths. He also asks treatment for draught mares which were scoured for few days and then went stiff in legs and had labored breathing. The mares have been stinted, and also have foals suckling. He asks the Veterinary Lecturer to pay him a visit to investigate cause of trouble.

Reply—(1) The growths received are the natural thyroid glands which exist in every horse, and when removed the animal dies. In this case they are somewhat larger than normal, showing that they have to work harder than they should in their duty of regulating the animal's development; in other words, the mare during pregnancy did not receive proper nourishment either in quality or quantity, or both. They must on no account be removed from the living foal, but it should receive twice a day two teaspoonfuls of Parrish's chemical food for a month or so. As this has a sweetish taste it will probably eat it in a little bran, or it may be put into its mouth. (2) The symptoms of a complication of influenza and blood worms. The mares are working. suckling foals, and in foal, "Puir beasties." In all cases where the services of a veterinary surgeon are required, application should be made direct to the Chief Inspector of Stock, Adelaide, who has a staff of officers. The Veterinary Lecturer's engagements, made several months ahead, entirely prevent his attending special cases, although when he is in a district his services are willingly given to stockowners who desire advice as to the hygiene and sanitation of their animals ; but the veterinary officers of the Stock Department have the sole control in cases of disease, and much time is saved by carrying out the requirements of the Stock Diseases Act and communicating directly with the Chief Inspector of Stock, Adelaide, and the nearest Inspector of Stock—in this case at Gladstone.

"J. H. V.," Eyre's Peninsula, has a horse which, from symptoms described, is suffering from bloodworms. He asks for treatment.

Reply—Two teaspoonfuls of Fowler's solution of arsenic once daily in a little bran for a fortnight, also 1 dram sulphate of quinine in a little bran twice a week for six times. The drugs are obtainable on the Peninsula.

"J. C. H.," Booleroo Centre, writes for medicines for bloodworms, white worms, water trouble, and sand.

Reply—The Agricultural Department does not dispense or order medicines, but those recommended for the above diseases are :—Bloodworms—liquor arsenicalis (Fowler's solution), two tablespoonfuls once daily for a fortnight. White worms—1 pint raw linseed oil and two tablespoonfuls of ordinary turpentine given once on an empty stomach. Water trouble—¼ pint gin, 20 drops essence of peppermint in ½ pint of warm water. Sand—a quart of new milk and 1lb. honey, preferably on an empty stomach.

The Myponga Agricultural Bureau seeks advice regarding a horse which has cracks across legs just a few inches above fetlocks, reaching towards the hocks, causing the animal to raise his legs something like in the case of stringhalt, except that he throws his feet outward more than with stringhalt, very awkward at backing, and seems too uneasy to be worked.

Reply—The trouble appears to be erythema, due to blood being out of order. Give ½oz. sulphur in food daily for a fortnight, and dress legs daily with petrol 1 part, olive oil 8 parts.

"A. D." has a mare which had a wound between hoof and the hair on hind leg. She became very lame, and swelling of doughy nature extended to under belly. When the swelling was lanced there was very free discharge ; the opening was syringed with lysol, and there was marked improvement in animal's condition, but she still has slight swelling on hock.

Reply—This was blood poisoning from what was possibly a stake in the foot, extending along the large lymphatics of the leg and body. Probably hot fomentations, with a lump of washing soda in the water, will reduce the hock.

"A. V. N." asks treatment for cow which, two months after first calving, blood appeared in milk of hind quarter intermittently ; after four months the other hind quarter also became affected.

Reply—The blood is due to a break down of the structure of the gland, and may be due to some disease, such as tuberculosis, or possibly only to glandular weakness. It would be necessary for a veterinary surgeon to see the cow before a definite opinion could be offered; in the meantime, bathing the udder with a hot decoction of wattle-bark after milking, and give 10 drops of tincture arnica twice a day in the mouth for a week or so may afford relief.

"W. K." had draught mare which died after intermittent colic, suggestive of wheat gorging. The animal was relieved by soda and ginger, but sat up like a cat; the pain increased after eating, and she strained badly. The *post mortem* showed sand in bowel and patches on stomach like old scars; a few long round worms were found.

Reply—The stomach trouble caused the mare's death; the scars resulted from worms which live the first part of their lives in stable and house flies, which both breed in horsedung. Treatment was good, but only mashes should have been given, and a sedative like chloral hydrate 1oz. might have helped. The worms, *Ascarides megalocephalœ*, were only accidents, the almost microscopic ones, *Habronemata microstomata*, doing the mischief. The long round ones may be moved by any purge, such as an aloes ball or a pint of raw linseed oil and two tablespoonfuls of turpentine, preferably given on an empty stomach.

"W. H. S." inquires concerning mare in splendid condition which had one foal, now a yearling. Foal was weaned off and away from dam for months till a few weeks ago, when it started to suck again, the mare not objecting. About a month ago mare's udder and belly swelled. Epsom salts were given, the udder fomented with Condys, and carbolised vaseline applied. There was a mattery discharge from udder, which is still swollen, and the mare is lame in off hind leg. She is in foal.

Reply—Probably an attack of influenza caused the symptoms, which were aggravated by foal sucking. Try 10 drops of veterinary tinct. arsenicum twice daily in the mouth, and foment the swollen parts and inside the thigh with tinct. arnica 1 part, hot water 20 parts; also twice daily light feed, preferably green.

"T. P. D." asks—(1) Cure for sow eating young. (2) Best means of getting rid of "scavenger" ants.

Reply—(1) Fatten her off and kill her; or, if this is too drastic, give plenty of cinders in feed during pregnancy, and ½oz. of sulphur twice a week. The cause of the habit is generally indigestion arising from the fact of being in pig. Sometimes it is a mania. (2) Boiling water is the best exterminator, or kerosine; rings of tar on their runs restrict their travels.

"J. A. J.," Numaroo, asks treatment for draught mare which for 12 days had been continually lying down, and was uneasy and appeared in pain after drinking. She had lost her appetite and fallen off rapidly from good condition to poor.

Reply—The symptoms are those of sand, and it will be well to drench the mare with a pint of new milk and a pound of honey ; repeat in two days if necessary. Rub the flanks vigorously every day, and feed on bran mashes only. Give veterinary nux vomica 10 drops morning and evening; also a good big enema once, of several gallons of warm soapsuds.

"C. R. H.," Streaky Bay, requests treatment for horse suffering from what apparently is "poll evil."

Reply—Surgical treatment alone will effect a cure. The swelling must be opened and probed, the pipes or sinuses cut down to the bottom, and any black, foul-smelling tissue, diseased bone or ligament entirely scraped away, the greatest care being taken not to injure the spinal cord which is exposed at the poll. Then the horse should have the wound irrigated with cold water for an hour a day ; brackish or salt water will do. At the end of the irrigation the wound may be dressed with tinct. arnica 1 part, methylated spirit 20 parts. If the wound is treated to the bottom, a cure will ensue in about two to three months.

Agriculture.

"S. P. D.," Jamestown, states that on his farm are some salt or magnesia patches on which he tried to grow wheat, but failed. He asks for an opinion as to whether oats or barley would grow on them.

Reply—Whether any of the cereals will grow on your alkaline patches depends, of course, on the total amount of alkali present. Both oats and barley will withstand a total amount of alkali much greater than wheat will tolerate. In the case of barley, it can withstand about half more than wheat ; and oats, if anything, are more tolerant than barley.

"W. A. M." asks how to eradicate Cape tulip.

Reply—If the land infested with Cape tulip be arable land, it should be repeatedly and persistently ploughed deeply, and cultivated deeply after each ploughing, with, say, a spring tooth cultivator, to work the underground stem or cone to the surface. This excessive working in dry weather would be to the disadvantage of the first wheat crop following, but to get rid of the pest it should nevertheless be done systematically and thoroughly for one or even two years on the places infested. On non-arable land the plant should be grubbed up by hand thoroughly and the stems burned ; and in every case the plant should be prevented from vegetating and flowering, so as to exhaust the vitality of the root system, underground stem, or cone, as the case may be.

"C. R. H.," Streaky Bay, asks what is the best preparation for very smutty wheat required for seed.

Reply—It is foolishness to sow very smutty wheat under any circumstances, however pickled, unless it be a small quantity of some special variety that you do not wish to lose, as the pickling, under the circumstances, has to be so strong that the percentage of germination will be affected. Thorough pickling with a 2 per cent. solution of bluestone would prevent smut, but a percentage of the grains would be killed.

SOME PARASITES AFFECTING FARM ANIMALS.

By F. Murray-Jones, L.V.Sc., Veterinary Department.

(*Continued from page* 712.)

THE PALISADE WORM (*SCLEROSTOMA EQUINUM*).

This is one of the commonest and most harmful worms found in the horse. It is widely distributed and found all over the world. It is generally found in marshy land. Its length varies—in the male, from ¾in. to 1½in.; female, ¾in. to 2in.; roughly about 20 times as long as thick. This is a most dangerous worm, affecting the horse. Sometimes it causes death by anæmia, aneurisms, and peritonitis, to say nothing about predisposing influence in relation to absorption of toxic substances from bowel.

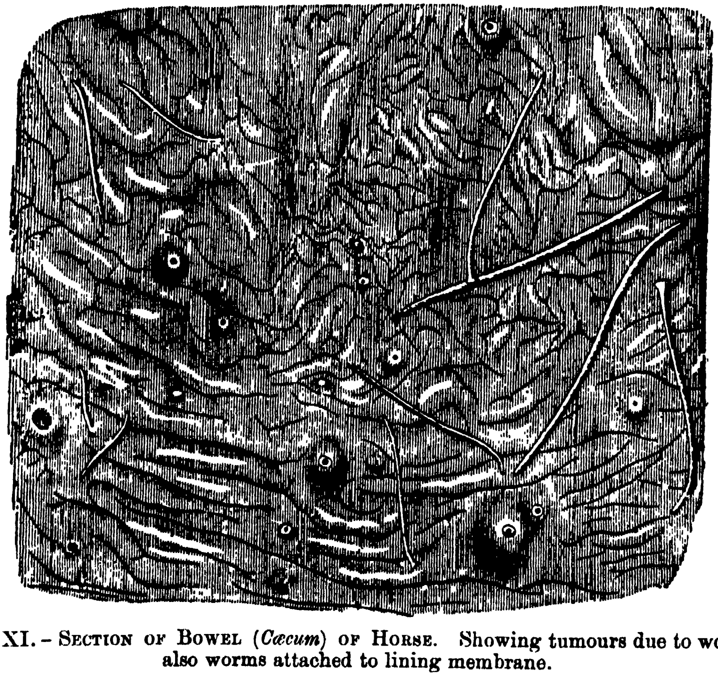

Fig. XI.—Section of Bowel (*Cæcum*) of Horse. Showing tumours due to worms, also worms attached to lining membrane.

It generally exists in two forms in horse—one the adult stage, when it is found in the mucous membrane of the large intestine, *i.e.*, cæcum and colon;

and in the immature stage, when it is often found in the blood vessels, especially in large trunks supplying the intestines with blood. Here it may cause the gravest of injury, and a condition often responsible for the death of the animal. In this stage it is occasionally found in the substance of brain and liver, &c. It is common experience to get the large intestines studded with them. They are often found together in couples. A horse gets infected, as a rule, by contaminated drinking water, or in damp fodder. The embryos, or immature worms, eventually reach the bowels and bore their way into the lining membrane, and cause thereby a cystic tumour. They are very small, about size of a pin's head. It is here that the worm is developed. After developing, the worm travels, some going into the intestine and attaching themselves to membrane, and afterwards producing eggs which are eventually expelled to the outer world with the manure. These eggs eventually become hatched in damp dung or water in from three to eight days. The embryos produced are about one-sixtieth of an inch long. They have a blunt head and a thready tail. However, by no means

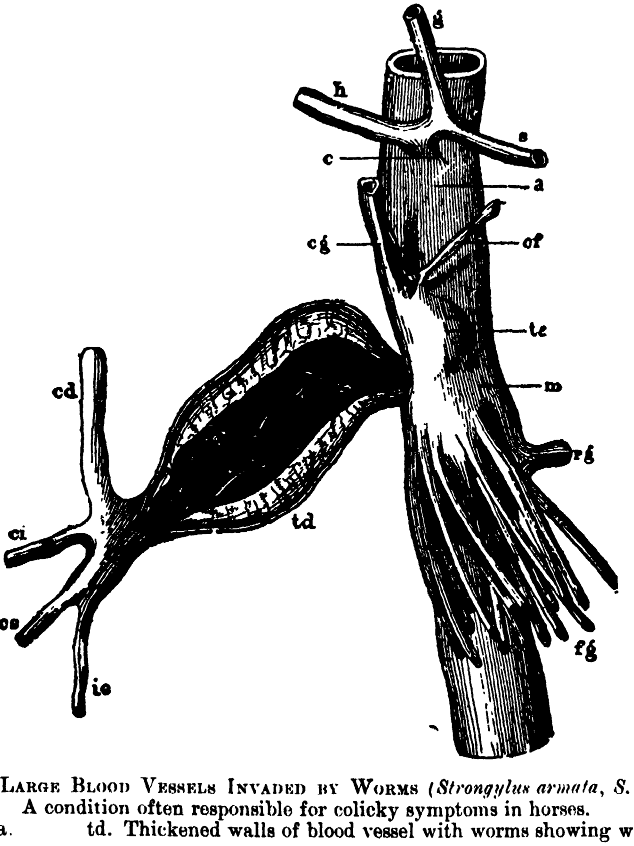

FIG XII.—LARGE BLOOD VESSELS INVADED BY WORMS (*Strongylus armata*, *S. equinum*). A condition often responsible for colicky symptoms in horses.
a. Aorta. td. Thickened walls of blood vessel with worms showing within.

do all the worms leave the cyst for the intestine. Some get into small blood vessels, and reach that part which supplies the intestines with blood. They set up inflammation, and a sac is formed by the bulging of the blood vessel wall. These sacs often reach the size of a man's two fists. The wall of this sac gets thickened as the result of an inflammatory exudate and a fibrous deposit, although a channel is still left open for blood to pass along. These sacs are called aneurisms, and the clot forming in them a thrombus. In the centre of the clot one may find a number of worms (as shown in our illustration) ½in. to 1in. long. Very often an animal so affected may suffer colicky pains, and this may be due to a breaking away of small bits of the clot and so obstructing the blood supply of the intestine. A condition of bowel paralysis of the wall may result. These aneurisms are generally found in the aged animals. If a sac ruptures, hæmorrhage would follow and the animal would die.

TREATMENT.

When in blood vessels treatment of little avail. In intestines, give ½ dram dose of tartar emetic with 2 drams iron sulphate as powder in food once daily for four to five days. Stop for three days and then resume. Follow up with 1pt. linseed oil. Fowler's solution of arsenic may be given—tablespoonful twice daily in food or water for adult; treat for 10 days. Teaspoonful for foals. Thymol in powder with sugar in 15gr. doses, given sprinkled in food once daily for a week. Foals, give 9grs. to 10grs.

FILARIIDÆ.

Spiropteras.—This is a variety of worm belonging to the group of *Filariidæ*. There are three varieties—*Spiroptera megastoma, Spiroptera microstoma, Spiroptera reticulata.*

The *S. megastoma* is generally found in the stomach of the horse, and cause the formation of fibrous tumours below the lining membrane of the stomach. Occasionally the wall of the stomach becomes eroded, and results in a small rupture. The result of this is a condition of peritonitis and death. The worms are about 18in. long; very thin and spiral shaped. Infection is by the alimentary canal.

S. microstoma is generally found in stomach of horse, but usually only in the surface of the lining and not below.

S. reticulata is occasionally met with in the flexor tendons or suspensory ligaments of the fetlocks, and may cause a parasitic growth.

TREATMENT.

The only advice under this head is to follow the broad lines of preventive treatment already set out for other parasites.

BOTS (*GASTROPHILUS EQUI*).

Under the heading of " Parasites of Farm Animals " it will not be amiss to mention the trouble familiarly spoken of as the " bot fly trouble."

Now the fly responsible for the stomach bot met with in horses, &c., belongs to the order *Gastrophilæ*, and is named *Gastrophilus equi*, whilst the bot in the stomach is the grub or larvæ. Now the common grub is too well known to need any further description beyond referring the reader to the illustration in this article. The only object in dealing with this subject will be to offer a few suggestions as to the best way of dealing with the trouble, more especially from a preventive standpoint. Firstly, the presence of bots in a horse's stomach, providing they are not too numerous, need not cause any special alarm. When they are present in great numbers they may interfere with digestive processes, but as a rule they are apparently productive of little or no inconvenience to the animals.

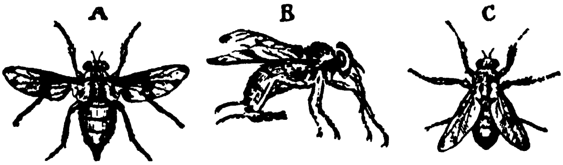

Fig. XIV.—Bot Flies (*Gastrophilus equi*).
A. Female, dorsal view. B. Female, in profile. C. Male, dorsal view.

The method of reaching the stomach is as follows :—The fly deposits her eggs between the months of November and February, generally more plentifully during hot, dry weather than when cold and damp. The eggs are deposited in regions of throat between the jaws, flanks, shoulder, and forearm. They are affixed to hair by a sticky fluid deposited by fly. (The illustration

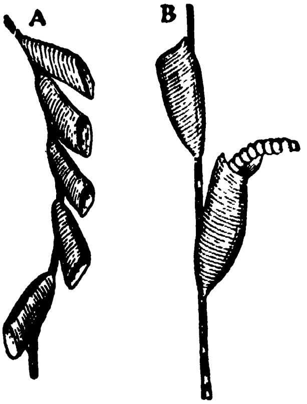

Fig. XV.—Eggs of Bot Fly Deposited on Hairs.
A. Eggs. B. Larvæ just hatching.

depicts the mode of arrangement on hair.) The eggs may reach the stomach by the animal licking, or, a most common way, by means of food. These reach food in manger as result of animal rubbing or scratching the neck on the edge of manger or feed box, the eggs being detached and falling into food. Having reached the stomach, the covering of the egg is dissolved by the action of the stomach juices, and is followed by the liberation of the bot grub. Here the bot attaches itself by means of armed hooklets to the mucous membrane of the stomach. It remains here for several months, to be followed by the next stage of development, namely, the chrysalis, which is ejected with the excreta. The next stage is the evolution of the fly. The fly in turn lays her eggs, and once again the cycle is repeated.

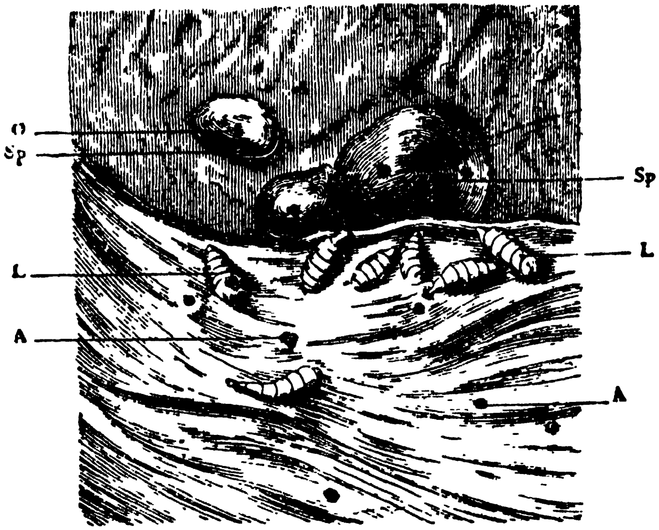

Fig. XIII.—Spiropteral Tumours, caused by Spiropteral Worms; also Larvæ of Bots Attached to Lining Membrane.
Sp. Tumour. L. Larvæ of bots. A. Punctures caused by bots.

TREATMENT—PREVENTIVE.

From the end of September attention should be directed to the animals in order that the special parts referred to shall be the least favorable for the deposition of the eggs by the fly. Firstly, clip the hair as short as possible in the region of throat between the jaws; follow this by singeing. Sponge the throat, shoulder, forearm, and flanks twice daily once before and after work with the following mixture:—Linseed oil (raw), 1pt.; oil of tar, 2ozs. This not only destroys the eggs, but tends to prevent the fly depositing the eggs. Kerosene is often used, but the objection to this is that it tends to irritate the skin, and that it lacks a necessary oily character. Another mixture for smearing is sweet oil, 1pt.; turpentine, 4ozs., or even eucalyptus may be used.

INTERNAL TREATMENT.

Bisulphide of carbon, 1 dram doses given in protective gelatine capsules three times daily before food. To be given two days in succession. Follow up with a pint of linseed oil. Or tartar emetic, ½ dram doses mixed with food three times daily, given for seven days.

GENERAL PRECAUTIONS.

The general cause of parasitic infection is undoubtedly directly traceable to infected pastures and contaminated food and water supplies. Therefore, if any good is to be hoped for in coping with these invasions, combined efforts will have to be directed along the line of purifying and preserving these sources. The land becomes fouled through the droppings from infected animals. The rains following, carry the eggs or larvæ down the watercourse, and so results in fouling the water supply, especially where that supply is from dam or well water.

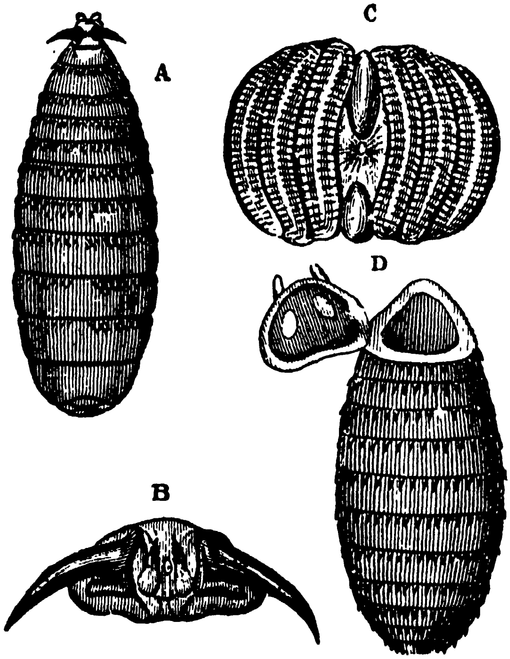

FIG. XVI.—LARVA AND PUPA OF BOT FLY (*Gas. equi*).
A. Larva in third stage. B Showing mouth and hooks. C. Tail stigmatas.
D. Pupa with operculum or lid.

The question is what can we reasonably do with those parts so infected? Parts that we know by experience year after year to carry stock badly infested with one or many varieties of this pest. The first step to be taken must be in the direction of providing a purer water supply, and so thereby reduce the chances of infection by this means.

Much attention is being given to this matter at the present time by Professor Rothera, of the Melbourne University. He recommends the use of chemicals as against filters. Infected or impure water contains a large amount of foreign substance suspended or floating at different degrees of depth. Contained within this suspended matter we find also the eggs of many of the parasites floating. Professor Rothera recommends the adding of certain chemicals to this water, and by the weight and chemical action of combining with these foreign properties to carry them down to the lowest level and beneath the ordinary depth of infection. The means he uses is that of chloride of iron. One pound of chloride of iron to 1,000galls. of the thickest of impure water is sufficient to carry down all the impure mud, &c., 7ft. in one night. The method of using it is to dilute your strong solution of chloride and sprinkle it on the surface of the water. I would suggest the following measures :—

1. Attention to water supply.
2. Cultivation of infected paddocks.
3. Treatment of animal excreta.
4. Periodical medicinal treatment.

1. The fencing of any waterholes and dams would prevent animals puddling and fouling with excreta. The elevation of water to storage tanks by means of pump or mill erected overhead; this can be done at a relatively little cost. Add to this supply chloride of iron in the proportion of 1lb. to 2,000galls. The erection of water tanks to water cattle from. The supply pipe to the trough may very easily be provided with a piece of flannel through which the water might percolate before entering the trough. This could be removed frequently and burnt, in order to destroy any arrested larvæ, &c.

2. Breaking up and turning of infected soil. Dressing with salt and lime. In low-lying land, efficient draining.

3. Treatment of all animal excreta with salt and lime before applying to soil and, in the case of animals reasonably believed to be infected, the total destruction of all manures by burning.

4. Periodical treatment of animals, especially those in suspicious districts with worm-expelling medicines. It is well to remember the young and immature animals are more vulnerable to parasites than are older animals; so it is wise to build up their resisting powers by good feeding, *e.g.*, with lambs it has been found beneficial in New Zealand to feed with ½lb. oats per day, and the results were excellent. It requires a day or two to accustom them to this diet, but afterwards they readily feed on it.

ROSEWORTHY AGRICULTURAL COLLEGE.

Harvest Report, 1913-14.

By Arthur J. Perkins, Principal Roseworthy Agricultural College.

THE WEATHER.

Since I find it my duty to report on the worst harvest I have ever had occasion to handle, and I am given to understand the worst season experienced by the district since the days of its first settlement, it behoves us to scrutinize rather closely the weather conditions mainly responsible for the thwarting of our well-laid plans. By way of preliminary statement I submit below in Table I., month by month, the rainfall registered at the College in 1913, comparatively with the means of the preceding 30 years (1883-1912).

Table I.—*Showing the* 1913 *Rainfall at the Roseworthy Agricultural College comparatively with the Means of the preceding* 30 *Years* (1883-1912).

Months.	1913.	Means of Preceding 29 Years	Months.	1913.	Means of Preceding 29 Years.
	Inches.	Inches.		Inches.	Inches.
January	0·11	0·86	August	1·64	2·09
February	1·94	0·50	September	2·55	1·79
March	1·63	0·88	October	3·89	1·60
April	0·31	1·74	November	1·21	1·04
May	0·31	1·80	December	1·16	0·78
June	0·22	2·65			
July	0·69	1·91	Total	15·66	17·64

Thus, then, 1913 closed with a total rainfall 2in. below the normal mean for the year; and with this total we, as farmers, cannot very well quarrel; but readily admit that 15·66in. of rain, reasonably distributed over the year, offer good solid foundations for heavy cereal crops. It is, therefore, in a careful analysis of the distribution of the yearly rainfall that we shall have to seek for the factors that led to the very low yields that we shall have to put on record.

"Useful" Rain.

In earlier reports I have called "useful" rain, from the point of view of cereal crops in this district, all rain falling between the 1st of April and the 30th of November. The mean "useful" rain for the 30 years extending between 1883 and 1913 is represented on the College Farm by 14·62in.; in 1913, however, it was reduced to 10·82in., i.e., about 4in. below the normal mean. This comparative low "useful" rainfall of 1913 was not as low as that of both 1902 (7·03in.) and 1911 (9·46in.), the two worst years in our 30 years' records; and yet both these years were agriculturally superior in their results to 1913. And it is only in the actual distribution of the "useful" rainfall over the season that we may gain some insight into the causes that have led to the practical failure of cereal crops.

DISTRIBUTION OF "USEFUL" RAINFALL.

Where annual crops are concerned the distribution of rain falling over their period of active growth is of greater importance than the yearly total, or even than that of what we have called "useful" rain. Following the precedent of previous years, I have summarised below in Table II. the distribution of "useful" rain in 1913, comparatively with that of the means of the preceding 30 years.

TABLE II.—*Showing Distribution of "Useful" Rain in* 1913 *comparatively with the Mean Distribution of the previous* 30 *years.*

	1913. Inches.		Means of Previous 30 Years. (1883-1912) Inches.
Seeding rains (April-May)	0·62	..	3·54
Winter rains (June-July)	0·91	..	4·56
Spring rains (August-October)	8·08	..	5·48
Early summer rain (November)	1·21	..	1·04
"Useful" rain (April-November)	10·82	..	14·62

The chief characteristic of 1913, therefore, is from the point of view of cereals in this district, almost complete absence of seeding and winter rains, and copious spring rains. In order to show how anomalous was the 1913 distribution, I append below in Table III. the distribution of useful rain in all years on our records in which the yearly total was below 15in.

TABLE III.—*Showing Distribution of "Useful" Rain in all Years between* 1883 *and* 1914 *in which the Yearly Total was below* 15*in.*

	1885. In.	1888 In.	1891. In.	1895. In.	1896 In.	1897. In.
Seeding rains	2·84	2·45	1·06	4·18	4·50	2·61
Winter rains	3·83	5·14	3·67	4·39	4·38	3·64
Spring rains	3·93	2·99	5·49	3·19	2·35	4·26
Early summer rains	0·11	0·20	1·28	0·15	0·38	0·47

	1899. In.	1902. In.	1904. In.	1911. In.	1912. In.	1913. In.
Seeding rains	2·43	0·28	2·70	2·12	1·10	0·62
Winter rains	2·89	3·55	4·20	3·89	3·55	0·91
Spring rains	3·89	2·92	3·83	3·41	6·56	8·08
Early summer rains	1·44	0·28	0·87	0·04	1·84	1·21

It will be noted, therefore, that if we compare it with our years of lowest rainfall 1913 stands quite alone in the almost complete absence of seeding and winter rains; the shortage of seeding rains in 1891, 1902, and 1912 were in a measure made good by fairly satisfactory winter rains, which was not the case in 1913.

Seeding Rains.

Seeding rains (April-May) may be taken to have been practically nil in 1913; 62 points of rain scattered over nine days are not sufficient at this time of the year to moisten even the surface layers of the soil. Seeding, therefore, took place under dry conditions of soil, and germination remained dependent on the winter rains.

Winter Rains.

Following on an exceptionally dry autumn, the winter rains (June-July) were on the whole insufficient to bring about the satisfactory germination of seed that had been lying in the ground for two or three months. The 91 points of winter rain were distributed over 10 rainy days; the highest aggregate, and, indeed, the only one that can have had any influence on the germination of seed, reached us between July 16th and 20th, when we were vouchsafed 61 points of rain in four days. The net result of these unfavorable seeding and winter conditions was that seed that had been sown in April and May did not show above ground until the month of August. It goes without saying that in these circumstances germination could not but be unsatisfactory and patchy; and the crops eventually very thin and weedy.

There is another important feature connected with late germination which at all times inhibits anything like even mere average yields of corn; and that is the shortening of the growing period of the crops which it usually implies. Thus, in ordinary circumstances, wheats like King's White take about 180 days, or six months, in this district to complete their normal growth; *i.e.*, there elapses between germination and ripeness a period of 180 days, and grain germinating on the 1st of June would in normal circumstances be ripe about the 27th of November. Now the ripening off of the wheat crop is not at all dependent on the date of its germination; but rather it is a direct factor of climatic conditions obtaining in the early summer. And however late it may have germinated, the wheat crop will ripen off so soon as hot and dry weather conditions begin to set in. Now, with crops germinating, say, on August the 1st, there will only be 122 days of growth to the 30th of November, a time when they generally begin to ripen off. And experience is there to show that whenever the growth and ripening off of a crop is hurried over a relatively short period of time, the resulting grain yields are invariably low and of inferior quality.

SPRING RAINS.

With August a change for the better began to set in; although the rainfall for this month—1·64in.—still continued below the normal mean. September, and particularly October, however, proved to be exceptionally wet months, and notwithstanding a late germination, our general harvest prospects took on a more rosy outlook. Unfortunately, we were to experience the disadvantages, as well as the advantages, of a quite exceptional spring. The heavy spring rains, coupled with seasonably warm growing weather, led to somewhat weak sappy growth in the cereals that had germinated too late to have become hardened by winter low temperatures; and in this condition they were more or less helpless when suddenly beset by fierce November heat. The crops practically withered away at sight; nor was this all. The damp spring weather brought upon us such an attack of red rust as had not been seen for over 20 years, in this district at all events. If there was one thing this visitation did well, it was to settle once and for all the credentials of many a so-called rust-resistant variety. In the long run there were but few varieties on the College Farm that did not suffer more or less severely from the attacks of the disease. I do not propose going into details on this subject in this report, as I anticipate dealing with the subject of rust resistance in the light of 1913 experience in a later report. It will suffice for the present if I state that crops that had at one time looked quite promising, shrivelled away before the combined attacks of red rust and fierce heat, and resulted in the end in yields that were quite deplorable. As to the character of the sample, it may perhaps be left to the imagination; as a clue thereto I might add that we were favored with the unusual experience at harvest time of seeing bags of wheat weighing lighter than bags of barley.

FALLOW RAINS.

In preceding reports I have called "fallow rains" rain reaching land lying out as bare fallow between August 1st of one year and March 31st of the year of seeding. In this connection the "fallow rains" immediately preceding the 1913-14 season were represented by 13in. against a normal mean of 9·54in. (1883-1912). It is often put forward, and apparently with good cause, that one of the chief advantages of the practice of bare fallow before wheat lay in the fact that it led to the storing up in well-tilled land of portion of the rainfall reaching the latter between the dates indicated. We might have expected, therefore, that the unusually heavy fallow rains above indicated would have shown up to particular advantage in a comparatively dry season like 1913-14. We shall have occasion to see that in this instance facts do not bear us out in these expectations; and yet, never in my recollection have our fallows been earlier or more thoroughly tilled than was the case in 1912-13. We must conclude, therefore, that heavy fallow rains and good tillage are more or less impotent for good in the face of an almost total absence of seeding and winter rains

Ensilage Crops.

If there is one type of crop that needs to be heavy, if it is to be at all advantageous, it is an ensilage crop. Unfortunately, under conditions that have already been described, it became abundantly evident quite early in the season that we should have no heavy rank-growing crop of any kind, and consequently no ensilage worth cutting. But with a dairy herd on our hands, to us in this district ensilage is practically indispensable between January and the first appearance of the new season's grass. Our pits, therefore, had to be filled in the best conditions that the season permitted of, and from the sources that appeared the least unpromising. We first turned our attention to some irregularly-grown portion of a wheat crop in the field known as "Daly's." Here we cut out 12·555 acres, which yielded 3 tons 5cwts. 45lbs. of greenstuff to the acre. Next, from a very weedy portion of a wheat crop in "Flett's" we secured only 1 ton 9cwts. 109lbs. to the acre from 7·256 acres.

On August the 1st we had sown in Dahlitz 41·8 acres to Early Dun peas at the rate of 75lbs. to the acre. The plants did not show regularly above the ground until the middle of August. This field had carried wheat in the preceding season. The general growth of the crop was not very satisfactory; but since we were in urgent need of greenstuff for ensilage purposes, and had already proved the great value of peas in this direction in the preceding season, we decided to cut out this field for ensilage. This was done between November 8th and 19th, which gave to the peas barely three months of growth. The crop was thin and not at all rankly grown, hence the yield of greenstuff was very much below our usual experience. The yield to the acre ultimately proved to be 1 ton 10cwts. 76lbs.

Thus, in sum total we secured 115 tons 14cwts. 24lbs. of greenstuff from 61·511 acres, representing a general average of 1 ton 17cwts. 70lbs.; and the complete filling up of the ensilage pits was left to summer-grown sorghum. How disappointingly low is such a yield will be gathered by a reference to Table IV., in which is indicated the 1913 yield comparatively with those of the previous eight years.

Table IV.—*Showing Average Yields of Ensilage Crops*, 1905-1913.

Season.	Rainfall.		Yields per Acre.		
	"Useful." Inches.	Total. Inches.	Tons	cwts.	lbs.
1905	14·23	16·71	8	10	0
1906	16·30	19·72	11	18	0
1907	13·81	15·06	5	7	34
1908	15·53	17·74	7	12	44
1909	21·15	23·05	10	0	3
1910	16·79	23·87	8	15	32
1911	9·46	13·69	4	19	47
1912	13·05	14·97	3	9	45
1913	10·82	15·66	1	17	70
Average yield of nine years			6	18	93

HAY CROPS.

If we had difficulty in finding material to fill our ensilage pits, even greater difficulties awaited us when we were set the problem of making a provision of hay adequate to our normal requirements. As a rule, in order to find myself in a position to meet the emergencies of a bad season, I like to see at least 300 tons of hay stacked away for future use. In 1912, with over 432 tons of hay on hand, I thought that I had made ample provision for the worst possible of seasons. Indeed, I confidently anticipated that we should have been able to meet the new season with fully 100 tons of old hay on hand, instead of which there was not a sheaf of hay over when hay-carting was first put in hand. And where the hay for the new year was to come from, unless the whole of our crops were cut down for this purpose, it was difficult to see. Eventually I decided to cut about 200 tons, and to trust to sorghum hay for later requirements. Unfortunately it has to be stated now that the sorghum crops of the season were exceedingly poor, and we are certainly not in a position to meet another season like 1913.

As we certainly had no crops that could be called good hay crops, I decided to cut out those that appeared least promising for wheat; and as in the course of time red rust spread most insidiously, I adhered rigorously to the plan originally determined upon. And with the miserable yields that ultimately awaited us, it is a matter of regret that, apart from seed and feeding requirements, every field on the farm was not cut out for hay.

The crops cut for hay are referred to below under each field from which they proceeded.

FIELD NO. 9.

I summarise the past history of this field below:—1898, bare fallow; 1899, wheat; 1900-03, pasture; 1904, sorghum and millet; 1905, barley; 1906-09, pasture; 1910, maize; 1911, wheat and oats; 1912, barley; and 1913, peas and wheat.

It will be seen, therefore, that the 1913 crop was the fourth successive crop carried by this field in four years. The season cannot be said to have been too propitious for a crop of this kind; nevertheless, as we shall have occasion to see, it yielded quite as well as other hay crops sown on bare fallow.

The barley stubble of 1912 was broken up in June, 1913, and on the 26th of the same month was drilled over with 100lbs. of Early Dun peas and 1cwt. of superphosphate to the acre. Immediately afterwards 100lbs. of King's Early were broadcasted over the field. The field was subsequently rolled and harrowed. I may state here that the quantity of wheat broadcasted was exactly double what I intended. As matters turned out, however, germination was so unsatisfactory in this field that the heavier seeding gave rise to more satisfactory results than would otherwise have been the case.

This crop was originally intended for ensilage purposes. Although thin, it was so clean and well grown that I decided eventually to cut it for hay. It yielded 15cwts. 15lbs. per acre of very good hay.

FIELD NO. 6D.

The past history of this field is given below in summarised form :—1895, oats ; 1896, peas ; 1897, wheat ; 1898, pasture ; 1899, bare fallow ; 1900, wheat ; 1901, pasture ; 1902, bare fallow ; 1903, wheat ; 1904-05, pasture ; 1906, bare fallow ; 1907, wheat ; 1908-10, pasture ; 1911, bare fallow ; 1912, wheat, oats, and beans ; and 1913, wheat.

Here again, then, we have a wheat crop following another wheat crop ; and it must be stated that the yield, although low, compares favorably with that of other hay crops raised on fallow land. The stubbles of the preceding season were broken up with a disc plough in February, 1913, the field was rolled and cultivated in March, and between March 29th and April 1st drilled over with superphosphate at the rate of 275lbs. to the acre. Between April 30th and May 1st King's White wheat was broadcasted over this field at the rate of 155lbs. to the acre. The seed was cultivated in, and the field subsequently harrowed. On May 5th lucerne seed was broadcasted over the field at the rate of 12lbs. to the acre, and rolled in on the day following. The crop was always intended for hay. Like all our crops, however, it turned out very thin and light, the yield being represented by 11cwts. 74lbs. per acre. It may be stated that the lucerne made very good growth and may be depended upon to give very good pasture for the next three years.

FIELD NO. 7B.

The past history of this field may be summarised as follows :—1897, pasture ; 1898, wheat ; 1899, pasture ; 1900, oats ; 1901, pasture ; 1902, oats ; 1903, pasture ; 1904, bare fallow ; 1905, wheat and oats ; 1906, crimson clover ; 1907, pasture ; 1908, maize and sorghum ; 1909, barley ; 1910, maize and sorghum ; 1911, wheat and oats ; 1912, peas ; 1913, wheat and oats.

This field has been continuously under crop ever since 1907, *i.e.*, for a period of seven years ; and in the course of 17 years it has been treated as bare fallow only on one occasion, and that in 1904. The pea stubbles, after having been grazed over with sheep, were broken up with a disc plough in February, 1913, and subsequently rolled and cultivated. Towards the end of March the field was drilled over with superphosphate at the rate of 255lbs. to the acre, and on April 29th it was broadcasted with a mixture of 60lbs. of Calcutta oats and 90lbs. of White Tuscan wheat to the acre. From May 3rd to 5th the field was harrowed, and subsequently broadcasted with 12lbs. of lucerne seed to the acre, which was rolled in. The early growth of this crop was exceedingly poor ; it recovered somewhat, however, towards the end of the season. This field yielded eventually 17cwts. 90lbs. to the acre of very fair hay.

FIELD No. 6C.

The past history of this field may be summarised as follows :—1895, oats ; 1896, peas ; 1897, wheat ; 1898, pasture ; 1899, bare fallow ; 1900, wheat ; 1901, pasture ; 1902, bare fallow ; 1903, wheat ; 1904-05, pasture ; 1906, bare fallow ; 1907, barley ; 1908, pasture ; 1909, bare fallow ; 1910, wheat, oats, and rye ; 1911, kale and rape ; 1912, bare fallow ; 1913, oats.

This field, which was treated as bare fallow in 1912, was drilled over with superphosphate at the rate of 2cwts. to the acre in March, 1913. On April 27th and 28th Calcutta oats were broadcasted over it at the rate of 80lbs. to the acre ; the field was subsequently cultivated, harrowed, and rolled. Lucerne seed was broadcasted over at the rate of 12lbs. to the acre between May 8th and 10th, and subsequently rolled in.

The oats did not show above ground until August, and the early growth of the crop was exceedingly poor ; so much so that at one time I contemplated using the field for grazing purposes. It improved somewhat later on, and eventually it was cut for hay rather on the ripe side. The yield proved to be 15cwts. 48lbs. to the acre ; no better, it will be noted, than the yields of the other fields already quoted which had not been preceded by bare fallow.

" FLETT'S.

This is a field about 175 acres in area, about 33 acres of the worst grown crops of which were cut out for hay. The balance of the field carried special wheat and barley crops, and the previous history of the field will be indicated under a later heading. It will be sufficient to state here that the field had carried wheat, barley, and rye in 1911, and had been treated as bare fallow in 1912.

The hay yield in this field was 1 ton 0cwt. 89lbs. to the acre ; the heaviest hay yield we are able to boast of in 1913.

" DALY'S."

This field, too, about 150 acres in area, was under various varieties of wheat, close on 92 acres of which were cut out for hay, chiefly because of the progress of red rust. This field came into our hands in 1912, and was fallowed by us for the first time in July of the same year. The portion of the field cut out for hay yielded 16cwts. 4lbs. to the acre.

" EBSARY'S B."

Of this field, about 73 acres in area, 38 odd acres were cut out for hay, the balance of the field was left under various varieties of wheat. It will be sufficient to state here that whilst this field carried wheat and barley in 1911, it was treated as bare fallow in 1912. The hay yield turned out to be 17cwts. 90lbs. to the acre.

GENERAL AVERAGE HAY YIELD IN 1913.

Eventually we took 207 tons 7cwts. 111lbs. of hay from 258·185 acres; this works out to a general hay average for the year of 16cwts. 7lbs. to the acre, by far the lowest average that we have ever had to place on our records. I have summarised below the recorded averages of preceding years.

TABLE V.—*Showing average Hay Yields on the College Farm*, 1904-13.

Season.	Rainfall. "Useful." Inches.	Rainfall. Total. Inches.	Area. Acres.	Average Yield per Acre. Tons	cwts.	lbs.
1904	11·60	14·70	93·0	2	11	22

General average of 10 years				2	3	38

BARLEY CROPS.

In 1913 we had 31 acres under barley sown on bare fallow, and 60 acres of barley sown on the stubbles of a 1912 wheat crop; and, as will be seen in the sequel, this is the first season in our experience in which barley did not do tolerably well as a second crop.

FIELD EBSARY'S A.

The past history of this field may be summarised as follows:—1904, wheat; 1905, pasture; 1906, bare fallow; 1907, barley; 1908-10, pasture; 1911, bare fallow; 1912, wheat, barley, and rye; 1913, barley.

The 1912 stubbles were broken up in February and March, 1913, with a stump-jump plough, and the field was subsequently rolled and cultivated. On May 6th and 7th an area of 20·65 acres was sown to Roseworthy Oregon barley at the rate of 70lbs. of seed to the acre and 2cwts. of superphosphate. This plot yielded 8bush. 8lbs. to the acre.

Immediately after the preceding plot, 33·47 acres were sown to Short Head barley of the 6th selection, at the same rate of seeding and manure. The yield of this plot was 6bush. 39lbs. to the acre.

These results, of course, are very unsatisfactory. It can be said that the season was wholly against a second crop of the sort; indeed, the barley can be said never to have got a start until October, when it was too late to make up for lost time.

FIELD "FLETT'S."

This large field was mostly under various varieties of wheat, and its past history will be indicated when dealing with the latter. It will be sufficient to state here that the field was under wheat in 1911, and treated as bare fallow in 1912. About 31 acres were sown to various varieties of barley in the first week of May. Full details concerning the latter are shown below in Table VI.

TABLE VI.—*Showing Details concerning Six-Row Barleys sown in "Flett's."*

Variety.	Selection.	Date Sown.	Germinated.	Area. Acres.	Yield per Acre. Bush.	lbs.
Square Head	8th	May 8	July 28	2·688	20	15
Roseworthy Oregon	5th	May 7–8	?	9·442	27	38
Roseworthy Oregon	6th	May 8	July 28	5·571	22	8
Short Head	6th	May 7	?	7·711	18	18
Short Head	7th	May 7	July 29	5·545	19	28
Albert	1st	May 1	July 29	0·107	16	32
Total				31·064	22	14

In ordinary seasons it has been our general experience that barley crops sown after bare fallow make far too rank growth for heavy grain yields. In a season such as this, however, the results have proved satisfactory, and it may be pointed out that had the College Farm been one worked purely for monetary profit, barley crops would have proved far more profitable in a season such as this than wheat crops.

GENERAL AVERAGE BARLEY YIELDS IN 1913.

Including the plots of the Permanent Experiment Field, we reaped 1,128bush. 30lbs. of barley from 91·093 acres, which represents an average yield for the year of 12bush. 19lbs. to the acre, by far the lowest average yield on our records. I append below in Table VII. a statement showing the average barley yields on the College Farm since 1904.

TABLE VII.—*Showing General Average Barley Yields on College Farm,* 1904-13.

Season.	Rainfall.		Area.	Yields per Acre.	
	"Useful." Inches.	Total. Inches.	Acres.	Bush.	lbs.

Mean of 10 years				32	32

OAT CROPS.

Our chief oat crop was sown in Field No. 6c, and, as has already been stated, was cut for hay. In "Flett's" we had two small plots—0·801 and 0·525 acres respectively—of Scotch Grey oats, the yields of which were 28bush.

26lbs. and 25bush. 34lbs. to the acre. On the other hand, the two-acre plot of Calcutta oats in the Permanent Experiment Field, grown in continuous rotation, yielded only 1bush. 21lbs. These few data represent a yield of 11bush. 36lbs. from 3·326 acres.

Below, in Table VIII., I have indicated the yields of preceding years of which we have any record.

Table VIII.—*Showing Average Yields of Oats on the College Farm*, 1905-13.

Season.	Rainfall.		Area Sown.	Yield per Acre.	
	"Useful." Inches.	Total. Inches	Acres.	Bush.	lbs.
1905	14·23	16·71	20·00	43	10

Average of eight years (omitting 1907)				27	39

RYE CROPS.

As has been the case since 1909, we had a few acres under four varieties of ryes originally imported from France. The ryes were sown in "Flett's." Details concerning these crops are shown below in Table IX.

Table IX.—*Showing Details of Rye Crops sown in "Flett's" in* 1913.

(*To be continued.*)

DEPARTMENT OF AGRICULTURE.—FARMERS' EXPERIMENTS.

TESTS OF MANURES.

Conducted by Mr. F. Coleman, Saddleworth.

During the last nine years Mr. Coleman has very carefully conducted tests of the effect of different manures on his farm. The results, from year to year, prove interesting, and the value of the work increases with the extension of the period of test. The plots, 16 in number, are each one half-acre in extent, and eight of them are cropped each year, the other eight being carefully fallowed, so that the land carries wheat after fallow each alternate year.

Mr. Coleman reports that "though sown in May, the seed did not germinate till July. The late start and subsequent rapid growth in October rendered the soft, sappy plant subject to red rust, which affected it a good deal, and no doubt rendered it less able to stand the hot days at the end of November, the wheat drying rather than ripening. Screenings were exceptionally large, each half-acre averaging over 2bush., compared with 20lbs. each last year. Plot No. 5 yielded nearly half of the total as screenings, and was a very poor sample."

Plot No. 7, which from 1905 to 1911 inclusive, had received ½cwt. sulphate of potash and ½cwt. nitrate of soda per acre, was in 1912 and 1913 dressed with 2cwts. of superphosphate, which dressing will in future years be continued. It is well to point out that as the plots are fallowed each alternate year, the 1912 and 1913 dressings constituted in each year the first application of phosphates for the period during which these tests have been conducted.

Manurial Tests, Saddleworth.

Sown May 27th, 1913. Harvested December 16th, 1913. Rainfall, May 27th, 1913, to December 16th, 1913, 10·38in.

TESTS OF VARIETIES OF WHEAT FOR GRAIN AND HAY AT ALDINGA.

These tests were conducted by Mr. Pengilly on his farm.

The land had been carefully and thoroughly fallowed, and the crop was dressed with 2cwts. of superphosphate per acre. Each plot was 2 acres in extent, and one-half of each plot was cut for hay. The following are the results for 1913 :—

Table 5.

CARRYING CAPACITY OF DIFFERENT FORAGE CROPS.

FEEDING-OFF TESTS.

Each plot 2 acres in extent, and manured with 1¾cwts. superphosphate per acre.

Table 6.

Natural Grass Plot.—63 sheep 7 days ; 157 sheep, 14 days ; 157 sheep, 3 days ; equivalent to 10·22 sheep per acre for five months in spring and early summer.

Italian Rye Grass.—100 sheep, 14 days; 157 sheep, 14 days; 157 sheep, 3 days; 157 sheep, 3 days; equivalent to 14·92 sheep per acre for five months in spring and early summer.

Calcutta Oats.—110 sheep, 14 days; 157 sheep, 14 days; 157 sheep, 5 days; equivalent to 14·85 sheep per acre for five months in spring and early summer.

Peas—157 sheep, 18 days; 24 sheep, 11 days; equivalent to 10·15 sheep per acre for five months in spring and early summer.

Barley.—100 sheep, 14 days, 157 sheep, 14 days; 157 sheep, 5 days; equivalent to 14·4 sheep per acre for five months in spring and early summer.

Mustard and Rape.—51 sheep, 9 days; 70 sheep, 7 days; 100 sheep, 14 days; 157 sheep, 7 days; 157 sheep, 3 days; 100 sheep, 2 days; equivalent to 13·53 sheep per acre for five months in spring and early summer.

The plots are each enclosed with permanent fences. The natural grass plot is top-dressed each year with the same quantity of manure per acre as is applied to the cultivated plots.

These cultivated plots are rotated from year to year, manured each year, and grazed.

The quantity of seed used per acre for these respective forages was as follows:—Italian rye grass, 30lbs. per acre; Cape barley, 1½bush. per acre; oats, Calcutta, 1½bush. per acre; peas, 2bush. per acre. Seeds, such as Italian rye grass, rape, and white mustard, not being hitherto in much demand, are quoted by seedsmen at special prices, but if the extension of the cultivation of these forages became general, it would no doubt follow that the seed could be obtained here much cheaper, as obtains elsewhere. The prices might be expected to rule somewhat as follows:—Rape, 4½d. per pound; white mustard, 4d. per pound; Italian rye grass, 4d. per pound.

It will be noted that the grazing capacity would be considerably lower if a certain smaller number of sheep were turned on to the plots and kept there for anything like the period indicated, as the land would become sheep foul, and much of the feed would be trodden down. It is of great advantage in favor of higher results that the sheep are turned into these two-acre plots as each grazing becomes ready, and taken out immediately that it is fed, in order that the forage may grow again.

Table 7.—Grazing Equivalent of the Different Forages in Number of Sheep per Acre for Five Months in Spring for Three Years, as follows:—

	1911.	1912.	1913.
Grass and herbage uncultivated, but dressed with artificial manures	9·33	6·55	10·22
Italian rye grass	8·80	8·16	14·92
Oats	9·40	7·36	14·85
Peas	5·20	8·11	10·15
Barley	10·46	8·53	14·40
Mustard and rape	8·80	8·76	13·53

POULTRY NOTES.

By D. F. **Laurie**, Government Poultry Expert and Lecturer.

Early Greenfood.

March is a good time to prepare the ground for early crops of greenfood. The first to be sown should be berseem, the Alexandria or Egyptian clover. This valuable fodder has given remarkable results at Roseworthy College, and Professor Perkins recommends sowing in March, while the ground is warm, and flooding till the wet weather commences. Several breeders have grown berseem and find it much liked by poultry. Sow seed at the rate of 30lbs. to an acre. Following on berseem one may sow seeds of the three kails for transplanting later on, also silver beet. Lucerne may be sown in April, also barley, rye, and oats for greenfood. Small areas of well-prepared liberally manured soil will, if well watered, supply more and better greenfood than much larger areas not so well attended to.

The Breeding Stock.

Up-to-date market breeders already report successful hatchings of chickens. No time should be lost in overhauling the breeding stock and selecting for breeding—(1) Those hens still in full feather and which have not ceased laying. (2) Those which have moulted and are likely to lay soon. Leghorns and Wyandottes may be generally relied upon for successful autumn hatchings, and many good lots of Rocks and Orpingtons have been seen.

Eggs.

The warm weather may last six or more weeks, and unless eggs for market are infertile there are the usual risks. Farmers, especially, can do much to improve the conditions of the Adelaide egg market by adopting modern methods and keeping all male birds away from the flocks of layers. The price is steadily rising, and of all times one cannot now afford to risk eggs. We have recently seen the mammoth *Australia*—the great war ship of 19,000 tons—at anchor where the old *Buffalo*, the 600-ton warship, lay when this State was proclaimed. Just as much difference as is between the ancient and the modern ship is also between the old style (and one might also say ancient eggs) and the new methods demanding fresh infertile eggs. All producers should progress and take pride in the fine quality of their produce.

CLEAR OFF USELESS STOCK.

Get rid of all useless and inferior stock; it does not pay to keep. If you have no good stock, lose no time in obtaining some. There is plenty of reliable stock, and good breeders are legion. Do not buy the cheap and nasty—for good reliable stock you must pay a fair price.

INCUBATION.

It is essential to success that successive batches should be hatched within a given time. You cannot afford to depend upon hens; so many rarely go broody until the hatching season is drawing to a close. Modern incubators are reliable and easily managed. Lose no time in ordering one. Later on the makers will be rushed with orders and you may have to wait. Buy honest machines from a reputable maker; beware of so-called "gift" machines. No one can afford to sell a good incubator for the price of a jam box.

POULTRY TICK.

Poultry owners are not doing their best to eradicate this terrible pest. If you do not know how to deal with them write for a bulletin, which can be had gratis.

ANNUAL REPORT.

Last year's annual report of the Poultry Expert is now available, and can be had gratis on application. There is much in this report that will interest you.

TO BREED LAYERS.

To properly breed layers you must single test your hens before breeding from them. You can obtain free a bulletin from the Poultry Expert giving full particulars of how to proceed. Plans of the yards and houses are included.

D. F. LAURIE, Poultry Expert.

PARAFIELD EGG-LAYING COMPETITION.

REPORT FOR FEBRUARY, 1914.

Health.—The general health of the birds has been good, although the sudden changes in temperature which have been experienced might have produced ill effects. This is an important consideration, as the birds are now in a general and seasonable moult. There were 15 deaths; six were due to heat, others to various causes.

Weather.—The weather has been very trying; temperatures ranged from 80° to 112° in 24 hours, and then a drop to 90°. These sudden changes have a bad effect on the birds. The month has been a very dry one; on the 7th, 15 points of rain were recorded. There has been a lot of wind, chiefly from the north.

Moulting.—Moulting is general, but more erratic than usual. In the various pens some birds are almost through, and others have barely started.

Broodiness.—Section 1, 20; Section 2, 34; Section 3, 6. Total for the month, 60. There has been an unusual amount of broodiness among Leghorns this year.

Egg Production.—Owing to the general moult there has been a considerable falling off. The totals show 4,656 less eggs than were recorded for January. Unless there is a decided improvement during March the averages, which were so good, will not be maintained. There are no champion pens, and very few have any staying powers.

Visitors.—Fifty-four visitors inspected the Station during the month.

D. F. LAURIE, Poultry Expert and Lecturer.

ADVISORY BOARD OF AGRICULTURE.

A meeting of the Advisory Board was held on January 14th, there being present Messrs. G. R. Laffer, M.P. (Chairman), C. J. Valentine, C. J. Tuckwell, T. H. Williams, C. E. Birks, J. Miller, F. Coleman, A. M. Dawkins, Col. J. Rowell, C.B., Professors Lowrie and Perkins, and the Secretary (G. G. Nicholls).

Publication of Veterinary Lectures.—A report was received from the Minister to the effect that it would be preferable to have articles from the Veterinary Lecturer printed in the *Journal* and issued later as bulletins, rather than to attempt to print the whole course of lectures. The lectures were varied according to local conditions and were not so suitable for printing in book form. Matter agreed to.

Proposed Duty on Super.—The Stockport and Narrung Branches drew attention to the proposal made in another State that an import duty should be imposed upon chemical manures, and asked that action to prevent such might be taken. After discussion the following resolution was carried, on the motion of Col. Rowell, seconded by Mr. Dawkins, viz.:—"That, as representative of the producers of this State, the Board is strongly opposed to any import duty on super., and draws attention to past resolutions of the Agricultural Bureau Congress and of the Board on this subject." It was then resolved that the Minister should be asked to take action, and the Secretary was instructed to confer with the Minister in respect to the circulation of forms for a petition of protest.

Wind Breaks and Shelter.—This matter was brought under the notice of the Board in a letter from Mr. Josiah Bonnin, who urged the need for action in the country between the main railway line and the River Murray, to avoid drifting of land in future years and to provide adequate shelter for stock, which would undoubtedly be carried in that country before long. It was decided to ask the Branches in that district to discuss the matter and to refer it to the next conference of the Pinnaroo district.

Life Member.—Mr. H. A. Davis, of Riverton Branch, was appointed a Life Member of the Bureau.

New Members.—The following gentlemen were approved as members of the Branches shown :—Renmark—D. D. Price, W. R. Woodham, W. Cuttle ; Berri—A. G. Hardwicke, J. Ferme ; Cherry Gardens—J. Flatman ; Lyndoch —F. Moore, L. Moore, S. Martin, A. Alexander ; North Bundaleer—A. L. Steele ; Myponga—H. Bartle, C. Muller ; Kalangadoo—D. E. Ellison ; Hartley—P. J. Clark ; Mount Barker—G. Craig, G. R. Rouse, J. E. Bruce, J. W. Brinkley, F. W. Smith, F. J. Paltridge ; Lameroo—W. Campbell, O. Meyer ; Tarcowie—A. W. Muller, T. H. Stagg, H. Edwards ; Riverton— F. K. L. Gray, H. Davis ; Mount Gambier—A. A. Kilsby, A. Manser, W. A. Palamountain.

FEBRUARY MEETING.

At the meeting held on the 11th February there were present Messrs. F. Coleman (Vice-Chairman), C. J. Valentine, C. J. Tuckwell, J. Miller, and A. M. Dawkins, Professor Perkins, Col. Rowell, and the Secretary.

Import Duty on Super.—The Secretary reported that forms for a petition had been supplied to the Bureau Branches. The Board appointed Messrs. Coleman and Dawkins to appear before the Commission, and suggested that the Director of Agriculture (Professor Lowrie) should be called to give evidence if possible.

Experimental Farms.—A report was received from the Director of Agriculture in respect to a request from the Penola Branch for an experimental farm in the drainage area, South-East. It was decided to inform the Branch that the Board could not see its way to support the request.

Export of Small and Unsound Fruit.—In respect to this matter, brought forward by the Forest Range Branch, it was decided to send with the Board's indorsement the following report, submitted by the Chairman and Col. Rowell, *i.e.* :—" The Fruitgrowers' Conference held in Adelaide in October considered it inadvisable to move in this matter. We agree that small, unsound fruit is not only a bad advertisement, but, in some instances, detrimental to the business ; but if any alteration were made we would rather that inspectors should be given power to reject immature fruit, as complaints come back every year in this respect from London. We think the co-operative packing centres are going to put the shipment of fruit on a much better basis, and they are coming fast. It is not so much a question of the size as of grading, thus securing uniformity of size and quality. The market for Tasmanian apples is just as good for small grades, for which there is a demand, provided they are uniform. To say that no apples under 2¼in. or 2½in. should be shipped in a year when the fruit, through climatic conditions, fails to come up to the usual standard, would result in the growers having to pay dead freight for much of the space previously ordered. Inasmuch as unsound fruit means diseased fruit, a good deal of dead freight would have to be faced this season, in which fusicladium is rampant throughout the hills districts, as in some gardens it would be almost impossible to get clean fruit, especially Cleopatras. Really, we consider the matter should be left alone."

Marine Fibre for Cornsacks.—Following on a suggestion from the Kadina Branch, the Secretary was requested to secure information as to the practicability or otherwise of utilising the marine fibre, such as is found at Port Broughton, for the manufacture of cornsacks.

Berseem at Roseworthy.—Professor Perkins placed before members the appended tables showing the results obtained from the two berseem (*Trifolium alexandrinum*) plots at Roseworthy College during 1913 :—

Plot I—1·336 Acres.

Cuts.	Total Greenstuff.			Greenstuff per Acre.		
	Tons	cwts.	lbs.	Tons	cwts.	lbs.
July 7th to 15th	4	17	16	3	12	80
August 21st to September 20th	15	18	19	11	18	17
October 10th to 23rd	14	3	16	10	11	105
November 14th to 28th	11	9	12	8	11	55
December 18th to 21st	2	13	64	2	0	11
Total cut	49	1	15	36	14	44

This plot was sown on March 27th. Watering was begun on April 16th. The plot was watered from June 25th to 30th, and watered between each cut with sprinklers. After the cuts had been taken off the plot carried 20 sheep for six days.

Plot G—1·865 Acres.

Cuts.	Total Greenstuff.			Greenstuff per Acre.		
	Tons	cwts.	lbs.	Tons	cwts.	lbs.
June 2nd to 17th	9	6	83	5	0	14
July 21st to August 4th	8	8	34	4	10	27
September 21st to October 10th	17	11	56	9	8	53
October 23rd to November 8th	15	8	29	8	5	32
November 28th to December 11th	9	3	104	4	18	70
Total cut	59	18	82	32	2	84

This plot was sown on March 27th, and watering was commenced on April 1st. The plot was watered between each cut with sprinklers, and, after the cuts had been made, it carried 37 sheep for seven days and 41 sheep for four days. Professor Perkins pointed out whereas the former plot had kept the dairy herd, of between 25 and 30 cows, going for from 12 days to a fortnight, the same area under lucerne had lasted only about three days. He was perfectly satisfied that four acres of berseem would keep the herd going continuously. There were very few crops, indeed, that would give 36 tons of green feed to the acre, and had plot G been better prepared the yield would undoubtedly have exceeded the 32 tons. The seeding was at the rate of 30lbs. to the acre. Fairly heavy soil was the most suitable for the clover. The seed must be sown while the ground was warm, and the plants must be showing above ground the first week in April, preferably a little earlier. Cutting should be started (under favorable conditions in about eight weeks) when the fodder was about 16in. high, and after that it could be cut regularly. He was surprised that the berseem had not succeeded better on the Murray swamps, and had suspicions that it had not received a fair chance. Personally he would not think of trying to go through a winter without it. At present, unfortunately, one of the difficulties in the way of it becoming anything like so popular as it should be was the exorbitant charge of 1s. 6d. a pound made for the seed locally. He imported his seed direct, and had it delivered at the College at under 4d. a pound.

Pigs at the Royal Show.—Professor Perkins suggested that the council of the Royal Agricultural Society should be approached with a view of securing an alteration in the schedule of prizes for pigs at the September show. He said prizes now offered were for aged and one-year boars, but in the case of sows for aged animals only. He submitted that prizes should also be awarded for one-year-old sows. The Board decided to bring the matter under the notice of the society.

New Branches.—Approval was given to the formation of new Branches, as under :—Laura—Messrs. E. G. Blesing, J. Sibly, sen., H. Hollis, G. Bundey, T. A. Sandow, R. Cleggett, sen., R. Cleggett, jun., J. H. G. Rohrlach, F. de Silver, H. Rohrlach, H. Sloan, C. Walter, J. P. Walter, W. Wilson, W. H. Campbell, R. Lines, C. Felstead, T. Hincks, A. W. Adams, J. F. Roennfeldt, W. Stevens, F. L. Bundey, W. G. Pledge, P. T. Bowker, G. E. Cleggett, J. H. Cleggett, R. J. Rose ; Mantung—Messrs. L. J. Pearce, J. P. Tonkin, F. W. Lehmann, W. Stewart, A. H. Stewart, A. E. A. Tonkin, E. Hannaford, G. N. Baker, E. Nobes.

New Members.—The following new members were approved, viz. :—Myponga—E. Baxter, J. Grant ; Two Wells—P. McLouchney ; Kadina—R. Truscott ; Woodside—P. J. Jackett, C. L. Palm ; Redhill—A. R. Barrett ; Narrung—C. Burnside, A. Allan ; Utera Plains—H. Braunack ; Keith—W. J. E. West ; Meadows—N. Masters, A. E. Maidment ; Clare—R. Hill ; North Booborowie—F. E. Waddy ; Blackwood—E. Conlon, H. James ; Quorn—J. E. Snell ; Port Broughton—J. J. Vanstone ; Kadina—M. Quinn, T. E. Ashton ; Mallala—H. Jury.

THE AGRICULTURAL BUREAU.

CONFERENCE OF NORTHERN BRANCHES.

The Annual Conference of Northern Branches of the Agricultural Bureau was held at Gladstone on Thursday, 19th instant.

The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), Professor Lowrie (Director of Agriculture), Mr. F. E. Place, B.V.Sc., M.R.C.V.S. (Government Veterinary Lecturer), and Mr. P. H. Suter (Dairy Expert), represented the Department of Agriculture, together with Messrs. F. Coleman, Geo. Jeffrey (Advisory Board), and G. G. Nicholls (Secretary). The undermentioned delegates attended on behalf of the following branches :—Beetaloo Valley—J. Joyce ; Belalie North—F. D. Bladon, A. H. Warner ; Blyth—A. L. McEwin ; Booleroo Centre—J. M. Carey, W. G. Whibley, N. L. Brooks ; Crystal Brook—W. W. Lovelock, W. W. Robinson, G. Sargent, T. L. Kelly, H. Billinghurst ; Freeling—A. J. Kuhlmann, E. Morris ; Georgetown—J. Higgins, W. B. Sanders, R. King, M. Bond, S. Eyre, E. J. Tucker, A. F. Thomson, J. Wyatt, G. Hill, J. Bond ; Gladstone—J. Growden, W. H. Brayley, K. S. Wilcox, J. A. Coe, G. A. Fisher, A. B. Blesing, R. H. Coe, T. Hollitt, E. H. Davies, J. S. Fisher ; Laura—E. G. Blesing, W. Stevens ; Narridy—W. F. Nicholls, R. M. Satchell ; North Bundaleer—J. L. Burton, C. E. Smart ; Port Pirie—H. G. Hawkins, D. L. McEwin, E. B. Welch ; Redhill—F. A. Wheaton, W. Pengilley, E. Steele ; Riverton—F. Phillips, E. A. Gray ; Saddleworth—F. H. Kelly, ; Tarcowie—J. Symons, W. S. Ninnes ; Whyte Yarcowie—E. J. Pearce, E. F. Pearce ; Yongala Vale—T. D. Keatley, C. Fowler, J. Lloyde. The chair was occupied by the President of the local Branch (Mr. R. E. Lines), the local arrangements being in the hands of the Hon. Secretary to the Gladstone Branch (Mr. A. E. Dinning).

MINISTER'S OPENING ADDRESS.

In his opening address the Hon. Minister of Agriculture said he had been associated with the Conference of Northern Branches for many years as a member of the Whyte Yarcowie Branch. He therefore felt at home amongst them. The first conference of the district in 1892 was held at Gladstone. Although the Gladstone Branch had gone into recess for a few years, he was pleased to find that it had been galvanised into life. A district like that surrounding Gladstone was altogether too good, and the farmers in it were too successful to rob the farmers of South Australia generally of the advantages of their experience and wisdom. In the formation of Branches they looked at it from a wider standpoint than mere local advantage. The influence of the South Australian Agricultural Bureau extended even to the borders of the Commonwealth itself. This institution was the envy of the Agricultural Departments of the other States.

He had perused the report of Professor Perkins, Principal of the Agricultural College, Roseworthy, and had noticed some points that would be of interest to them. There were two periods of the year during which it was essential that they should have a fair amount of rain. The first was the germination period, and the second was the close of the season. At Roseworthy this year the fall in April had been ·31, May ·31, June ·22, July ·69, all below that which they should have been. That meant that in the four months of the year in which they were expecting their heaviest rainfall at the College they only got 1½in. The average for the previous 30 years for these four months had been a little over 10in. Following this they had a very much heavier rainfall than usual in the months of August, September, October, and November. The seed had secured a poor start, and the rain forced it very quickly towards the end of the year. If they got the wheat away with a good start, it did not much matter what happened between June and December. During the year under notice red rust had been very troublesome. As a result, the yields at the College had been the lowest since Professor Perkins had been at Roseworthy. The season was peculiar, in that heavy rains were experienced in March. It did not look as though it would be safe to sow then, but those who did put in their wheats in many districts came off best.

He had pleasure in declaring the Conference open, and was especially pleased that Mr. Geo. Jeffrey and Mr. F. Coleman, who was certainly one of the leading farmers of the State, were present.

"SOIL BACTERIA."

Mr. H. Billinghurst, B.A. (Crystal Brook Branch), treated with this subject in the following paper :—" In many parts of the world, especially those where agricultural processes have been carried on for a great number of years, farmers expend large sums of money annually to maintain the fertility of their soils. Governments also have considered it incumbent upon them to establish and finance experimental stations for the purpose of constantly testing and making chemical analyses of the different artificial fertilising compounds. Speaking generally, the soils of South Australia do not at present require more than one of these artificial fertilisers, viz., superphosphate, and consequently we are not called upon to expend very much money upon any others. That our soils will not continue to answer to the calls we are making upon them for an indefinite period is certain. If means are not taken to prevent a diminishing fertility the time is not far distant when we, too, shall have to expend large sums upon artificial fertilisers other than superphosphate, as is now done in the older countries. The natural fertility of the soil depends to a large extent upon bacterial fertility, and if our soils be cared for properly the expenditure of these sums will never be needed. It is more economical to maintain the natural fertility than to apply artificial fertilisers. There is little doubt that by a series of experiments methods could be determined whereby the bacteria in the soil could be so increased and their products so utilised as to maintain, or even increase, the fertility. In the ordinary way bacteria or germs are usually spoken of as antagonistic to mankind. This is a popular error. If some varieties of a certain group of organisms are injurious it does not follow that the whole group should be so. One order of the vegetable kingdom includes the deadly nightshade and other poisonous plants, but it also includes the potato and tomato, both of which we use extensively, to our great advantage, as food products. Twenty years ago any knowledge of bacteria, outside the medical profession, was not thought of, but now almost all institutes of learning have well-equipped laboratories for the investigation of these friends and foes of man, for from comparatively recent investigations it is known that upon a knowledge of their functions depends the future progress of dairying, agriculture, preservation of foods and many other industries, as well as medicine.

WHAT BACTERIA ARE.

Bacteria are plants. Although they were formerly classed as animals, it is now universally conceded that they are plants. They differ from higher plants in that they contain no chlorophyl (green coloring matter). They resemble more closely the yeasts and moulds. There are many different varieties of bacteria; hundreds have been isolated and studied, and many more are constantly being discovered.

SIZE AND GROWTH.

In size bacteria are very small. It would take about 10,000 average-sized bacteria, placed end to end, to make an inch in length, and one and a half millions to make a mass large enough to be seen with the unaided eye. For food the requirement varies according to the species, but as a rule they require organic food, though some soil bacteria apparently thrive best, or only, on mineral foods. It is to their rapid reproduction that bacteria owe their wonderful influence in nature. They reproduce by simple division of the parent cell. The rate of multiplication depends upon food supply, environment, and species. Some, under favorable conditions, divide, thus doubling their number in 20 minutes, while some take three or four hours. They also reproduce by spores. Bacteria are everywhere, except in the interior of the earth and the upper layers of the atmosphere. A certain amount of moisture is necessary for all life. The temperature requirements of bacteria vary according to species, some sea bacteria are active at the freezing point and some soil bacteria thrive almost at the boiling point. Ordinary daylight is not as a rule very injurious to them, but sunlight has a decidedly injurious effect. It has been proved by test experiments that two hours' exposure to sunlight will kill most of them. Bacteria also require certain mineral foods and certain respiratory gases.

WHAT BACTERIA DO.

The general function of bacteria is the reduction of complex organic compounds to simple substances. Plant life is built up from the mineral substances in the soil and atmosphere at the expense of solar energy. Animals obtain their food directly or indirectly from plants. When life ceases, either in plants or animals, bacteria disintegrate the dead bodies, returning the composing elements to the soil or atmosphere, to be again used in the construction of new forms of plant life. If the destructive bacteria should cease their work the surface of the earth would be covered in a few years with mummies, unless cremation was universal. The law of perpetuity of life depends on the use of food elements over and over again. The storage of food elements in the form of mummies year after year would in time exhaust the supply, and life would become extinct. Although the general function of bacteria is destructive, there is a group that is constructive—building up simple substances into more complex substances. The problem of rendering his poor soil more productive, and his good soil better, is one in which every farmer is particularly interested. The failure of land to produce crops is not due in most cases to a lack of plant food in the soil. Chemical analyses show that in average soils there is in the top 8in. enough nitrogen to last 90 years, enough phosphoric acid to last 500 years, and enough potash to last 1,000 years. Why, then, if the soil contains such stores of plant food, does it fail to support continuous and heavy crops ? Simply because these essentials are locked up in such chemical combinations that the plants are unable to use them. The great problem, then, of modern agriculture, is not so much the conservation of plant food as the unlocking of the rich stores already in the soil, and placing them in a condition to be assimilated by plants. This unlocking process is carried on naturally by the soil bacteria. These myriads of little plants, in taking their food from the chemical compounds in the soil, produce in those compounds just the changes necessary to render them useful to the higher plants in making their growth.

NEED FOR CULTIVATION.

In the soil there must be moisture present or the bacteria will fail to grow and carry on their functions ; in fact, many of them will die, hence the necessity for the conservation of the soil moisture by frequent and thorough cultivation, not only for the benefit of the crop, but also for the benefit of the soil bacteria. The bacteria of the soil may be divided broadly into four groups, though there are some others of less importance. These four are the ammonifiers, the denitrifiers, the nitrifiers, and the nitrogen-gathering bacteria. When dead organic matter falls upon the ground it immediately begins to undergo a process of decay. Dead animals left upon the ground or buried in it are decomposed, and the elements of the animal tissue are incorporated into the soil. Manure placed upon the land rots and enriches it. Dead plants decay and become again a part of the earth from which they sprung. All this decay is brought about by bacteria assisted by the elements. The first change that takes place is a breaking down of the complex nitrogenous substances. The result of this breaking down is to resolve the nitrogenous substances into free ammonia and other simple compounds. Now, ammonia is a very valuable ingredient in the soil, for on becoming oxidised it is immediately available as plant food. A series of experiments to test the amount of ammonia produced by bacteri were conducted at the Michigan Agricultural College and demonstrated th advantage of a bountiful air supply. Four sets of tests were conducted in flasks. In the first all oxygen was removed, in the second the flasks were sealed with wax, in the third they were plugged with cotton wool, and in the fourth they were thoroughly aerated. After 11 days a careful examination was made. In the flasks devoid of oxygen only the merest trace of ammonia was found, while the others all showed ammonia in larger quantities, the amount increasing steadily and consistently with the increased amount of oxygen supplied. This, then, shows the second reason for frequent and thorough cultivation, *i.e.*, that the soil should be aerated as effectively as possible, that the maximum amount of ammonia may be produced by these bacteria.

THE DENITRIFIERS AND NITRIFIERS.

These bacteria carry on a process of nitrate destruction. They attack the nitrates in the soil, reducing them to nitrites and free ammonia, and sometimes resulting in the liberation of free nitrogen—a serious loss. Fortunately, however, research has taught us that these bacteria work best when oxygen is excluded. If the soil is allowed to become packed and hardened through lack of cultivation the air is excluded, and one of the conditions favorable to denitrification is furnished. This provides a third reason for frequent and thorough cultivation, *i.e.*, to prevent the loss that might be caused by the action of the denitrifying bacteria. Opposed to the above nitrogen waste another process which is being carried on simultaneously is nitrification or nitrate building. In most species of plants the nitrogen necessary for their growth must be in the form of nitrates. The nitrifiers seize upon the ammonia which is formed by the degradation of the complex nitrogenous bodies by the ammonifiers, and by the addition of oxygen to it they form nitric acid, which combines readily with chemical bases in the soil to form nitrates, thus placing the nitrogen at the disposal of the plants. The nitrifying bacteria differ from the preceding classes in their food requirements in that, whereas the ammonifyers and denitrifyers require at least a trace of organic matter for their best development, the nitrifyers do not require organic matter; in fact, they are incapable of growing in the same, although its presence in the soil does not prove fatal to their existence. Also, they require an abundance of oxygen. Hence a further necessity for thorough cultivation in order to afford this supply.

LEGUMES.

Crops of leguminous plants, such as peas, beans, vetches, clover, lucerne, etc., do not exhaust the soil in the same way as many others, such as cereals, root-crops, &c. This knowledge has long been made use of in the rotation of crops, but until recent years its true significance was unknown. When seeds of plants not being legumes are placed in soil entirely destitute of nitrogen, but containing all the other chemical elements necessary for plant growth, they start to grow, but as soon as the food material stored up in the seed itself is exhausted the plants wither and die. On the other hand, if seeds of legumes are placed in the same soil, they also make a start. Then they begin to wither, and undergo a period of " nitrogen hunger," after which they revive and make a vigorous growth. If examination is made of the roots of peas, beans, and other plants belonging to the leguminous family, there will be found on the roots small tubercles or nodules. When cut open and examined under a microscope these are found to contain myriads of bacteria, which possess the property of extracting free nitrogen from the air. Besides gathering the free nitrogen from the air these bacteria cause the nitrogen to unite with substances such as calcium, magnesium, and potassium in the soil, and so form nitrates suitable for plant food. The legumes then use part of this food in their own growth, both in the tops and roots of the plants. Here, then, is still another reason for thorough cultivation, viz., that these bacteria may have a supply of air from which to extract the nitrogen. It will now be seen how it is that a crop of leguminous plants leave the land richer than it found it. The tubercles on the roots vary in size according to the variety of the legumes, being especially small in the clovers, and very large—about the size of a pea—on cowpeas, and some of the larger beans.

OTHER BACTERIA.

Besides those already enumerated there are other bacteria which, by their action upon the complex substances of the soil, change those substances into potash compounds, sulphates, phosphates, and silicates readily available as plant foods. It will thus be seen what an important part these tiny organisms play in plant life. Nitrogen in the soil is being constantly used up by growing crops, by leaching, by our system of bare fallow, and by other means. Very little of the supply of nitrogen in the soil is immediately available as plant food. So the inevitable conclusion is that sooner or later the problem of replenishing the supply will be before us. Then the question will be—How shall that replenishing be accomplished ? Nitrogen may be bought in the markets in such forms as sodium nitrate (containing 15 or 16 per cent.

of nitrogen), ammonia sulphate (containing 20 to 21 per cent. of nitrogen), and dried blood (containing 12 to 15 per cent. nitrogen); but, when we bear in mind that such commercial nitrogen costs about 10d. or 11d. a pound, and that 1bush. of wheat contains about 1lb. of nitrogen, it will be seen at once that the purchase of nitrogen cannot be considered practicable in general farming. Considering all these facts, and the additional facts that there are about 75 million pounds of atmospheric nitrogen resting upon every acre of land, and that it is possible to obtain unlimited quantities of nitrogen from the air for use of farm crops, and at very small cost, the inevitable conclusion is that the inexhaustible supply of nitrogen in the air is the store from which we must draw to maintain a sufficient amount of this element in the soil for the most profitable crop yields.

CONCLUSIONS.

There is absolute necessity for frequent and thorough cultivation of the soil—(1) To supply and maintain a sufficient quantity of moisture for the growth of plants and for successful bacterial activity. (2) To thoroughly aerate the soil; (*a*) to supply oxygen for the ammonifying and nitrifying bacteria; (*b*) to check the injurious activity of the denitrifying bacteria; (*c*) to supply nitrogen for the nitrogen-gathering bacteria; and there is urgent need for the careful study and for exhaustive experiments to ascertain the best, simplest, and least costly means of inducing the greatest possible activity of the bacteria of the soil.

DISCUSSION.

In the discussion which followed, Mr. F. Coleman (Saddleworth) emphasized the need for the farmers experimenting largely if they desired to solve many of the problems which at present confronted them. On his property, over a period of 10 years, bone super. had given better financial results than mineral super., and he suggested that others should try its effects comparatively. (Hear, hear). The Director of Agriculture (Professor Lowrie) complimented Mr. Billinghurst upon his address. There were many things which still puzzled them in relation to the soil. Some men, for example, year after year took off crops, burnt the stubble, and fallowed, and yet obtained regularly returns equally as good as were secured by those who cropped with cereals only once every three or four years. The trouble in their cases would probably come—not so much in the matter of lost nitrogen—as in the detrimental effect, through the loss of humus, upon the physical condition of the soil. It was quite likely that the continued thorough working of the land would ensure the maintenance of the nitrogen supply, but it was certain that such a practice would lead to the depletion of the humus. The question was, when they had used up that humus would the direct acquisition of nitrogen keep pace with the demand. In the northern areas particularly, it was absolutely essential to conserve as much moisture as possible, and the best agency in that connection—quite apart from its nitrogen content—was humus. In Mr. Coleman's case it appeared as though the trace of nitrogen in the bone super. accounted for the superior financial results. If everybody used this fertiliser extensively, however, the time would soon come when there would not be nearly enough to go round, and the price would rise to a prohibitive degree.

FEEDING COWS FOR MILK PRODUCTION.

The Dairy Expert (Mr. P. H. Suter) contributed an address on this subject. He said this State cannot claim to possess such favorable dairying conditions as exist in the Eastern States, New Zealand, or Denmark. There the rural population is blessed with not only fertile soil, but natural pastures, the result of a good rainfall, nicely distributed over many months of the year. There the cow enjoys an ideal life and yields liberally. Only in limited areas can we dairy profitably without recourse to a freer use of the plough and growing of special crops for conservation to feed in times of scarcity. I am well aware of the great disadvantages under which we raise and market dairy produce, but hold the opinion that we can do better, for we have in the State people quite as industrious and intelligent as in any other country, many of whom are doing good work in spite of all the drawbacks.

I need not remind you that this State is subject to periods of drought, when there is a scarcity of natural food suitable for the dairy cow. During these periods of shortage of green food, dry pastures only are obtainable, and these often are inadequate to satisfy the body demands, and certainly insufficient to stimulate a vigorous milk flow. At such times we find many totally unprepared, and thousands of good cows perish.

During the flush or spring months the cows milk well, for there is nothing better than good natural pasture to produce heavy yields of milk and butter of the finest flavor. This is on account of its being in proper condition, palatable and succulent, and having the right proportion of food elements present, viz., protein, &c. It is with the hope of stimulating some to provide their cows with a sufficient and suitable food ration, that I have chosen as my subject, "The feeding of dairy cows." This is the weakest spot in Australian dairy practice ; it is more important, I feel, than breeding.

The high price of land, labor, and increased taxation make it very necessary that those keeping dairy cows should adopt more approved methods. Practically one-half of the cows kept are short of sufficient food to maintain condition, much less to make milk to profit. Such cows, when freshening or calving, are brought in to be milked and usually receive a little extra food. This food is used almost wholly to satisfy the body wants, being directed to replenish waste tissue before any goes to milk production. The right kind of cow, fed to her full capacity with suitable food will show a substantial profit, but a poor or wrong sort fed to its capacity with the same food will not yield milk to profit. I do not propose to go into the question of increasing the fat content of milk by feeding; there is a wide difference of opinion held by cow keepers on this point. I will just here say that by no method can the fat content be permanently increased. A cow weak and in low condition owing to insufficient food cannot be made to increase the fat content until a normal condition is reached.

After most exhaustive experiments, various food standards have been laid down. Assuming that a dairy cow has a live weight of from 800lbs. to 1,000lbs., and is producing 3galls. of milk daily, she will require the following ingredients or nutrients in her daily ration:—Dry matter, 25lbs. to 28lbs.; protein, 2lbs. to 2·5lbs.; carbohydrates, 12lbs. to 15lbs.; fat, ½lb. to ¾lb. And of these the body demands for maintenance—Fat, ¼lb.; dry matter, 13lbs.; protein, ¾lbs.; carbohydrates, 7lbs. The full amount is required for the following purposes:—(*a*) To replace waste tissue; (*b*) to produce heat for the body; (*c*) to supply building material, such as muscle, bone, hair, flesh, &c.; and (*d*) for the formation of milk.

For the purpose of considering the value of a food, fat and the carbohydrates may be grouped together, 1lb. of fat being equal to 2½lbs. of carbohydrates. For milk production we require for every 1 per cent. of protein 6 per cent. of carbohydrates; consequently, to gauge the value of a food as a milk producer we must consider the proportion in which the nutrients are present. Very few foods contain them in the best proportion for milk production, one exception being natural mixed pasture. The value of the majority of foods must therefore depend upon the possibility of mixing them with other foods, in order to have the carbohydrate and protein in the right proportion. This is referred to as the nutritive ratio.

Let us take, for example, wheaten hay and wheat straw. The composition is as follows:—Wheaten hay); protein, 3·6; carbohydrates, 46·1; fat, 1·1; nutritive ratio, 1 : 13½. Wheaten straw; protein, ·4; carbohydrates, 36·3; fat, ·4; nutritive ratio, 1 : 93. Such bulky foods fed alone are not good milk producers, because they are not concentrated enough, and do not contain the protein and carbohydrates in right proportion. Hay is very much superior to straw; nevertheless, the hay has too little protein and must be mixed with concentrated food rich in protein and fat, such as bran, linseed, lucerne chaff, &c.

There are a number of concentrated foods which can be used on the farm, viz.:—Oats, which is an excellent grain for feed; the husk, whilst carrying a little nutriment, renders it a food of light character and of easy digestion. Soaked wheat can be used at the rate of 4lbs. morning and night. Lucerne—Every ton of lucerne hay grown upon the farm and well prepared has approximately an equivalent value of a ton of bran. Soaked barley is a rich food, and is largely used in Denmark for feeding dairy cows in conjunction with oats; I do not recommend exceeding 6lbs. daily. Peas are excellent food for dairy cows; give them 2lbs. morning and night, crushed. When values are low these can be fed instead of bran. These foods, and also linseed, oilcake, lucerne chaff are too valuable in protein content to be fed alone in large quantities, and must, therefore, be fed with cheap bulky foods, such as straw, hay chaff, and cocky chaff; the latter, being deficient in protein content supplies at little cost all the dry matter and carbohydrates required by dairy cows.

Thus the farmer can produce the bulky food at a minimum of cost. Where peas, lucerne, or any leguminous crops are grown the necessity for purchasing bran, &c., is lessened.

Protein is the nitrogenous matter contained in food stuffs such as bran, lucerne, peas, beans, all leguminous or pod-bearing plants, and goes to the formation of muscle, flesh, and milk.

Carbohydrates and fat are mainly utilised to supply heat and energy and increase of weight. Foods such as oilcake, maize, potatoes, carrots, sugar beet, and sorghum have a high percentage present, but are deficient in protein content.

The composition of vegetable bodies and animal bodies is much the same, and every element or nutrient in the animal body must be given in the food supply. The value of the food depends upon the relative proportion of the three classes of digestible elements they contain.

It is due to protein, carbohydrates, and fat being in right proportions that our natural pastures are so excellent as milk makers. There are only 3½lbs. of protein contained in 100lbs. of chaff, whilst there are over 46lbs. of carbohydrates. So, for a cow to get sufficient protein to make 4galls. of milk she would have to consume nearly 90lbs. of chaff daily; carbohydrates would then be wasted, for the cow could not utilise these profitably, seeing that she only requires, say, 15lbs. daily. In 100lbs. of wheaten straw there is only about ½lb. of protein, and as a cow requires, say, 3lbs. to make 4galls. of milk, she would have to eat 600lbs. of straw to get sufficient protein. Such are termed bulky foods, and must be mixed with concentrates.

A cow in full milk will require for a day's ration (if either wheaten chaff or straw are to form the bulk, and oilcake the concentrate) the following, viz.:— 16½lbs. of wheaten chaff and 12½lbs. of copra oilcake, or 16½lbs. of straw and 16lbs. of copra oilcake.

From this it will be seen that the 100lbs. of wheaten straw requires to be supplemented by 22lbs. of copra oilcake to make it equal to 100lbs. of wheaten hay. In the first mixture there are six daily rations, viz., (6) 16½lbs. of hay —100lbs.; (6) 12½lbs. cake—75lbs. However, such a ration is unsuitable, as so much oilcake would sicken the cow, but it is given to show the comparative values of the different foods.

In determining the quantity an animal is to have, regard must be had to what the beast is expected to do with the food. In the case of a mature animal neither milking, growing wool, being fattened, not doing work of any kind, food to supply heat for the body, and to replace any small waste going on, only is required. The amount of food would almost entirely depend upon the size of the animal; if it is 1,200lbs. weight it would require twice as much as a 600lb. animal. That is really a maintenance ration. Young growing animals must be fed with rich food containing all the ingredients necessary over and above maintenance. An animal being fattened must have an excess of carbohydrates.

Finally, in the case of cows giving or expected to give milk, a productive ration is required, for the caseine and albumen in milk is made from protein, and the fat and the sugar from the carbohydrates, all of which were originally assimilated from the food consumed, then manufactured into blood, and finally into milk. If, however, sufficient nutrients are not supplied to maintain the body wants and the production of milk, the cow may give a little milk at the expense of her vitality. Under such circumstances the cow loses weight or condition, becomes poorer, miserable, and non-profitable. A cow having been a very generous milker and used to good feeding, will often continue to yield milk, sacrificing her body, and practically milk herself to death. If no feed is available I recommend farmers to cease milking the bulk of the cows. Select those most recently calved, or the best, and feed them properly.

Under generous feeding the cow is stimulated to heavy milk production. Cows kept in a semi-starved state must quickly decrease in their yields, but many continue to yield some milk whilst undergoing this starvation. As milk is designed for the support of the young calf, nature has provided for its supply to the limit of animal endurance.

The ration fed to the dairy cow must not only contain the food ingredients to allow of her performing the work required of her, but it must be palatable and succulent, otherwise she cannot relish it. Palatability and succulence of the ration is essential, as it ensures better digestion by way of creating an active and vigorous secretion of the digestive fluids of the stomach. This can be readily supplied by feeding any green crops, ensilage, mangolds, pumpkins, piemelons, or damping the feed with molasses and water.

Farmers, when asking their horses to do the extra cultivation of the land, always see to it that they receive more grain and less bulky food. So it should be with the cow; a portion of her food must be concentrated, and it is indeed well to aid her by reducing the food to a condition readily consumed and assimilated, be it grain by crushing, or hay by chaffing, &c. As a rule, when feeding, provide as much roughage with succulence as a cow will consume, and sufficient concentrates to bring her ration up to a required standard. The true value of the cocky chaff and the various straws as food is not sufficiently appreciated. They are made very valuable when properly fed to cows with richer foods. Their composition varies very considerably.

Pea straw is very valuable, then comes in order of merit oaten straw, cocky chaff, barley, and wheaten straw. In feeding these it pays to sprinkle with molasses, diluted with hot water the afternoon previous, each day's requirements. If molasses is not used I recommend linseed made into a very thin gruel, diluted with hot water, the cocky chaff, &c., being saturated with this. Also, mix an ounce of salt with every gallon of water. This stimulates the appetite and aids digestion. The addition of the hot water, &c., creates a slight fermentation and makes it much more palatable for the stock.

Pure water is almost as important in milk production as the food a cow consumes. She will drink on an average 4galls. of water to every gallon of milk she secretes. In every 100lbs. of milk there are 87lbs. of water, and bad, stagnant water means less milk, poorer flavor and keeping quality, and the cows lose condition.

In my list of food compositions I have taken cocky chaff as equal to the average of the straws; thus it is only approximate, no analysis having yet been made in Australia so far as I am aware.

Some most valuable work carried out at the Agricultural College by Professor Perkins and his staff distinctly showed what wide differences obtained in the food value or percentage of digestible nutrients contained in hay cut in full bloom, and that cut when more advanced in maturity; a difference of 12 per cent. was found in the digestiblity of the ingredients, principally protein—our most valuable ingredient—thus lessening its food value considerably; and that cut at a later period was also accompanied by a loss in weight.

It does not matter how good a dairy cow may have proved herself, unless she receives a suitable daily ration in excess of maintenance she can prove but little, if any, better than the greatest scrubber. There are many factors which must be observed if money is to be made from cows—(1) Feed good cows generously with suitable food, viz., a ration containing not only the ingredients necessary to maintain the body; go further, supply more, and produce milk. (2) Study foods and their value, provide good water.

TABLE I.

The dairy cow, weighing approximately 1,000lbs. live weight, and yielding 3galls. daily, requires in her daily food ration the following food nutrients :—Dry matter, 25lbs. to 28lbs.; protein, 2lbs. to 2½lbs.; carbohydrates, 12lbs. to 15lbs.; fat, ½lb. to ¾lb. The body requires—Dry matter, 13lbs.; protein, ¾lb.; carbohydrates, 7lbs.; fat, ¼lb. Amount available for milk production—Dry matter, 12lbs. to 15lbs.; protein, 1¼lbs. to 1¾lbs.; carbohydrates, 5lbs. to 8lbs.; fat, ¼lb. to ½lb. Each pound of milk produced (after the body demands are satisfied) requires—Dry matter, ·46lb.; protein, ·067lb.; carbohydrates, ·26lb.; fat, ·02lb.

TABLE II.

Economical maintenance rations suitable for northern dairymen, who wish to save their best cows during times of drought—The cows should not be milked unless the owner provides increased food containing the ingredients (note in Table I.) required to produce 1lb. of milk. All these rations should be damped with hot water. No. 1—16lbs. wheaten straw, 20lbs. pumpkin, 3lbs. copra cake; cost, 5d. per day. No. 2—12lbs. wheaten straw, 4lbs. wheaten chaff, 5lbs. bran; cost, 4d. per day. No. 3—12lbs. cocky chaff, 4lbs. wheaten chaff, 2lbs. copra cake; cost, 4d. per day. No. 4—20lbs. cocky chaff, 2lbs. bran, 2lbs. linseed; cost, 4d. per day. No. 5—10lbs. wheaten straw, 5lbs. wheaten chaff, 3lbs. bran, 1lb. copra cake; cost, 3½d. per day. No. 6—20lbs. wheaten straw, 2lbs. linseed; cost, 3½d. per day.

TABLE III.

Rations which can be Fed for Milk Production (Northern Areas).—No. 1—15lbs. wheaten and oaten chaff, 4lbs. oaten straw, 8lbs. bran, 2lbs. copra cake; cost, 11½d. per day. No. 2—10lbs. oaten chaff, 8lbs. lucerne chaff, 6lbs. crushed barley, 4lbs. bran; cost, 8·8d. per day. No. 3—16lbs. oaten chaff, 6lbs. crushed barley, 6lbs. bran, 1lb. linseed; cost, 10½d. per day; No. 4—20lbs. pumpkins, 10lbs. wheaten chaff, 5lbs. straw, 7lbs. bran, 2lbs. linseed; cost, 9½d. per day. No. 5—25lbs. piemelons, 8lbs. wheat, 12lbs, chaff, 5lbs. straw, 2lbs. copra cake; cost, 11d. per day. No. 6—30lbs. green lucerne, 12lbs. wheaten chaff, 5lbs. oaten chaff, 6lbs. bran.

DELEGATES' VIEWS.

Mr. F. H. Kelly (Saddleworth) mentioned that he had found the straw of Le Huguenot wheat preferable to any other for feeding to cows; sheep also took to it very readily.

Mr. A. L. McEwin (Blyth) agreed with the view of the Dairy Expert that dry bible was due to bad feeding. He was strongly opposed to the practice of giving cows extra feeding within three weeks of calving.

Mr. Kelly asked whether it was advisable to have rock salt always available for cows. Mr. Suter said it should be there, if the cow wanted it she would lick it; if not, she would leave it alone.

Mr. E. H. Davies (Gladstone) asked whether better results were obtained with milking machines or with hand milking. Mr. Suter replied that good hand milking was best. Some milking machines were absolutely useless. Others were very useful if the cows could be kept up to 3galls. of milk per day. Under present conditions, where a man was milking 10 or 15 cows, he was better off without the machines.

Mr. E. B. Welch (Port Pirie) asked what food should be given cows that were running on saltbush country, that caused them to scour badly. Mr. Suter said a little cocky chaff and pollard fed at night would have a good effect. Saltbush contained a large percentage of protein.

AFTERNOON SESSION.

LUMPY JAW.

Mr. F. E. Place, B.V.Sc., M.R.C.V.S. (Government Veterinary Lecturer), delivered an address as follows :—" In venturing to occupy the attention of the delegates for a little while with lumpy jaw, I offer no apology, because I have during the last two years found that in the northern districts there is a good deal of lumpy jaw ; and I trust the explanation now to be given will tend to somewhat allay the feeling which the subject has aroused, and at the same time throw a little light on the matter. It will be noticed that there is no limitation in the title of the subject to any particular class of stock, because it is not intended to limit the remarks to cattle only, but to endeavor to show that other stock may also be involved in the disease. Also, at the outset it must be made plain that the common forms of lumpy jaw cover three classes of diseases which are notifiable under the Stock Diseases Act in this State, and that it is every one's legal duty to immediately notify the Chief Inspector of Stock, Adelaide, and the nearest local inspector, which would be at Gladstone, Quorn, or Gawler, of the existence of a case of lumpy jaw, so that an inspection may be made and advice given as to the disposal of the beast, pending which procedure the animal should be kept from contact with others. These regulations are framed entirely in the interests of the stock owner, and it is to be hoped that the reason for them will become apparent as the explanation proceeds. They are not irksome, and the due fulfilment of the requirements of the Act is a social duty, because lumpy jaw may mean tuberculosis, the congener of consumption among ourselves, or actinomycosis, which frequently results in fatal liver abscesses among men, or cancer, the very name of which is fraught with horror. While on the other hand the use of such a loose expression as 'lumpy jaw' may mean no more than a glandular swelling due to the irritation of the bail, or an abscess produced by the presence of grass seeds in the soft structures of the throat. One desires to be able to separate the virulent from the harmless. To do this a little anatomical knowledge will be found useful, for if one looks at a beast's throat, especially if it is thin skinned, like a Jersey cow, one can see lying between the jaws, two glands or kernels, and can also discern behind and below the ears outlines of similar organs. Portions of these glands are lymphatic glands, or in plain words, filters and traps for catching germs ; but they are more than this, for they are outposts of the defensive forces of the body, garrisoned by cells whose duty is to seize and devour the invader, so that many a hard-fought fight is waged in these barbicans of the body, and assailer and assaulted lie dead side by side in huge numbers, so that there is swelling, pain, and tenderness. If the cause of the attack is little understood by the defending cells, reinforcements are called up to hold the outer walls, and one finds the glands showing beneath the skin as hard kernels, freely movable on the softer structures among which they lie, the result of irritation such as of a sharp-edged bail, or that abomination, the stick wired on. Now such irritation will not in itself produce either tuberlosis or actinomycosis, neither will it in the course of an ordinary beast's life induce cancer; but it is hard to conceive why a beast should be made to suffer in such a way. Facing the matter from a purely practical standpoint, such irritation is not conducive to the economical production of either meat or milk, but as it is not a disease notifiable under the Act, it is likely to continue indefinitely; it is doubtful whether there would be a single case if the actual loss produced in this way could be tabulated and expressed in terms of £ s. d.

GRASS SEEDS.

"Then comes the much-debated grass seed abscess. The symptons of this are manifest discomfort long before any external swelling is visible; the husky cough, the dribbling from the mouth, and poking out of the tongue at times, and then the external swelling, at first ill-defined, but later sagging between the jaws, hardish on the outside because of the thickness and tenseness of the skin, but if grasped will be found to fluctuate and not attached to the sides of the jaw or involve any well-defined enlargement of the glands, because their structure is being broken down. Later, if nothing is done, the abscess will possibly burst, and a free discharge of matter occur. What has happened is that grass seeds have found entrance, possibly through the ducts under the tongue through which saliva reaches the mouth, or possibly through the wound in the jaw caused by a new molar being cut, or by the side of an old one loose in its socket, and the soldier cells of the glands, ever on the alert, have called up reinforcements to repel the invader; but the bulk of the latter has been too much for them and the camp followers of the foe, the ever present germs which make pus—the staphylococci and streptococci—have battened on the corpses of the defenders, utilising also the rotting stalks of the enemy as food, till the whole area has become one mass of putridity, as is clearly evidenced by the stink of the discharge, followed in many instances by the rotten grass seeds. Here is a case for the amateur surgeon, if the value of his beast and the distance from a veterinary surgeon do not warrant calling him in; and the requisites for the operation are a bold mind and a sharp clean knife. The animal is secured in any way that can be relied upon, the Swedish triple hitch is probably as easy and good as any, and the knife is driven well into the abscess. From below a good big cut of quite an inch or more in length is made to let the matter out. When it has finished draining, the hole it leaves wants well swabbing out, and with the fingers or forceps, made possibly out of a bit of fencing wire, the grass seeds should be cleaned out, after which the hole should be well swabbed out with any strong antiseptic, such as washing soda, Stockholm tar, or any carbolic preparation such as lysol, cyllin, &c., used in quite 20 per cent. strength, and further treatment will not be needed. Should it be, however, for any reason, then probably a further application of Stockholm tar will meet the case. There is no advantage in leaving grass seeds to be their own surgeons. Take the thing early and do it well.

TUBERCULOSIS.

"Now we come to the diseases with which the Stock Department will deal on receipt of notification. First of all the lumpy jaw of tuberculosis gradual in its onset and causing enlargement of the glands between the branches of the lower jaw or below the ear, with accompanying cough, especially when the animal is hustled ; the bright tubercular eye, and possibly, though not always, the wasting and scouring that so often accompany the disease. The swelling is very different from that just described ; each gland is enlarged separately, often unequally, and it can be felt distinctly in the hard fibrous case, movable, not adhering to the bone at all, and in extreme cases going on to suppuration ; but the matter will not have the foul stench of the grass seed unless there happens to be a complication of such, and the other symptoms of the disease will ratify the opinion formed. Should there still be doubt, the Stock Department would be able to settle the matter definitely by applying the tuberculin test, which, however, is rarely required, the inspectors being men of experience and well able to detect the disease. If the disease is localised to the glands of the throat, they would probably pass the rest of the carcass for food, destroying only the head or parts affected. In these days when everyone talks glibly of bacteria and bacilli, one may be forgiven for just mentioning that that kaleidoscopic science, bacteriology, has decided that the well-known bacillus tuberculosis is not a bacillus at all, but one of the family of discomyces, or mould-like fungi to which the actinomyces also belong, likewise the blue mould on harness ; and Metchnikoff, who was going to turn us all into centenarians with sour milk, suggests that in honor of its discoverer it should be renamed *Sclerothrix kochi.* But amenities of this sort have little interest for the man on the land, and it is much more important to remember that the discharges from a beast with tubercular lumpy jaw are highly virulent to others of its kind, especially calves and young stock, who, obtaining them either on their food or breathing them in, will rapidly contract the disease, and in their turn pass it on to others. Waiving for the nonce the question as to whether the disease is transmissible from man to beast or beast to man, one is faced with the stern fact that its existence means diminished profits—possibly 2 per cent., possibly 20 per cent. ; but in either case stock-breeding is not so profitable nowadays as to be able to pay a tax of that sort, especially when with a little care the disease can be stamped out, conditions in South Australia being especially favorable for so doing, and the vigilance and skill of the Stock Department ever ready at the stockowner's call.

ACTINOMYCOSIS.

Actinomycosis will be shown by the somewhat rapidly growing lump, generally on the side of the jawbone, inside or out, but firmly connected with the bone, and eventually breaking and discharging a whitish stringy matter practically without smell, unless, again, there are complications of grass seeds. This matter has a distinctive characteristic, which allows one to diagnose the disease even by the naked eye. If a little fresh matter is collected on a piece of glass, such as a microscope slide, and squashed out with another piece, small whitish or sulphur-yellow specks may be discerned, varying in size up to a millet seed. These are colonies of the fungus actinomyces, but in a degenerate state, and very likely to be destroyed by the pus-forming germs in the matter; hence the necessity for examining the fresh discharge at once. Under the microscope they are distinguishable as masses of club-shaped moulds which were taken to be the casual organism of the disease, but they are now known to be degenerate forms of discomyces similar to the one of tuberculosis, and very nearly allied to the organisms often found in the mouths and throats of men and animals which produce the white cottony growths sometimes called thrush. But while our knowledge of tuberculosis informs us that the germ almost invariably requires a living animal body in which to grow, that of actinomycosis lives freely upon cereals and grasses, especially those possessed of awns like barley and barley grass; and undoubtedly man becomes infected in most cases directly from the vegetable saprophyte by inhaling dust while threshing. But once the organism obtains an entrance to the body, be it animal or man, it will not stay in the jaw only, but become generalised in the lungs, pleura, liver, and so forth, and causes many deaths in man from liver abscesses with which it is not always credited. But it may be argued, 'why worry about it in cattle if the source is common to them and men from grasses?' For this reason, that the germ passing through the animal body becomes modified in its virulence, but passing from the animal to the plant again becomes more virulent; so that the lumpy-jawed beast scattering the germs is a very real menace, both to its own kind and to the human race as well, and, therefore, apart from the legal necessity to do so, he should be knocked out at once. Unfortunately, in South Australia, there seem to be different species of the discomyces which sometimes cause confusion in the mind of the owner or inspector, as the symptoms do not run a regular course; but in such cases it would be better to take the view that it is actinomycosis and get rid of it. The germ has a great resistance to heat, and for this reason is found in dry, hot districts, where one would hardly expect to be troubled by such forms of life. It will be readily seen from the foregoing that the connection between grass seeds and actinomycosis is likely to be a very intimate one, and such is really the case, so that an apparently simple case of grass seed abscess may readily become the focus of an actinomycotic growth; and this should never be overlooked. From a practical point of view slaughter is by far the cheapest way of dealing with this disease; but from some curious perversity of human nature, a cow has only to get a lumpy jaw to immediately become, in the owner's eyes, the most valuable beast in his herd. Her price, like that of Solomon's good housewife, is above rubies, and demands for treatment are loud and long. This, being a matter entirely for the Stock Department to decide, need not detain us now, beyond saying that the disease is in some cases amenable to treatment, and that the cost of such is generally more than the market value of the beast, without considering time or risk.

CANCER.

"Now just a word or two about cancer. It is generally conceded by present-day scientists that the various forms of cancer are produced by the cells which make up the tissue running riot, and not to germs of any specific nature, but the cause of this mad suffragetism among the cells is prolonged irritation; and in grass seeds, actinomycosis germs, and so forth we have just the class of irritant that is likely to set up cancer, and, as a matter of fact, often does. The hard, bony swelling which accompanies lumpy jaw is known as *Osteo sarcoma*, and by the courtesy of a practitioner in a neighboring town I have lately become possessed of two highly interesting photographs of *Osteo sarcoma* on the jaw of a 4-year-old filly, in which the cancer growth is hugely developed, giving every indication that the origin of the mischief was the actinomycosis fungus. If the outcome of this dissertation is to call the attention of stockowners to the folly of keeping lumpy-jawed beasts about, the speaker's object will have been attained; but in closing, he would once more remind them that it is not a matter of personal like or dislike, but a matter of social duty and legal requirement that such cases should be brought under the notice of the Stock Department without delay. He does this with the more emphasis because, as an officer of the Agricultural Department, his rights and duties are just those of any other private individual, but his knowledge of the mischief the diseases commonly called jumpy jaw do makes him urge stockowners to endeavor for their own interests to stamp them out."

Mr. F. D. Bladon (Belalie North) asked whether cancer could be eradicated from the jaw of a horse by means of an operation.

Mr. Place said there was no reason why this should not be done. Cancer was a riotous growth of the tissue of the part, and if they cut out all the cells they should be rid of the trouble. Success only followed early operation, however.

Mr. W. Ninnes (Tarcowie) had a bullock with a lump on the jaw. About 12 months ago he destroyed the animal and burned the head. Just lately he examined the bone of the jaw, and the growth seemed to have begun from the inside of this.

Mr. Place said this was a typical case of actinomycosis. The germs had evidently entered through an opening into the jawbone, and multiplied there.

Mr. G. Jeffrey (Advisory Board) referred in eulogistic terms to the address of Mr. Place.

In reply to Mr. Kelly, Mr. Place said there was an analogy between the lumpy jaw and fistula in horses. When an injury occurred where the blood circulation was slow, the act nomycosis fungus grew, and the result was a continuous breaking out and running, unless they cut well down into the tissue, and followed down every pipe, scraping away any diseased bone or tissue. The wound should then be irrigated for half an hour, or an hour, per day.

BULK HANDLING OF WHEAT.

This subject was dealt with in a paper by Mr. F. H. Lock (Whyte-Yarcowie), which read as follows :—" The present system of handling and marketing wheat is expensive, wasteful, and unscientific, and with it we cannot expect to get the best results. The conditions of handling and marketing under the bulk system are as far in advance of it as the modern drill and harvester are in advance of the old seedsower and mower. The fact that over 80 per cent. of the wheat imported into Great Britain arrives in bulk, and that much of the Australian wheat arriving there is handled in bulk by the bags being cut in the holds, goes to show the general acceptance of the bulk system at one end, whilst the fact that most of the wheat in Russia, U.S.A., Canada, and Argentina is shipped in bulk proves that it is just as acceptable to the grower. The adoption of the bulk system not only involves a change in methods of handling, but would practically alter our whole system of marketing. The change should not take place until serious consideration has been given to the cost thereof from every point of view. South Australia is lagging behind in this question. New South Wales is launching out on a scheme of her own, and Victoria is seriously considering ways and means, whilst in each of these States the handling and storing in bulk is practised by different milling firms. Much could be said against the present system, but it would be the ' old, old story,' so it is enough to say that so long as any system puts a premium on malpractices, whether great or small—and our present system most certainly does—many peoples' honesty will be strained to breaking point; and further, the farmer undoubtedly gets the worst of the deal. That the introduction of the system of bulk handling in this State is fraught with many difficulties is without question; but they are not insurmountable. Other countries where this system is in operation have overcome similar difficulties. The cost of the scheme in its entirety—as we see it in America and elsewhere—would be considerable, but no one would dream of launching the whole scheme in one act. It would be far more reasonable to spread the cost over a number of years; then it would not be burdensome. Certainly in considering the cost thereof we must place against it the annual expenditure on bags (for the other charges will be about equal for both bags and bulk), and the fact that bags are an ever increasing outlay, whilst the elevator would be a permanent asset once erected. If a sum equal to that lost by the farmers annually on bags, viz., £145,000, were put into installing the bulk system each year, in 10 years this would mean about £1,500,000, which would give us at least a fairly up-to-date elevator system in this State. In America the elevators are owned by the railways and worked under Government inspection, the railways there being privately owned. Here, where our railways are the property of the State, the elevators should be a State enterprise, and if it pays the railway companies of America to put the money into it—as it unquestionably does—it should certainly pay as a State concern here. One of the difficulties as regards this State is the number of ports where wheat is loaded direct for export; but more than two-thirds of the wheat exported goes from three, viz., Ports Adelaide, Wallaroo, and Pirie, so the trouble is not so great as appears at first sight. Then, again, the quantity of wheat produced is said not to justify the cost. Even if such is the case, production is decidedly on the increase, and we can confidently look forward within a few years to having on an average 20 to 30 million bushels for export. Another is that the shipping companies do not at present cater for bulk transport; but no doubt if the change were made they would quickly accommodate themselves to it, for the shipping companies generally favor the bulk handling, as it is quicker to load and unload, and less space is taken up by the cargo. Then, again, it is said that insurance on bulk cargoes would be hard to obtain, as the Underwriters' Association are opposed to the system. On a trial shipment from New South Wales some few years back no difficulty in this way was experienced as far as I can ascertain, and doubtless if the bulk system were adopted the Underwriters' Association would conform to it, as the fact that over 80 per cent. of the wheat imported into the United Kingdom is in bulk goes to prove, not only the general acceptance of the system, but that the risk of loss is no greater. Doubtless there are other difficulties, but they are more apparent than real. One thing is certain, I consider, and that is the opposition of the merchants and millers. When we consider that at present the traders fix the standard, fix the general level of prices in the country, determine the practice in relation to the purchase of wheat below and above the standard, determine the bag system (excepting the size), and also the conditions for storage, can we wonder if they see strong reasons for retaining the present system? Under the bulk system practically all these powers would be taken from them, and they would be placed on the same level as the farmers, and have to conform to the system, whereas at present the farmers have to conform to a system created and worked by them. The difference is great, and not likely to appeal to them; but the farmers have the numbers, and if they will, they can make the way. Now for some of the advantages of the bulk system. The first of these is the saving in cost of bags, which would perhaps be hardly noticeable for a year or two, but which would eventually be great. It makes grading possible, and instead of as at present only one standard, several grades could be recognised, both at home and for export, as is done in other countries, encouraging the farmer to grow better wheat and clean it better, and place each district on its right level. At present the districts which grow the better quality have their profits reduced to make up for the less favored. This also applies to the individual farmer. The cleaning of the wheat, which would be done in the elevators, would be a decided advantage, as the export of a purer sample would tend to create a better demand, and hence a better price; for at present it is estimated that South Australia exports 15,000 tons of rubbish in the wheat annually, which cannot be welcomed by the millers, although they are able to save themselves by grinding same and selling as pollard and bran. Nevertheless, a pure sample of wheat up to a certain grade must be more acceptable and worth more. There is also the reduction in manual labor, minimising the cost of handling. The difference would be much on the same scale as the difference between filling and handling a hundred-gallon tank with water, and filling, corking, and handling 100 gallon bottles. Then comes the question of weighing. Under the bag system each bag is weighed, and each time the buyer gets the advantage of the draft, whilst wheat in bulk is automatically weighed in 2-ton lots. The weighing question appears to be one of the chief objections of the English merchant against bulk, for although the draft is very small, when there are thousands of bags in question it mounts up considerably. Another consideration is damage by weather. Further, it would overcome very much of the present risk from reaping damp or underripe wheat with the harvesters, in that on being received at the elevators it would all be cleaned again. What is perhaps of most importance to the farmer is the question of storage. At present the farmer delivers his wheat to the merchant, and if he does not wish to sell, he receives his cartnote, and the merchant has his wheat to trade on. When the farmer wishes to sell, he has to take what the merchant offers, or receive an equal amount of grain at considerable expense to himself. Under the bulk system the farmer delivers his wheat at the elevator; it is cleaned and graded, and he receives a certificate which he can operate on as a credit note if he wishes. When he desires to sell, he is in a position to make the best possible terms with the merchants. It has been stated that bagged wheat brings 3s. per quarter more than bulk in London, and that an extra 2s. 6d. per ton freight and 1½ per cent. insurance would be incurred on bulk grain. The weight of evidence is decidedly against this. Even if Australian bagged wheat brings 3s. per quarter more than Argentine bulk, that does not prove anything, for the fact is, as related by one of the New South Wales leading millers who has lately returned from a business trip to England, that the quality of Australian wheat makes it very desirable for mixing with other wheats, thus increasing the demand for it. It is really worth more. There is no reason to believe that Australian bulk wheat would realise less than bagged, especially considering that it would be a much cleaner sample and therefore more valuable. Whatever can be said to support the above statements, it is very certain that the handling charges are considerably less, which would, together with the saving of bags, probably more than cover the difference if the statements quoted were proved to be true. It has been questioned whether wheat in bulk can be exported owing to the great distance to the oversea markets, but some years back a trial shipment sent from New South Wales by way of the Cape of Good Hope, was received in England in splendid condition, and realised practically the same as bagged wheat. Bulk handling is not unknown to Australia, for in New South Wales several milling firms have erected elevators for their own use, and as an instance of the minimising of labor under this system, in one of these elevators 13,680 bags were received by 12 men in one day. Receiving includes weighing and cleaning. Now to consider briefly the outline of a scheme for initiating the system in this State. In the first place attention must be given to the three ports (Adelaide, Wallaroo, and Pirie) by the erection there of what are known as terminal elevators, which would, for some time to come, be ample, as wheat could still be bagged, carried by rail as now, and when emptied into the elevators, returned to the farmers, as is done in some parts of America still. The bags, well cared for, would in this way last for several seasons. As this arrangement might lead to confusion, and the mixing up of different farmers' bags, a better system would be for the bags to be loaned to the farmers from the elevators from year to year as required, as is also done in America to a certain extent, and in England by the elevator companies to millers in the country to carry the grain which is received in bulk to their various mills, no facilities for carrying grain in bulk being provided by the English railway companies. As time went on the system could be further extended by providing elevators at the lesser ports, and by the Railways Department gradually and systematically replacing the present trucks by one suitable for the carriage of grain in bulk, which would at the same time be as useful for the carriage of other goods. Receiving elevators could then be erected at the country centres, preference being given to the places from which the greater quantities of grain were railed. This could be gradually extended until we would have the complete system, which would be permanent and far more economical than the present. The farmers would accommodate themselves to the new order by providing box wagons, facilities at home for the storage of grain in bulk, &c., thus practically doing away with bags altogether and effecting a great saving in cost. I have refrained from referring to the probable cost of initiation, for the fact that such information as is available is naturally conflicting to a layman, the difference in the material used being such an important factor of cost, and also that my object is not to urge the immediate undertaking of so great a scheme, but rather to impress on members the need of a better system than we have at present, and throw a little light on the system of bulk handling. Let me say, in conclusion, that it must look almost ridiculous to those on the other side of the world who see how very particular we are in classing our wool and grading our butter, apples, eggs, honey, &c., and yet we still continue to handle and market our wheat—which is Australia's second greatest source of wealth—in a most slipshod, rough and tumble fashion."

The Hon. T. Pascoe, M.L.C. (Minister of Agriculture) said that as this subject was mentioned at the Congress held in September last, he immediately set about making inquiries with the idea of seeing whether the Government could be helped in some way in coming to a conclusion on the matter. In a previous paper on the subject Mr. Lock had stated, perhaps a little more definitely than he had in his paper this day, that New South Wales had obtained an independent report from an outside gentleman on the matter. The gentleman who reported to the New South Wales Government, Mr. Burrell, was a member of a firm that supplied elevators. The trial shipment made from that State was really no test as to whether wheat in bulk cargoes will carry safely to Europe, because there were 1,000 tons of wheat in bulk in a ship carrying about 10,000 tons of cargo. The result of the sale of the bulk sample, so far as the information was available, was that the bulk sample averaged 3d. per quarter less than the bagged. He had had a report on the question prepared, and this read :—In dealing with the question of the adoption of the American system of handling wheat in bulk, one has to consider whether it is possible to adopt the system in its entirety or to modify it to suit local conditions. Under the American method most of the crop is harvested with the binder and threshed by steam or other power, the grain going direct from the thresher into small farm elevators or into box wagons which convey it to the country elevator or to the railway truck. Under local conditions this is impracticable. While modifications and improvements in our havesting methods will undoubtedly be effected, the principle of harvesting the wheat as rapidly as possible at least expense and with a minimum of labor will hold good for the bulk of our crop for many years. It follows, therefore, that if the system of bulk handling is adopted it must be modified to suit local conditions, and that it will not entirely obviate the use of sacks. Recently a Victorian Royal Commission furnished a lengthy report on this question, while in New South Wales Mr. Burrell, one of the principals of a large elevator construction firm, was engaged to investigate and report on this subject. The Victorian Commission unanimously recommends the bulk handling of wheat on the grounds of economy and efficiency, and for the benefit of the State generally. To start with, a system of storing partly in bulk and partly in bags at country stations, conveying the wheat in bulk to port of shipment and there bagging it for shipment, is recommended. Mr. Burrell recommends the adoption of bulk handling in New South Wales, carrying the wheat in bags to the terminal elevator until such time as country elevators can be established and proper covered trucks provided for carrying wheat in bulk. The Victorian Commission suggests that terminal elevators be erected at Williamstown and Geelong with a total holding capacity of 4,000,000bush., and later Portland, and country elevators at 194 centres, with a total capacity of 10,000,000bush., a gross total of 14,000,000bush. The cost of this provision is set down at £1,206,753, while the cost of alterations to present type of trucks to make them fit for carriage of wheat in bulk is set down at £95,435, or a gross total of £1,302,188. If covered trucks are used the cost would be £1,544,253. This elevator provision for only 10,000,000bush. at one time in the country districts, out of a total crop of 30,000,000bush. to 36,000,000bush., appears under the conditions prevailing in South Australia to be inadequate owing to the fact that all this wheat is reaped within a short period, and only a small portion is shipped during that period. Under this proposal the farmer would probably bring his wheat in tied bags to the country elevator, or railway truck or shed where there is no elevator. As the farmer must be prepared to go straight ahead with his reaping so long as the weather and crop are favorable he must make bag provision for at least 75 per cent. of his crop. As tied bags would not hold within 10 per cent. of sewn bags he would therefore require approximately 84 per cent. of the bags he now uses, even if the elevator capacity were sufficient to deal with the wheat as rapidly as it reached the station. These bags, under the best conditions, would not be safe to use after the second year, and even then special receptacles would be needed to store them to prevent injury by mice, &c. Each year, therefore, the minimum cost for bags would be 42 per cent. of the cost under the present system. On a 24,000,000bush. crop the cost of bags at 6s. per dozen would be £200,000, but the farmer receives back approximately £50,000 in selling bags as wheat; the net cost, therefore, is £150,000. Under the system recommended by the Victorian Commission the cost for bags would be 42 per cent. of £200,000—£84,000, or £66,000 less than under the present system. This equals an annual charge of ·8d. per bushel for the use of the bags.

The Victorian Commission estimate the cost of loading in and out of trucks and sheds and into vessels under the present bag system at 2·98d. per bushel. Under the complete elevator system with bulk shipment by steamers specially fitted for the trade the cost would be 1·90d. per bushel; if bagged for shipment 3·93d. a bushel; under the scheme proposed involving shed accommodation for portion of wheat bagged, 3·37d. a bushel. No storage beyond two weeks is provided for in these figures. Although the report states explicitly that the estimate of 2·98d. per bushel under the bag system is for handling alone (page 67), figures elsewhere (appendix, page xxiii.), show that this cost includes cost of bag, which is equal to 1½d. per bushel net. Under the system recommended it would be necessary to provide for the cost of conveying the wheat in bags from field to elevator as under:—Use of bag, ·8d. per bushel; unloading and emptying bags into bin or truck, and looking after bags, say

·1d. per bushel; total, ·9d. per bushel. If these figures are added to the estimated cost of the complete elevator system with bulk shipment it shows a total of 2·80d. per bushel, against 2·98d. under the bag system. While, as will be shown later, the cost of the elevator system is probably too low, the handling cost of wheat in bags is not under-estimated. In South Australia lumping is done at piecework at 1s. 1d. per ton of 12 bags in and out of stack. A certain portion is loaded direct to truck and goes direct to the ship's side, in which case the total cost is about 1s. per ton. Where the wheat has to be wheeled or carried from truck across wharf to the ship the cost is approximately 7d. per ton. The practice is to avoid extra handling as far as possible, and when all these points are considered it is fair to assume that the cost averages nearer 1½d. per bag than 2d.

New South Wales.

Mr. Burrell, the American expert, in his report to the New South Wales Government, recommends terminal elevators at Sydney and Newcastle, the construction of covered box-cars, and also the erection of 25 country elevators. The total capacity of these elevators is, however, only 4,500,000bush., and he suggests that the Farmers' Co-operative Associations should erect their own country elevators. The capital cost of the proposed scheme is £854,000, compared with the Victorian estimate of about £1,250,000 for over three times that amount of storage. The Sydney terminal elevator, to hold one and a half million bushels, is estimated to cost £163,000, against the Geelong terminal elevator to hold one and a quarter million bushels at a cost of £124,700. Mr. Burrell's estimate for country elevators to hold 100,000bush. and 50,000bush. is £13,400 and £7,800 respectively, against the Victorian cost of £4,500 for a 60,000bush. elevator. It will be seen that the capital outlay per 10,000bush. in large elevators is £1,080·66 in New South Wales, and in Victoria £997·6; for the country elevators the costs are £1,560 and £750 respectively. Mr. Burrell recommends as a start that the terminal elevators be erected and the wheat sent to them in bags, to save loss on bags shipped, which he put at £160,000. As the farmer will need a full number of bags, which will only last two years, the supposed saving is reduced at once to £80,000; then, as the farmers get the equivalent of 1½d. a bag in the sale of their wheat, this must be further reduced to from £40,000 to £50,000. Mr. Burrell does not enter into much detail as to cost of handling from start to finish, but puts the cost at a country elevator handling 400,000bush. at ·4d. per bushel, and at terminal at ·25d. per bushel; but it is not clear whether this includes loading into the ship, interest on capital, &c., as given in the Victorian estimate of 1·90d. per bushel. Mr. Burrell's recommendation appears to be based almost entirely upon losses sustained in the present system of bagging and the saving of cost of handling bags, and he quotes the following figures of costs and losses on 1,000 bags of wheat:—(*a*) Damage from damp ground when stacked in field, £1 5s.; (*b*) loading and unloading at railway station, £4 10s.; (*c*) damage from weather at railway station, £5; (*d*) rebagging at railway station, 10s.; (*e*) handling and power at Darling Harbor, £4 13s.; (*f*) waste from bags, £4 17s. 6d.; (*g*) bags, £29 1s.; (*h*) covering stacks and railway wagons, 12s.; or a total of a little over 4d. per bushel, against a cost of ·65d. per bushel (?) for handling in bulk at country and terminal elevators.

These figures, however, are open to serious criticism. (*a*) Damage in the field will be no less where the wheat is bagged from the harvester and carted to the country elevator. (*b*) There will be some expense for unloading, opening, and emptying bags into the elevator or truck. (*c*) Damage from weather is excessive in comparision with local experience, amounting to approximately the loss of 10 bags in 1,000 (1 per cent.). Mr. Miller (of the South Australian Farmers' Union) stated in Parliament that two years ago, when losses were above the average, the Union, on the handling of 3,500,000bush., lost in actual weight 11,000bush., or about ·3 per cent. In the average of years it is very doubtful whether the loss equals ·1 per cent., against Mr. Burrell's allowance of 1 per cent. (*d* and *e*) Comparison is difficult, but the cost per ton from shed or truck to ship under South Australian conditions would not be more than 6d. or 7d. per ton; Darling Harbor charges are apparently 1s. 1d. in and out. (*f*) This waste from bags is again nearly 1 per cent., surely an excessive figure. (*g*) Bags—as previously shown, even under the elevator system, the farmer would still be at an expense of about ·8d. per bushel with the complete elevator system, and over 1d. under a system by which there are elevators only at the principal stations.

Taking these figures together it appears that under South Australian conditions the estimated cost under the bag system should be reduced to about 3d. per bushel, and the cost under the elevator system increased by 1½d. to 1¾d. per bushel. It may be noted here, however, that the Victorian costs of working the country and terminal elevators is 1·90d. against Mr. Burrell's ½d. In America the charge for this work (including cleaning) is ⅞d. at country and ⅜d. at terminal elevators (storage for 15 days and insurance included), or a total of 1¼d. per bushel. A partial adoption of the elevator system will cost more than the present bag system, apart altogether from the question as to whether wheat in 3-bush. bags will realise more than bulk wheat. It is admitted that in the old 4-bush. bag this was the case. The whole advantage of the elevator system appears, then, to be (1) in the saving of waste—and it is extremely difficult to say what this amounts to; and (2) in relieving the farmer from alleged disabilities imposed by the wheat buyers.

Certain aspects have not been touched on in arriving at these alleged savings in cost set out in either proposal. (1) There will only be a partial saving in handling and losses unless there are elevators at every station or sufficient trucks to enable the farmer to empty his bags without delay. (2) In neither scheme does sufficient elevator provision appear to have been made to handle the wheat in the short period in which it must be handled if there is to be so much economy in bags and handling. To deal with the wheat as it arrives, it is more than probable that the elevator capacity required would need to be one-half—certainly not less than one-third—of the wheat received. The Victorian Commission's report (page 12) shows that the maximum quantity in storage at any one week in the different districts varied from 25 per cent. to 52 per cent. of the total aggregate received for the season. Of the total quantity of 26,000,000bush. received at railway stations in 1910-11 during 10 consecutive weeks the quantity of wheat stored at country railway stations exceeded 33 per cent. of this aggregate (Appendix 7, page xxx). (3) The Victorian figures of cost of handling in bulk are based on shipment in steamers specially equipped for handling wheat in bulk. It is not shown that the freight in such steamers would be the same as for bagged wheat. For sailer shipment it is admitted that the handling cost per bushel would be over ½d. per bushel more than quoted, *i.e.*, 2·42d. against 1·90d. (4) Our wheats are used chiefly for mixing with other wheat for milling, and when bagged can be handled in large or small lots at any port. This could not be the case with bulk wheat without added cost in many instances.

COST TO SOUTH AUSTRALIA.

It is difficult to even suggest with any claim for accuracy what elevator provision would be found necessary under actual working conditions, as the rapidity with which the wheat crop is handled depends upon—(1) the amount of the crop; (2) the ruling prices for wheat, and consequently, whether farmers sell or hold their wheat; and (3) the freights available. Taking the Victorian basis (of working an elevator capacity of approximately one-third of the quantity of wheat actually received at the railway station), provision would be necessary for—terminal elevators, capacity of 2,000,000bush.; country elevators, capacity of 6,000,000bush. Total, 8,000,000bush. This would cost for the elevators and necessary machinery (according to Mr. Burrell's estimates) approximately £1,059,000. That the provision of 6,000,000bush. country storage and 2,000,000 terminal is the minimum, even with present area under crop, is shown by the following facts:—(1) During 1911, for a period of about 15 weeks, the quantity of wheat stacked at railway stations and railway ports, not including Port Adelaide, exceeded 6,000,000bush., and for four weeks exceeded 9,000,000bush. (2) Of the total quantity of wheat shipped oversea as wheat the quantity not shipped by February 1st, in 1911, 1912, and 1913 varied from 11,500,000bush. to 16,000,000bush; and quantities not shipped by April 1st, from 7,000,000bush. to 14,000,000bush. Storage for all this, in addition to local and export requirements for flour, would require to be provided for, unless the wheat was shipped much more rapidly than it has been in the past. This does not include any provision at country stations receiving less than 20,000bush. in either 1911-12 or 1912-13.

It must also be remembered that wheat must be handled in bags at all our shallow-water ports, or ports where the oversea ship anchors some distance from the jetties, or where the business does not warrant an elevator.

The following figures, supplied by the Marine Board, show the quantities of wheat shipped from the various ports under the Board's control where the elevator could not be used economically :—

Port.	Shipped— January-July, 1913. Bushels.	Stored— July 31, 1913. Bushels.
Kingscote	675	—
Hog Bay	75	—

Stored	380,853	
Total	2,895.336	

In trying to arrive at the cost per bushel for handling wheat in bulk under South Australian conditions it must be borne in mind that out of a total crop of 24,000,000bush., between 3,000,000bush. and 4,000,000bush. are retained on the farm for seed and feed purposes, and say 3,000,000bush. are handled at shallow-water ports where elevators cannot be used. It follows, therefore, that interest, depreciation, and working expenses will form a charge on 17,000,000bush. Some of this will be handled more than once, but as this cannot possibly be estimated it must be ignored.

The following figures show what these charges would amount to (based on Victorian estimates) :—Interest at 4 per cent. on £1,059,000, £42,360 ; depre ciation and maintenance of buildings at 2½ per cent., £12,500; depreciation and maintenance of machinery at 8½ per cent., £47,515; total, £102,375; equal to 1·44d. per bushel. The Victorian estimates of working expenses (labor and fuel) based on the assumption that the country elevators will handle three times their total capacity each season, varies from ·5d. per bushel to ·9d.; in addition the working expenses of the terminal elevators, on the assumption that a 1,000,000bush. elevator will treat 6,000,000bush. during the year, came to ·14d. per bushel. Assuming that the actual working expenses at both country and terminal elevator will average ·75d. per bushel, we have the following figures as the cost per bushel of bulk handling under South Australian conditions:—Use of bags, ·9d.; interest, depreciation, and maintenance, 1·44d.; working expenses, ·75d.; inspection, weighing, and trimming cargo, ·15d. (Victorian estimate); total, 3·24d. Against this the present cost of shipping in bags (Victorian estimate):—Bags at 6d., 2d. per bushel; stacking in shed at 1d. bag, ·33d. per bushel; out of shed at ½d. per bag, ·17d. per bushel; local agent's charges, ·50d. per bushel; weighing, ·01d. per bushel; stevedoring at 1s. 6d. per ton, ·50d. per bushel; total, 3·51d.; less value of bag sold as wheat, ·53d.; net cost, 2·98d. per bushel.

On these figures bulk handling is, under local conditions, directly more costly than bag handling. It must be pointed out that in the Victorian estimate of 1·90d. per bushel for bulk handling, country and terminal elevator charges amount to 1·75d. per bushel, whereas in this estimate they total 2·19d., due to difference in cost of elevators, and further the Victorian estimate makes no provision for cost of bags which the farmers must use. In the circumstances it would appear that whatever the indirect advantages to be derived from the adoption of bulk handling in South Australia, there would be an added cost of approximately ·26d. per bushel in the 17,000,000 bush. handled by the elevators.

Mr. H. G. Hawkins (Port Pirie) said apparently previous speakers on this subject had based all their calculations on shipment to the United Kingdom. A large business in wheat was done with South Africa and South America. which places had no facilities for bulk handling. Nothing but wheat in sound sacks would be accepted there. South America would not accept wheat from the United States, because it was in bulk or in hessian bags. He read the following extract of a letter from Messrs. Berry, Barclay, and Co., of 15, Leadenhall Street, London, E.C.:—

> SHIPMENT IN BULK.—This is a question which seems to arise whenever bags are dear, and shippers seem to lose sight of the fact that the buyers also take this question into consideration, and would not be able to pay so much for the wheat if the bags were not included.
>
> The chief objection to shipping in bulk is that the cargo would be much more liable to shift in a storm, and the dangers of the voyage would be increased, so that the rates of insurance would be greatly enhanced. An attempt was made some years ago to ship parcels by general cargo steamers provided with separate bins, but this was not repeated because, although the wheat travelled fairly well, the lower prices obtainable for it took away the anticipated profit.

The bags are of great advantage when the wheat has to be transhipped into other vessels, or forwarded by rail, as frequently happens, and in those ports where elevators are employed, the wheat can be easily shot down and worked through the elevators.

After considering the matter thoroughly we have come to the conclusion that the plan of shipping in bulk would not be feasible from Australia. It would upset the present system of shipping and handling on the farms, as well as on the railways, and we think the disadvantages we have named would greatly outweigh any benefit that might be gained by it.

Our friends, the Yankees, are generally fully alive to their own interests and have no doubt considered the question in all its bearings. They ship their red wheat, which is harder, and comes by steamers in seven or 14 days across the Atlantic in bulk; but their white wheat from California, Oregon, &c., which is brought mostly by sailing vessels on the three or four months' voyage from the Pacific round Cape Horn, is invariably shipped in bags.

Mr. F. Coleman (Advisory Board) said his opinion on this question had been very much strengthened by the report read by the Hon. Minister. It would be wise for this State to wait and see the result of the action of New South Wales. Conditions were more favorable in that State. With regard to the question of grading, he said Australian wheat was valued higher than any other on the English market. It was a fact, nevertheless, that they were sending home a great deal of grain of which they should be ashamed. He had used the harvester, and in his opinion this machine had come to stay. From Cardiff came a complaint that the wheat from Australia was smelling of eucalyptus and lavender. The elevator system would enable them to clean and grade their wheat. Australian wheat was too thin in the skin to stand the handling that it would receive in bulk, according to the statement of a leading English miller. He urged farmers to send out their wheat in the best possible condition.

Mr. W. F. Nicholls (Narridy) had noticed a tendency in South Australia to underrate the quality of the wheat produced in that State. They should not decry that article which they had to market. Merchants should take a stand against the practice of farmers rushing their wheat into the stacks so soon as a damp day was experienced during harvesting.

Mr. E. J. Pearce (Whyte-Yarcowie), who had read Mr. Lock's paper in the writer's absence, thanked the Conference for the manner in which it had discussed the subject. In Canada, they had portable granaries which they used to transport the grain from the harvesters to the elevators. He thought that not more than 50 per cent. of the bags at present in use would be required if the system were introduced. In shallow ports they could use floating elevators to take the grain to the deep-sea boats.

EVENING SESSION.

NEXT CONFERENCE.

After a lengthy and animated discussion, it was decided that the next conference should be held at Crystal Brook.

SHEEP AND FORAGE CROPS.

At the Agricultural Bureau Conference held at Saddleworth last year, the Director of Agriculture dealt with the subject "Sheep and Fat Lambs." In continuation of this subject, this year he spoke on the growth of fodder crops for feeding off with sheep.

LIME.

At the outset, he mentioned that he had been requested to deal with the subject of lime; but he explained that, although the practice of using lime in many parts of South Australia was one to which the farmers could scarcely give too much attention, in the Northern Areas the pressure did not obtain. It was characteristic of the class of country with a rainfall of from 13in. to 20in. that the elements in the soil which were most likely to be lost were not leached out, and the percentage of ingredients such as lime was always high. Except possibly on the excessively stiff claypans, they would scarcely see any advantage from an application, and it certainly would not repay the expenditure.

GROWING CROPS FOR STOCK.

The greatest development in agricultural practice that could be made at the moment, and the most profitable, was the better management of sheep on the farms. Farmers had grown so accustomed to pay their whole attention to wheat that the other factors which made for the wealth of the output were to a large extent lost sight of. He did not advocate that less attention should be devoted to that product for which those regions were so admirably adapted, but was convinced that if they gave more attention to sheep they would grow better crops of wheat, and, although the area might be a little reduced, the total output would be greater. There was a monotony about the continuous fallow and wheat, fallow and wheat. If they grew wheat, however, and kept stock, and tried to excel with that stock, there would be no desire on the part of the farmer to retire—it would be impossible to drag him off the farm.

MIXING THE BREEDS.

In the matter of horses, they would find uninformed men mixing Shire and Clydesdales, without any qualms of conscience whatever, and taking up positions as breeders. If the men would work up a knowledge of the biology of stock and the principles of heredity, they would never mix up two breeds like that. If the one breed did not meet their demands, in weight, or something else, they would bring about the improvement from within the breed itself. They would not find sheep men who were properly informed putting the Lincoln on to first-class Merinos with the idea of getting a longer staple. They would never get it. Mendelism had shown that the correlation of these different characters was such that they could not separate the dominant and the recessive. In his opinion, when they were dealing with the stock they had to go back to the traditions of breeding, and work by that knowledge.

WHEAT AND SHEEP.

With the idea of demonstrating the results likely to be secured from the judicious use of sheep on the wheat farm, he took as an instance a 640-acre holding; 300 acres of this would be under wheat and 300 under fallow, if it were to be worked on the prevailing wheat-and-fallow system. At 3s. 4d. a bushel, a 21-bush. harvest would return £910, representing a net return, after seed, &c., had been taken out, of £820. The alternative system which he proposed would mean that there were 200 acres of crop, 200 acres of fallow, and 200 acres of stubble-growing. Probably the figures would be challenged if he were to give a bigger average for the 200 acres, but if he took it at 21bush. it would return, less the amount retained for seed, £571. That left £288 to be made up. With a large proportion of the land represented at that conference, the 200 acres left out would each carry a ewe and a lamb. With the little picking to be obtained from the fallow before it was ploughed, and the run on the stubble and the fallow, it would carry 280 or 300 sheep. A sheep of the proper type, well managed on the farm, was worth £1. They had then the lamb and the fleece. Taking it at 16s. 8d. he was well within the mark. The deficit on the wheat cheque from the 200 acres, compared with the 300 acres, was £288. The 280 sheep at 16s. 8d. would return £233, which brought the difference to £55. If there were a man in the room who could put in 100 acres of wheat with manure, and take it off, and buy the bags, and deliver it to the station for £55, he could teach them something.

GRAZING VALUES.

Most of those who were putting in the smaller area, however, were not getting the best of the sheep. There was an extensive area on which the rainfall averaged from 18in. to 25in., and where to have one-third of the farm under fallow was not the game. To some extent this was much more difficult to oppose than the ordinary wheat and fallow practice. In the higher rainfall district they could secure the fallow results, and at the same time get something more from the land than bare fallow. If they worked it up in the autumn and put in a fodder crop the following wheat crop would not suffer. The thoroughness of the fallowing on the three years' system left the grazing of less value, because few weeds remained. It was said that the harvester returned the weed seeds, but the fire was run over the stubble. This system was good, but they could go further. They could grow forage crops. Those with the lighter rainfall might work out the problem for themselves whether they could not put a portion of the fallow in with a forage crop to be grazed down with sheep, and throwing the rotation on that part out a year.

VARIOUS FORAGE CROPS.

The crops in the public attention at present were peas, rape, mustard, Italian rye grass, and vetches. Peas were not ascendant. If they tried the others in the normal season, they would very likely find that peas did not work out the most profitable. They should get this crop right round the farm in a cycle of a few years. Under similar conditions, in a season when the weather broke at the end of March or the beginning of April, they would find that rape, with a little mustard mixed, or barley, would produce more feed than peas.

The average carrying capacity for the last three years, of 2-acre blocks of land ploughed up and sown to Italian rye grass at Aldinga had been 10·6 sheep for five months. Of course, if the sheep had been put in for five months continuously the land would not have carried that number. A larger number had been put in for a short period, and when they had eaten the feed down they were put on to the next plot. It was in this respect that rape and rye grass gained an advantage, because while the other plots were being fed off, they were gathering strength. Oats had during the same period averaged 10·5 sheep; peas, 7·82; mustard and rape, 11·13; and barley, 10·36. The year just passed was very bad for peas, and thus had brought down the average.

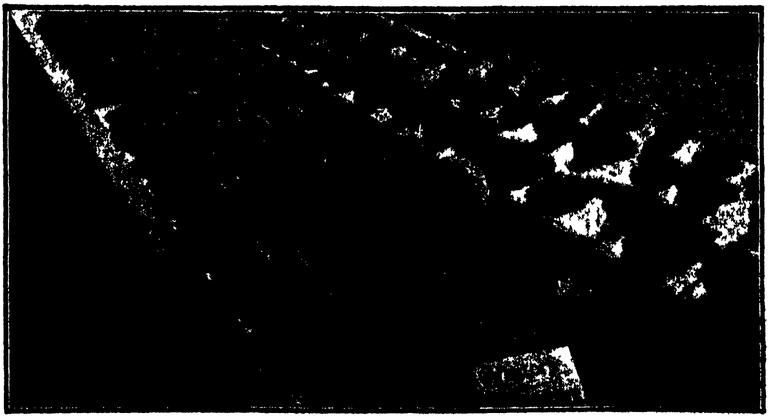
If they were able to get 3s. 4d. to 4s. for fattening a sheep, and could fatten that number, there was money in it. If they cared, they could increase the number of ewes, and fatten the lambs. When they were using manure on the wheat crop, they could spare a little to top-dress the grass land. The result would be astonishing. At Aldinga, natural grass dressed with 1½cwts. of manure had carried up to 10·8 sheep for five months. It was not fed continuously, and this was a point that had yet to be learned. It was essential to take out the sheep from time to time, to allow the field to become sweetened. Farmers should keep a bigger strength of horses. Under present conditions, they could not find time to put in the forage crops properly. To do this it might be necessary for them to keep two or three more horses than they would otherwise have. These should be brood mares. They could be worked at that time, and would not be wanted during the harvest, when they had foals at foot. They would earn their keep by getting a 20-acre or 30-acre crop put in well.

INFERIOR LAMBS.

At the slaughter-yards they could see thousands of lambs in a hard and unfinished condition. These returned from 11s. 6d. to 13s. If the growers had had forage crops on which to wean the animals the price would have been from 17s. to 19s. With a heavy rain in March, they should work the hay stubble well, and put on 1cwt. or 2cwts. of manure, and sow with 4lbs. or 5lbs. of rape, and 2lbs. or 3lbs. of white mustard, or some barley. If they got it in before the moisture was out of the land, they would fatten 10 or 14 sheep to the acre on it. This had been done at Aldinga in a dry year. They had the choice of rape, peas, Italian rye grass, oats (not Algerian), and barley (*i.e.*, the better type of six-row). If the latter were put in at the rate of 2bush. to the acre, it would be up a long way ahead of the grass, and this could be spared and allowed to gather strength. If one-twelfth of the area under fallow within the country represented at that conference in a normal year were thoroughly put under rape, given that one-third of the farm was out in stubble or herbage, they would be able to fatten half a million lambs.

ODDS AND ENDS.

In reply to questions, the Director said peas and vetches encouraged weeds, and the fallow crop was handicapped in that way. If the peas were put on fairly clean land, the wheat could be sown immediately following. Early Dun peas were the best. The Partridge variety would give a better wealth of feed, but it was later. He had had no experience with silver beet as a fodder, and would hesitate to expect a fraction of the results that had been obtained with it in New Zealand. He was sorry they were discarding the old strongly-built scarifier that was in favor 20 years ago. He did not see any advantage in use of super. at the time of fallowing as well as at sowing. If they applied it early in the season while the moisture was there they might get increased ferment activity, but the man who was using sufficient phosphatic manure would have the benefit of the reserve from the previous crop. It was practically impossible to leach phosphate out of the land. On the average the best time to feed off peas was when they had ripened and had been allowed to lie. When there was a good demand for lambs, and the lambs were well forward, and the peas were beginning to pod, there might be an advantage in feeding them off. However, when caterpillars appeared, the peas should be fed off at once. In the districts with a heavy rainfall—18in. to 20in.—they would find it an advantage to increase the quantity of seed to 2bush. of peas.



Fruit Exhibit, Adelaide Show.

THE WHEAT MARKET.

Commenting on the wheat position in England, *Beerbohm's Evening Corn Trade List* of January 23rd states :—" The world's shipments to all destinations last week were on an immense scale for the time of year, amounting to no less than 2,020,000qrs., of which North America contributed 990,000qrs. and Australia 375,000qrs. This is easily a record for January, the previous largest total being for the week ending January 30th last year, when the shipments amounted to 1,740,000qrs. The proportion to Europe last week was 1,840,000qrs., including 900,000qrs. for the United Kingdom and 'orders.' This shipment is all the more exceptional insomuch that India shipped practically nothing. Argentina has hardly commenced moving her new crop, and the recent holidays in Russia interfered with exports from that country. It is very improbable that, for a long time to come, North America will again give us such a large quantity as was shipped last week, but the movement is expected to continue on a fairly liberal scale, and, with Australia exporting freely, a moderate increase in shipments from Argentina, and fair quantities from Russia and the Danube, the weekly total promises to be fully equal to requirements. This week's total, however, promises to be quite a moderate one.

" Imports into the United Kingdom last week were quite small, so that, notwithstanding considerable deliveries of English wheat, the total supply was 65,000qrs. below the estimated requirements. Arrivals on the Continent were also quite moderate, and, as a result of the heavy exports, the quantity afloat increased by 790,000qrs. The United Kingdom imports promise to be fairly liberal in the next fortnight, and stocks will probably increase slightly.

" The estimates cabled over from Australia vary considerably as to the probable quantity of wheat available for export this year, ranging from about the same as last year, viz., 6,535,000qrs. up to 8,000,000qrs. ; in 1912 the exports were 5,100,000qrs. Meanwhile the outward movement is in full swing, and exports will, no doubt, continue large during the next three months.

" If the final official estimate of the last Canadian crop be correct, viz., 29,000,000qrs., against 25,000.000qrs. in 1912, then the reserves left in farmers' hands, notwithstanding that to date they have delivered 3,000,000qrs. more than last year, are quite as large as a year ago. This does not agree with the reports cabled over from time to time during the past few weeks, to the effect that much less wheat was in farmers' hands than last year. The reasons given for the much larger movement from the farms to date are exceptionally favorable weather for moving the crop, better railway facilities. and the financial state of farmers. Time will prove whether this latest estimate is correct or not, but, considering that it is based on actual threshing results, it ought to be nearer the real quantity than the earlier estimates. Winter wheat in the United States is coming forward more freely, and these supplies are likely to increase so long as crop prospects are favorable ; any serious change in the crop outlook would, however, probably check the movement."

Steamer Freights.—(March 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 25s. per ton (8d. per bushel); to South Africa, 22s. 6d. per ton (7⅓d. per bushel). Parcels, Port Adelaide to London-Liverpool, or Continent, 25s. per ton (8d. per bushel); Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel); to Sydney, 10s. 6d. per ton (3¼d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 25s. per ton (8d. per bushel); South Africa, 21s 3d. to 22s. 6d. per ton (6¾d. to 7⅓d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on March 2nd—

Butter Factory.

Owing to the hot spells experienced during the month the supply of cream has been somewhat unsettled and is falling off gradually. In consequence the prices have been on the rising grade, the present prices being—superfine, 1s. 4d. per lb., and pure creamery, 1s. 3d. per lb.

A. W. Sandford & Co., Limited, reported on March 2nd—

Butter.—The extreme heat experienced during February has lessened quantities of butter considerably, so that heavy importations have been necessary to fill up the shortage, with values improving about 2d. since our last report, but this applies only to top qualities, second and third grades being slow of sale. Best factory and creamery, fresh in prints, realised 1s. 1d. to 1s. 4d. per pound; choice separators and dairies, 11d. to 1s.; store and collectors, 8d. to 9d.

Eggs have experienced a seasonable advance, the supplies arriving being large for the time of year. Hen are selling at 11d. per dozen; duck, 11½d.

Cheese is also showing a firming in price, owing to the heavy parcels exported relieving the market. Present quotations 6d. to 6½d. per pound for large to loaf.

Bacon continues to rule at high rates, and as the live hog has been very scarce there has been no difficulty in placing all consignments coming forward. Best factory-cured sides, 10d. to 11d. per pound; hams, 1s. to 1s. 1d. per pound; lard in skins, 8d.; bulk, 7d. per pound.

Honey is in good request, both for local and export, purchasers realising that the take is not as heavy as was first anticipated. Prime clear extracted samples, 3d. per pound; beeswax, 1s. 2d.

Almonds.—Small parcels of the new crop are now arriving, but quantities are not nearly equal to trade wants. Brandis, 6d.; mixed soft-shells, 5d. to 5½d.; hard-shells, 3d.; kernels, 1s. 2½d. per pound.

Live Poultry.—Good demand continues for poultry, especially where quality is right. However, there is still a large proportion of small and light birds, and such only find slow sale. Good table roosters realise 3s. to 3s. 6d. each; nice conditioned cockerels, 2s. to 2s. 6d. (small and light birds lower); ducks, 2s. to 2s. 6d.; geese, 3s. to 3s. 6d.; pigeons, 5½d.; turkeys from 9d. to 11½d. per pound live weight for fair to prime table birds.

Potatoes and Onions.—There has been an uninterrupted supply of potatoes from Mount Gambier and local sources, and values have not altered. As usually happens after a spell of dry weather, the grub pest has made its appearance in the ripened crops, and there has been some difficulty in getting samples reasonably free from damage. **Onions.**—Owing mainly to the operations of a few buyers for export this market has managed to hold its own, and as reports concerning the Victorian crops are not now so favorable, growers have a tendency to hold back supplies. Present prices—Potatoes, £4 2s. 6d. per ton on trucks, Mile End or Port Adelaide; 4s 6d. to 5s. per cwt. in the market. Onions.—£7 per ton on trucks, Mile End or Port Adelaide; 6s. 6d. to 7s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of February, 1914, also the average precipitation to the end of February, and the average annual rainfall.

Station.	For Feb., 1914	To end Feb., 1914.	Av'ge. to end Feb.	Av'ge. Annual Rainfall

* No report received during the month of February. † Formal report only received.
‡ Held over until next month.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

March 11th and April 8th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

QUORN (Average annual rainfall, 13·78in.).

February 7th.—Present: six members.

The Season's Harvest.—Mr. Brewster read a paper. The rainfall during the past season, he said, was the lowest recorded for some years. Very little wheat in this district germinated before August. Better results, he thought, would have been secured had the seeding been completed after the first good rains in March or April. Federation was the best wheat for the district. Baroota Wonder and Bunyip were also suitable. Cocky chaff had been of considerable value during the past two seasons, and on this account the use of the stripper was advisable. Mr. Cook preferred to distribute the seeding over a reasonable time. Mr. Schultze advised early sowing in clean land.

TARCOWIE (Average annual rainfall, about 15½in.).

February 10th.—Present: 12 members.

Storing Wheat.—Mr. T. Ninnis contributed a paper on storing wheat on the farm. A good barn was of great importance, especially in wet districts. Galvanized iron was the best and most economical material for building this. Good ventilation was necessary, and a good plan, where the farmer intended storing the wheat for a few months after harvest, was to stack it in a good shed with a straw roof. This was cooler than iron. Wheat for seed stored in the open should be placed on sufficient dunnage to keep it well off the ground and with an iron roof to keep out rain. There was less trouble with smut in crops sown from seed stored in the open. If mice were troublesome the bags should be placed far enough apart to enable a cat to get between them, pieces of newspaper being placed between the bags. The mice would then nest with the paper instead of destroying the bags. Where the farmer possessed a good barn, and intended keeping the wheat through the winter, and the mice were very troublesome, he could empty the wheat into a heap, as they could not burrow into loose wheat. The writer emphasised the necessity for protecting the wheat from damp and stacking it in the open. In the discussion which followed, Mr. Breuer said the barn floor should be made of concrete. Care should be given to ventilation. Mr. Symon preferred a wooden floor. Mr. Dempster thought that as wheat gained by storage, the practice of holding the wheat on the farm paid for the extra trouble. Competition for the line was encouraged also.

WIRRABARA (Average annual rainfall, 18·91in.).

February 14th.—Present: 18 members and several visitors.

Root Borer.—Mr. P. J. Curnow read a paper. "In every old garden in this district can be found old apple trees suffering from 'die back.' Various reasons are given for the dying off of the top branches of these trees. In some cases where rows of trees cross low-lying ground that becomes waterlogged in the winter, the feeding roots die off and the tree soon shows signs of loss of vitality. Even on dry, rising ground apple trees die off and finally die out altogether. This experience befel the writer years ago in the Wirrabara Forest, when planting his first orchard. On limestone land the apple trees grew well for a number of years, when many showed signs of 'die back' in the tops. A careful examination of the main roots showed no disease, and it was concluded that the dry seasons then experienced on land without a clay bottom were the cause. Quite two-thirds of this orchard was affected. Trees, when cut back, would grow again, and then die back to the starting point in one season. Realising that this orchard would become unprofitable, the writer then planted a new one on better land, although a strip of limestone crossed this. When the trees were four years old some on the lighter ground commenced to go off. The next season a large number were affected. Realising that some pest was at work, a careful search was made. Trees were dug out bodily and long roots were followed out to the feeders. The larvæ of a beetle was found in a tunnel 2ft. and 3ft. around the roots. A yellowish-white grub was found in August. It was about ½in. long, and afterwards developed into a beetle 1in. long. This insect has since been studied and its habits noted, and the following facts ascertained:—It is a root borer, and belongs to the family *Teptops*. The variety found in the Adelaide hills is known as *Teptops robusta*, and that at Wirrabara is a sub species, the markings not being quite the same. The fearfully destructive Victorian species is known as *Teptops hopei*, and is said to be worse than our own variety. Forty-four varieties of these root borers have been identified in Australia, so that these destructive insects are widespread in the various fruit-growing districts. During the winter months the larvæ remain dormant. As spring approaches the grubs gradually change to the beetle form and emerge at the end of September and into October and November. In October the two sexes go into the tree tops to copulate. The female deposits her eggs on an apple leaf, brings the edges together, fastens with a sticky substance, and then, presumably, dies. The eggs hatch, and the young feed on the leaf substance up to a certain period, when they descend the tree trunk, enter the earth, and start the work of destruction. They gnaw the root bark and eat spirally around the roots, really ring-barking the tree feeders. The orchardist first notices the leaves on an affected tree withering. Later, limbs start to die back, and in a badly affected case (where scores of grubs are eating at once) all the leaves drop in one season. If nothing is done, next season the same grubs go on gnawing, and the tree will die right out in a few weeks after starting growth. After soil fumigation had been tried picking the beetles from the trees was resorted to, with fair results. Nearly 600 beetles were caught the following spring after the application of the above remedy, and since then no other plan has been adopted. On the orchard at first attacked it was noticed that affected trees began to recover as soon as arsenate of lead sprays were adopted, and some of these trees have so far recovered that they now bear payable crops. On the new orchard the trees were yet young when attacked and had never been sprayed for codlin moth. They have now been sprayed for three seasons, and the root borer has been checked, for no doubt the beetles fed on the poisoned leaves and are thus destroyed. As many as four and five dead insects were picked last spring from under one tree the day after spraying. These root borers do not hatch after entering the soil for at least three seasons. They thus go on with their destructive work as they grow, and are very difficult to kill with a soil fumigant. The only plan to adopt with young trees in an affected orchard is to hand pick the trees every 10 days during the spring months. Give each tree a vigorous shake and the beetles curl up their legs as though dead and drop to the ground. They can then be killed. As soon as a good arsenate of lead spray is used no further trouble will occur. After the apple trees in the new orchard died out, peaches were at once put in. The grubs attacked these, killing many the first season. It is wise not to dig out the old stumps and plant peaches straight away. It would be better to leave the holes empty for one season. Then the grubs would hatch out and the trees would not suffer. This plan has been found to work very well.

COOMOOROO, February 14th.—Wounds in Horses.—The Chairman (Mr. E. Berryman) dealt with this subject in a paper. Mr. E. Brice advised the use of carbolic for treating wounds. Blacklead and lard, applied before the harness was put on and after the day's work, was good for sore shoulders. Mr. Barber recommended boot blacking and beer for treating skin deep wounds.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

NORTH BOOBOROWIE (Average annual rainfall, 16·35in.).

November 12th.—Present: 17 members and 12 visitors.

Wheat-Cleaning.—Mr. S. E. Mudge read a short paper. The winnower should be firmly fixed, he said, and if a good steady wind prevailed this should slightly cross the machine. A straight belt on the machine was preferable, and a fork or shovel far superior to a dish for filling. Two sieves were sufficient, an oat sieve only being used when the grain was being put through a second time.

Short addresses were also given by Mr. F. E. Waddy, "Stooking"; W. C. Warner, "Stack-building"; W. E. Hannaford, "Bag-sewing"; and E. J. Dunstan, "Carting."

NORTH BOOBOROWIE (Average annual rainfall, 16·15in.)

February 12th.—Present: 17 members and six visitors.

Harvest Report.—Owing to the lateness of the rains, seeding in this district extended from the end of April to the middle of July. In one or two cases early sown seed malted badly. The amount of super. used varied from 30lbs. to 100lbs. per acre, and the seed averaged about 1¼bush. The average yield on fallow was about 23bush. and on stubble about 15bush. per acre. No cases of rust were reported, and bunt only occurred where pickling of seed had been neglected. The sample in most cases was a trifle pinched. The lateness of the season and malting of seed prevented definite conclusions being drawn as to best yielding varieties for district. Federation and Yandilla King were mostly grown and yielded well, while Lotts, Leatherhead, and Viking also gave good results.

Demonstration Plots.—A committee, consisting of Messrs. W. B. Ashby, W. E. Hannaford, and A. V. Simpson, was appointed to supervise experimental and demonstration plots. It was intended to conduct a variety test of the following wheats:—Triumph, Bayah, Federation, Lotts, Leatherhead, Yandilla King, Marshall's No. 3, and Improved Dart's Imperial.

PORT PIRIE (Average annual rainfall, 13·21in.).

January 14th.—Present: 10 members and a number of visitors.

Demonstration Plots.—A committee, consisting of Messrs. J. Greig, W. R. Wright, and C. B. Welch, was appointed to supervise wheat variety tests to be carried out by the Hon. Secretary (Mr. A. M. Lawrie).

The Season.—Mr. T. Johns read a paper, in which he detailed the weather conditions which had prevailed during the season just passed. The absence of feed, he said, had impressed on farmers the need for conserving straw and cocky chaff to tide their stock over periods of shortage of rainfall. Messrs. Greig, Eagle, and Munday took part in a discussion on the subject.

Homestead Meeting.—The meeting was held at the homestead of Mr. T. Johns, and members inspected the buildings, machinery, &c.

WHYTE YARCOWIE (Average annual rainfall, 13·91in.).

February 7th.—Present: 11 members.

Treatment of Seed Wheat.—Mr. G. McGregor, in a paper on this subject, gave his experiences in connection with the grading and pickling of seed. The former practice he strongly recommended. Last year he sowed Bluey wheat, pickled and unpickled. There was slightly more smut in the latter than in the treated seed, but the untreated crop came up much thicker. Leatherhead, pickled, was slightly affected, but the crop from unpickled seed was very dirty with smut, although it was a one-third better crop, and the best piece he had for hay. Federation was quite free of the fungus. His conclusion was that whilst pickling to a large extent prevented the development of smut, it also destroyed the germinating power of a large portion of the seed. [One pound of bluestone to 10galls. of water is, in the opinion of Professor Perkins, quite strong enough. Stronger solutions are apt to impair the germinating powers of the grain. See page 1163, May, 1913, *Journal*.—Ed.]. Mr. Wittwer had used the grader with good results. In the year 1893 he sowed wheat dry and unpickled in March. That sown between sunrise and 10 a.m. was badly affected with bunt, whilst that sown later in the day was practically free. He noticed the same thing where he sowed pickled wheat, with the difference that the smut did not affect the crop nearly so badly where pickled. He was a strong believer in using salt with the bluestone. Last season he used one-eighth of a pound bluestone and a handful of common salt to the bag of seed [How much water?—Ed.], with the result that he could find practically no smut in the crop. Mr. McLeod had tried water heated to 130 deg. Fahr., but whilst his crop was free of smut it germinated very indifferently. He did not know if this was due to injury from hot water or to the season, which was not favorable to good germination. Mr. Sack believed that generally a plump grain would give the stronger plant. With regard to pickling, his experience had been similar to that of the writer of the paper. From his crop grown from unpickled seed he picked two heads, one of which was smut all the way up on one side and half-way up on the other, the balance of the sets being sound grain. The other head had smut on one side and sound grain on the other. Other members noticed similar heads. The crop referred to was not badly affected, and both the heads were from the same plant. The Hon.

Secretary had picked a head with only the top two grains sound and all the rest smut. This was from a very smutty crop. Mr. Robinson's crop had suffered severely from smut during dry weather. He had sown some unpickled and some pickled, and could not see any difference, both being badly affected. Where he fed the crop off in the early spring (August and September) it was worse than the portion unfed. Other members had noticed the same thing. One instance was given where a crop badly smutted had been cut for hay, being green when cut There was a fair quantity of second growth; on examination these plants were found to be all smut. The Hon. Secretary had a paddock of Federation badly affected. The seed sown on this was not entirely free of smut, but it had been carefully pickled with bluestone—¼lb. to the bag of seed. This was the first occasion in an experience extending over a period of 30 years that he had had a badly smutted crop when pickled as above. The Chairman had a long experience of the use of bluestone and had never had a badly affected crop. He had frequently had a badly smutted crop where, to save time and trouble, he had sown a small quantity without pickling.

Storing Grain for Seed in Bulk.—Mr. McGregor also read a paper on this subject. For those farmers who possessed a suitable barn, the best method for holding grain for seed was to erect a row of mouse-proof binns along one side of this. This year he had erected a series of galvanized iron tanks of 1,000galls. capacity, to hold wheat and oats for seed. A 4in. galvanized iron pipe socket outlet was put into each for the purpose of emptying. Each tank would hold about 125bush., and cost £2 19s. 6d., slightly over 5½d. per bushel. These could be used for holding water when so required. Larger tanks, not soldered, would be proportionately cheaper per bushel, but they could not be used for storing water. Grain stored in these was protected from the weather and vermin.

LAURA, February 20th.—Inaugural Meeting.—The inaugural meeting of this Branch was attended by Messrs. F. E. Place, B.V.Sc., M.R.C.V.S. (Government Veterinary Lecturer), and G. G. Nicholls (Secretary Advisory Board). Addresses were delivered by these officers.

MUNDOORA, February 13th.—Harvest Reports.—Members reported that the harvest returns were low, due to the light rainfall and the excessive wind. The averages were from 4½bush. to 11bush. to the acre. The following varieties gave the best returns: —Gluyas, German Wonder, Marshall's No. 3, Bunyip, and Carmichael. Mr. Dolling had tried summer fallowing for five years, and had found that land thus treated returned the best crops, free from takeall.

NARRIDY, February 7th.—Pickling Wheat.—Mr. W. F. Nicholls initiated a discussion on this subject. Members generally were of the opinion that the floor method was the best for pickling seed wheat.

SPALDING, January 24th.—Homestead Meeting.—The meeting was held at the homestead of Mr. E. E. Gill. A profitable hour was spent inspecting the homestead. A fine plantation of young gums was greatly admired. Mr. Gill had planted the red gum of South Australia mostly, and considered it one of the most valuable of the species. A plot of lucerne of splendid growth commanded attention; although it had been irrigated for several years with water that contained a high percentage of minerals, no harmful results were apparent. Mr. Gill had also grown a fine lot of onions. He carried on poultry-raising extensively.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16·46in.).

February 7th.—Present: 17 members and four visitors.

Forage on the Farm.—The Chairman (Mr. A. L. McEwin) contributed a paper under this heading, in which he said that farmers should, when the seasons were good, store extra fodder against periods of shortage. The following is extracted:—"My experience is that the farmer is too anxious to secure his 100 bags of wheat, and sell it for £50, rather than put the crop into fodder, which would be worth £100 later. Ten years ago a great deal was heard about dry bible and the tremendous loss of stock through it. To-day very little is heard of it, and only in dry districts, where feed was scarce and green fodder still more so. Most farmers have realised that prevention is better than cure, and that prevention is feeding. I have been farming in this district since 1884, and only in one season did I pay dearly through the loss of stock by not paying proper attention to the proper provision for fodder. If I could not grow hay I purchased it. Hay is the only practical fodder for farmers in the dry districts, and even in wet ones it has to be the main stay, in fact nothing can take the place of it. Whatever is grown has to be fed with hay. For working animals it must be the great standby. Good hay will always keep a cow in good heart and will give a good return for that which is given, especially if it is chaffed and fed with bran. The farmer should grow five tons of hay for every horse he has in the stable, unless he has a very good turn-out paddock for use during slack times. In a good season if half as much is carried over one would soon have a reserve, as bad seasons, in my experience, for hay-cutting are about one in three. It is rare that we get two successive seasons failures. My paper applies to country which has an average rainfall of 13in. or 14in. Country with an average of 16in. or 17in. rarely fails from the point of fodder if anything like proper cultivation is done and good farming methods are carried out. A great deal has been written about ensilage, and farmers have been encouraged to go in for it; but from all I have seen of it there is too much labor involved for it to be of very great use to the farmer. Generally, where one can make good ensilage he can make a good hay very much more cheaply. Ensilage is of no use for working stock, but is an advantage for milking cows, and, no doubt, if dairying is being carried on it is necessary to provide succulent food for the summer months. Farmers can grow a better quality of hay by mixing wheat and oats together and crossdrilling. A good mixture for our heavy lands is 50lbs. King's Early and 40lbs. Cape oats crossdrilled with not less than ½cwt. manures sowed with each. Algerian oats with Yandilla King makes good hay. These ripen very well together. Oats require to be cut on the ripe side. I recommend every farmer to grow some oats for feeding his horses in the winter when the work is heavy. They put condition on and life into a horse."

CLARE (Average annual rainfall, 24·30in.).

January 9th.—Present: 16 members.

Ration Sheep and Sheepskins.—A paper was contributed by Mr. A. Hill. When a sheep had been killed and skinned, the tongue should be removed and the head cut off, he said. The neck should then be opened and the paunch pipe tied. When cutting the brisket, one side of the sheep should be held in the hand, the elbow being placed against the other side. Skinning should be commenced at the off fore leg; the near fore leg should then be cut, and the brisket punched back as far as the crutch. The carcass could then be hung and opened down the front, the skin being punched off. The habit of throwing skins carelessly over a rail to dry in the sun was not a good one. As a consequence, there was a big loss in value. By exposure to the sun the basil became dry and shrivelled and lost in market value. It was a good plan to hang the skins on a rail and fasten them with a couple of nails by the neck and tail, leaving the trotters on. They then became evenly stretched and smooth in appearance, bringing a much better price than if no trouble were taken. In packing the skins for sale the trotters should be removed, and the skins packed wool to wool. For prevention of weevils a dressing made of arsenic and vinegar, or strychnine and vinegar, was very effective. Mr. Jarman stated that a wooden rack was used at Roseworthy College for hanging skins. They were fastened on to three hooks, hinder part up, and a stick placed between the front legs to stretch the skin out. Mr. Pattullo sent his skins to Adelaide as soon as possible, as he found that by keeping them until he would have a large quantity only encouraged the weevil pest.

CLARE (Average annual rainfall, 24·30in.).

February 7th.—Present: 17 members and two visitors.

Co-operation.—This subject was dealt with in a paper by Mr. J. C. Dux. If 50 farmers formed a co-operative society, he said, with the area they held, about 20,000 acres (which would mean that they would be cropping 7,000 acres annually), they would require about 300 tons of super. By purchasing this in bulk the executive could save the agent's commission, i.e., £37, and on their requirement of about 40,000 cornsacks they should save £333. The large parcel of wheat which they could handle could be sold in, say, 10,000 bag lots, for which they could secure an extra 1d. per bushel. A draught stallion could be procured conjointly, and fees for a first class animal would only cost the members about £1 per service, if the animal were used for five years. The same system could be applied to dairy cattle and other lines. Mr. Nolan was sorry that co-operation was not favored as it should be in Australia. The people only needed educating up to the benefits of co-operation amongst themselves to make them put it into practice. Mr. Pattullo said co-operation was tried some time ago by a number of northern farmers, but the scheme fell through owing to some of the members selling their wheat to outside merchants, who gave 1d. per bushel more than their co-operative body was prepared to give.

Elementary Education for our coming Farmers.—Mr. Pattullo read an article on the above subject printed in the *Register* on January 5th, and written by Mr. A. G. Edquist, Lecturer on Nature Study in State Schools. The subject was well discussed by all members. Mr. Jarman considered producers did not give their sons a proper agricultural education, especially when the Government offered facilities to ensure it. He spoke at length on the way some producers criticised the Roseworthy Agricultural College, and said that that institution should be judged by some of the ex-students—such men as Messrs. Richardson, Colebatch, and others who had gone through the course—and not by the duffers. He thought a high school should be established at Clare. Such a school would bridge over the gap between the time a boy left the State school and when he would be old enough to attend the Agricultural College. He would be one of the first to help get such a school established. He moved "That a committee be formed to work in conjunction with the Clare Vigilance Society with the object of making representations to the Government for a high school to be established in Clare; such committee to consist of Messrs. J. Dux, W. Pattullo, F. W. H. Lee, M. L. Nolan, R. Hunter, and the Hon. Secretary." Carried unanimously. It was resolved that Mr. Jarman be added to the committee.

FREELING (Average annual rainfall, 17·89in.).

February 5th.

Thatching Stacks.—Mr. A. J. Kuhlman read the following paper:—"The stack should be built with a gable, and not a hip roof, the latter being rather awkward for covering. Have a sufficient quantity of sheaved straw ready at hand, and dampen this well. This will cause it to lie closer and firmer on the hay. Begin to place the straw at the eaves on one end of the stack and finish one side before commencing the other. Before laying the straw fix a board 6in. or 8in. wide and 4ft. long by resting it on two small sticks driven into the stack at a sharp angle. This will prevent the first layer of straw from falling down. Then proceed by opening the sheaves of straw, just cutting the twine and placing the whole thickness of the sheaf with the thick end on the board, so that the sheaf lies at right angles to the eaves. Continue in this way until the layer is 3ft. wide. Then put the next layer with the butt end upwards, and so keep alternately reversing the sheaves until the ridge of the stack is reached. Beat the straw well down with a stick, and cover this 3ft. of straw with wire netting of 3in. mesh. See that the netting projects 6in. below the eaves and hang a small weight on to it. This weight can be prevented from swaying, and thus eventually cutting the netting, by tying it with binder twine to a stick pushed into the side of the stack. On the ridge of the stack roll up the netting required for the other side, and fix it firmly with a stick pushed through the netting into the stack. When the second width of 3ft. has been covered with netting, couple the netting in a few places with binder twine. This will obviate the necessity for attaching a weight on each width. Proceed in this way until one side is finished. Half of each length of wire netting will then be rolled up and fixed on the ridge of the stack. When a width of 3ft. has been laid down the other side, pull the netting over it and fix it as before, coupling the netting with the next width with twine, and continue so until the thatching is completed. No matter how strong the wind may be it will not be able to shift the least quantity of straw. Six feet wire netting is not so convenient for thatching or for when the stack is being opened. The initial cost to thatch a stack of about 160 tons of hay is £2 5s. for wire netting. Sticks and twine would cost £4 1s. 10d. The netting will last many years if taken off carefully, and there is no loss whatever from bad weather, it will be found to be cheaper than thatching with sticks and twine. Moreover, the sticks lead the rain into the stack. Some years ago I helped to remove two stacks of hay—one covered with sheaved straw and the other with loose straw. The latter was very much damaged by mice, whereas the one thatched with sheaved straw was only slightly damaged. Perhaps it was because the sheaved straw, not being put on so thickly, was too cold for the mice. This method of thatching haystacks is, in my opinion, the best and safest, as well as a very quick way of securing hay from damage."

MALLALA (Average annual rainfall, 16·88in.)

February 2nd.—Present: six members and one visitor.

Harvest Report.—Members discussed the results of the harvest just closed. Mr. A. V. Nairn reported that Gluyas wheat had yielded best, averaging 9bush., while King's

Red (which was best last year) averaged only 4½bush. The latter was badly affected by rust. Gluyas was slightly affected. Bunyip averaged 6bush. The Cape and English barley turned out as well as the previous year, *i.e.*, 25bush. He fed off 120 acres of his crop at the end of August, then scarified it over for fallow. He did not think that his crop would more than pay the expense of putting in and taking off. Mr. Konzag's best crop was that which he had sown during the first week in August. Baroota Wonder was very pinched. Le Huguenot, which would have cut 2 tons of hay to the acre, only averaged 6bush. His crop right through averaged 6bush. of grain and about 15cwts. of hay. Mr. Curnow's harvest turned out better than was at first expected, but not as well as the previous year's. His hay (Baroota Wonder and oats) averaged 18cwts. to the acre. Gluyas and Le Huguenot both averaged 9bush. of grain. Calcutta Cape oats averaged 12bush. Twenty acres of rye averaged 12bush. The grain sold for 3s. 3d. per bushel and the straw at £3 5s. per ton. Mr. Temby reported having had a better harvest than that of the previous year. Marshall's No. 3 had turned out best and averaged 10bush. Fifty acres of King's Red, sown during the first week in August, averaged 8bush. Baroota Wonder, which would have cut 30cwts. of hay. yielded between 6bush. and 7bush. of grain. Gluyas and Marshall's No. 3 were least affected by rust. Oats sown on stubble ground in May cut a ton to the acre. The same crop on fallow yielded 15bush. to the acre. Cape barley sown on stubble in April yielded 15bush. per acre.

SADDLEWORTH (Average annual rainfall, 19·69in.).

January 16th, 1914.—Present: five members.

Trees near Crops.—The Chairman (Mr. F. H. Kelly) drew attention to the influence of trees upon the adjoining crop in such a season as that just closed. He estimated that at least three acres of his wheat paddocks, fallowed, well cultivated, and sown, had been rendered quite valueless as a result of the presence of gum trees in or near the crop. The injury was worse from trees in the road near the fence and crops than from the few he had growing in the paddock, since the camping of sheep under the latter resulted in at least some hay being grown near the spread of the tree. With land at £9 to £10 per acre this matter was a serious one. On the other hand, there was a strong objection to the destruction of fine trees along the district roads when they were not in any way an interference to the traffic. Shade, shelter from strong winds, and beauty had their claims also.

TWO WELLS (Average annual rainfall, 16·36in.).

January 13th.—Present: 10 members.

Poultry.—This subject was dealt with in a paper by Mr. A. A. Wilson. It was essential he said, that the farmer should give proper attention to the breed of the fowls he kept. If eggs were the objective, a few first-class White Leghorns should be secured from a reliable breeder. If table birds were required, these could be crossed with the Black Orpington. The cockerels selected for breeding should be young, stand erect, be broad in the body, and active. Breeding hens should be two years old. Good houses could be made with jarrah uprights, deal runners, and iron. The height at the back should be 5ft,. the front being open. Perches could be swung from the roof. All the woodwork should be tarred. A shed 30ft. long, 5ft. wide, and 6ft. 6in. high in the front would accommodate 200 to 250 birds. A concrete floor should be put down. It should be cleaned weekly, and dusted with slack lime. Two or three times yearly it should be sprayed with a mixture of hot soapsuds and kerosene. At the beginning of the summer a coat of whitewash would result in the shed being cooler. In the mornings the birds should receive a hot mash of two parts pollard and one of bran, and at night hard wheat, with the addition of a little malting barley. Plenty of green feed, in the shape of lucerne, Egyptian clover, or maize should be provided. Grit and charcoal and good clean water were essential. Broody hens which were sitting should be given a mixture of barley and wheat, the former preponderating; soft feeds encouraged the birds to eat the eggs. Eggs placed in an incubator should be well shaped and of good size, and not over eight or nine days old. The machine should be working from the first week in April to the first or second week in October. Late chicks were not thrifty. The chicks should have plenty of grit during the first 24 hours after hatching, and then ground wheat. Plenty of water should always be available in earthern vessels. The sexes should be separated immediately they were determinable.

GAWLER RIVER, February 6th.—Subsoiling by Dynamite.—In the presence of 20 members, Mr. H. E. Laffer, of the Roseworthy College, gave a demonstration in subsoiling by explosives in Mr. A. M. Dawkins' orange garden. It was plainly seen by those present that this was a very easy and effectual method of dealing with established orchards where trees had apparently come to a standstill through the roots being unable to penetrate the hard and poor layer of subsoil to the richer and deeper soil below. Where each charge had been fired the subsoil was found by digging to be effectively cracked through and broken up. In one hole a hose was placed and let run for about an hour, at the end of which time no water was visible on the surface, as was the case where the subsoil had not been burst up. It was evident that by means of explosives the soil could be prevented from becoming set tight and waterlogged. All present were kindly entertained at tea by Mr. and Mrs. Dawkins. In the evening, at the Gawler River School, Mr. Laffer gave a lecture on the same subject, showing by means of a chart the different soils which may be successfully treated by explosives.

NANTAWARA, February 5th.—EXPERIMENTAL PLOTS.—Messrs. J. Nicholls, E. J. Herbert, and S. Sleep were appointed a committee to supervise experimental plots to be conducted by Messrs. Smith, Sutton, J. H. Nicholls, A. F. Herbert, T. Dixon, R. P. Uppill.

TWO WELLS, February 10th.—ANNUAL REPORT.—The Hon. Secretary read the annual report of the Branch.

SEASON'S RESULTS.—The Chairman reported that all varieties of wheat which he had sown last year were more or less affected with rust. Newman's Early and Bunyip suffered the least. Mr. Pratt said the rainfall for 1913 was the lowest for 10 years. Members mentioned that two days of severe heat, with cold nights, just before the grain ripened, had a very bad effect on the crops.

YORKE PENINSULA DISTRICT.
(TO BUTE.)

ARTHURTON (Average annual rainfall, 16in. to 17in.).
February 11th.—Present: 10 members and two visitors.

THE SEASON.—In a paper dealing with the season just passed, Mr. J. B. Rowe said the absence of rain to cause the weed seeds to germinate had delayed seeding operations. The land was dry sown, and as the season advanced without the expected fall, it was generally thought that the seed had malted. When rain at last fell, however, it germinated well and the wheat grew rapidly, but a hot spell and the appearance of rust just when the grain was maturing, blighted hopes of a good return. There were exceptional cases of good yields, however, one farmer in the sandhills having secured an average of 24bush. per acre from 200 acres.

KADINA (Average annual rainfall, 15·38in.).
February 7th.—Present: nine members.

DEMONSTRATION PLOTS.—The Branch elected a committee, consisting of Messrs. G. P. Bruce, J. N. Pedler, and B. N. Rodda, to supervise demonstration plots to be conducted by Mr. R. Correll.

PASKEVILLE (Average annual rainfall, 16·10in.)
January 8th.—Present: 12 members and one visitor.

HANDLING WHEAT IN BULK.—Mr. C. S. Lee read a paper on this subject; the following is extracted therefrom:—"The great wheat-producing centres of the world have long since adopted this system of handling their wheat, and with the high price of cornsacks and other disadvantages we, in the Commonwealth, are awaking to the fact that sooner or later we must adopt the same system. By comparison with our method of using sacks, Canada claims that her method of bulk handling is cheaper as regards labor, the dispatch is much quicker, and the waste of grain by vermin and other causes is reduced to a minimum, to say nothing of the big saving in cornsacks. By Canada's method quite half of the process is done by gravitation, which one can see at a glance must reduce the cost of handling. The question that naturally concerns everyone who contemplates a new process is the cost of installation. There are 1,025 terminal elevators near Lake Superior, with a holding capacity of 131,800,000bush., the largest being 6,500,000bush. and the smallest about 100,000bush. The cost of erecting a small building and plant is about £2,000, while some of the largest would cost from £40,000 to £50,000. The handling of wheat in the United States of America, with the exception of some ports on the Pacific coast, is done in bulk, in some cases even from the thresher to the wagon box. In considering the subject we must not lose sight of the fact that the threshing plant is used far more extensively than the harvester in these countries where bulk handling is adopted. As far as I can ascertain, the harvester is not mentioned in connection with bulk handling, although I see no insurmountable difficulty in applying the system where our class of harvesters is used. If we had to use bags to take the wheat from the harvester to the elevators, or even to the ships' sides, with care the same bags could be used at least four times, so that without elevators at our wheat-growing centres. and shipping wheat in bulk, we could save at least one quarter of the money we pay for bags, which at the present price would work out at about £7 per thousand. In America railroad companies in glut times make numerous concessions for wheat carrying. The cheapest transportation in the world is on the great lakes, where the cost is ·75 cents per ton per mile. There are three classes of elevators in the United States. Those owned by the farmers, by local grain dealers at the primary wheat markets, and those owned by elevator companies. Farmers from Australia and New Zealand now resident in Canada are enthusiastic in their praise of bulk handling as compared with our system, and some have even said that the Canadian system of bulk handling, coupled with their labor-saving implements, is equal to a saving of 1s. per bushel. If ever the system is adopted in South Australia, I should certainly advocate State-owned elevators. Farmers could then store their wheat with the State, and get liberal advances at a minimum rate of interest to meet any pressing engagements, and eventually sell when the market best suited them." Members agreed that the high prices ruling for cornsacks rendered the adoption of some such scheme as this necessary for the handling of grain.

PINE FOREST (Average annual rainfall, 14 15in.).

January 13th —Present: nine members, and three members of Port Broughton Branch.

Experimental Test.—The reports of experiments conducted during the year were received and considered. Mr. S. Barr had conducted a wheat varieties test, with the following results, which shows the variety and yield per acre :—

Variety.	Bush.	Lbs.	Variety.	Bush.	Lbs.
Gluyas Early	11	2	Baroota Wonder	9	6
German Wonder	11	0	Marshall's No. 3	9	2
Carmichael's Eclipse ...	10	27	Federation	9	0
Silver King	10	22	W.A. No. 4	8	51
College Section	10	19	Dart's Imperial	8	47
Marshall's Hybrid	10	17	Petatz Surprise	8	45
Yandilla King	10	15	Gallant	8	33
Nhill	10	3	Phillis Marvel.........	8	27
Comeback	9	7			

The plots were each one acre in extent, and were sown on 23rd and 24th May with 1bush. seed per acre and 80lbs. super.

Manurial tests were also conducted by Mr. Barr. German Wonder wheat was sown at the rate of 60lbs. per acre on May 22nd, 1913. The manures used and the yield secured were as follows :—

Plot.	Manure.	Yield. Bush.	Yield. Lbs.
1.	60lbs. super., 20lbs. ammonia	8	6
2.	80lbs. super., 20lbs. ammonia	8	48
3.	100lbs. super., 20lbs. ammonia	9	46
4.	130lbs. super.	11	8

The costs of the manurial dressings of plots 1 and 4 were equal.

Mr. R. Goodridge also conducted tests.

MAITLAND, February 7th.—Farm Implements.—Mr. F. P. Wundersitz read a paper on this subject. Immediately implements were finished with, he said, they should be well cleaned and repaired, and put away in an iron shed with a roof not less than 10ft. high. A coat of paint should be applied to the implements at least once every five or six years. Mr. W. Bawden favored painting the woodwork every three or four years. Mr. Bentley advised painting annually.

MINLATON, February 5th.—Underground Water.—An interesting lecture on the subject of underground water supply, and the formation of salt lakes on Yorke's Peninsula was delivered by Mr. R. A. Riddle.

WESTERN DISTRICT.

ELBOW HILL (Average annual rainfall, 11in. to 12in.)

February 7th.—Present: nine members.

WHEAT.—Mr. W. Bradley contributed a paper, in which he dealt with the history of the wheat plant. He mentioned that it was cultivated in China 3,000 years B.C., and detailed the extent of its cultivation throughout the world at the present. The quality of the grain varied considerably when grown in different soils and climatic conditions. In addition to the bearded and beardless kinds, the varieties were classified into red and white, according to the color of the grain. Whilst the red kinds were generally more hardy than the white, the grain was inferior; but this was in many localities counterbalanced by the greater productiveness of the crop. Long-strawed varieties yielded best in dry seasons, but the short-strawed wheats were best when the season was wet. Whilst the plant was particularly partial to clay and rich heavy loams, excellent crops could be secured from light sandy, gravelly, or chalky soils, with good cultivation. European wheat consisted of 14·83 per cent. water, 19·64 per cent. gluten, 0·95 per cent. albumen, 45·99 per cent. starch, 1·52 per cent. gum, 1·50 per cent. sugar, 0·87 per cent. oil, 12·34 per cent. vegetable fibre, 2 36 per cent. ash; the ash was rich in phosphoric acid, magnesia, and potash. The quantity of flour yielded by the grain varied from 54 per cent. to 80 per cent. Mr. Bowey said long-strawed wheats yielded best in the Maitland district. Heavier dressings of manure were advised. Mr. F. Freeth thought Yandilla King and Marshall's No. 3 the best varieties for the Elbow Hill district. The Chairman (Mr. W. T. Cooper) said Marshall's No. 3 was badly affected with rust this season. Wheat after oats yielded well. Members generally agreed that the present method of marketing grain could be considerably improved.

GREEN PATCH (Average annual rainfall. 26·56in.).

February 9th.—Present: 10 members.

HARVEST RESULTS.—Members reported the results of the season's harvest. Mr. P. Sinclair had secured highest yields from land on which he had used no super. Mr. Sage's crops were very poor. Mr. T. Murray secured a two-ton oaten hay return from fallow, and 53bush. oats per acre. Malting barley yielded 25bush. per acre on fallow and 18bush. on green-ploughed land. From yacca land, a sandy loam, Mr. Venning obtained nearly two tons of hay per acre on fallow, the returns from which in every case were much higher than those on green-ploughed land. With the crops of the Hon. Secretary (Mr. C. J. Whillas) the position was reversed, the green ploughing returning more than the fallow. Barley yielded 12bush. per acre. He had sown kale with some of the hay. It grew well, but it spoiled the chaff sample for sale purposes, and dulled the chaffcutter blades very quickly. It gave a fair amount of feed, however.

PETINA (Average annual rainfall, 13·19in.).

November 1st.—Present: five members.

FARM TOOLS.—Mr. F. Goodhart read the following paper:—"A few pounds spent on tools when starting a farm will never be regretted. We look first at the man who does not buy the necessary tools for his work. He starts out in the morning to do some fencing, remembers he has no crowbar, and has to go to his neighbors; that means an hour or two before he gets to his job. Then we see him trying to fix up some machinery repairs. Maybe he is hacking away at a piece of wood with a cold chisel and screw spanner instead of a wood one and a mallet. Again, we see him trying to cut wire netting with an old axe and the same screw spanner; the latter having to do duty for a hammer at all times. We watch again as he goes to yoke up his horses; he has to make holes in his harness with a penknife, thus spoiling his straps, which, as soon as they begin to perish with age, break and have to be renewed. We see him again in the field trying to cover up his rabbit holes with an old spade with a mallee handle, which comes off every now and then. Thus all through the week he has delay after delay, wondering why he does not get as much done as his neighbor, although he always works longer. We watch the neighbor. He has a good stock of tools. He goes to the shed, picks up the crowbar and spade, perhaps oils the handle before going out, and sets to work immediately. There is no screw spanner used for hammer here, or cold chisel for wood chisel, or axe for snips when cutting wire netting. He has his tool-box and knows where to find his tools, and when the job is finished things are put back ready for next time. So through the week all goes well and he is well pleased with the work done Tools are too often left to take care of themselves, thrown down anywhere, left exposed to weather, and put away broken and useless. All tools should have their proper place in the shed. Handles should be oiled now and then, and broken ones repaired. A most important thing is to keep tools sharp. We might just as well have a cold chisel as a very blunt wood one when cutting wood. An axe chipped and blunt is next door to useless to the man who likes to see the chips fly; to saw a piece of wood with the saw found on most farms would make a carpenter's hair go grey. So we see, besides having a stock of tools we must have a place for them and keep them in good order. To mention a few most useful tools for the beginner: There is the axe—one does not need to say much about its uses, but if the handles were well oiled as soon as they were bought, and kept oiled, there would be fewer broken ones. I would recommend a long handled round-nose shovel for general use; when we can afford them, a short handled round and square nose tool will be useful. The crowbar, which is one of the most useful tools, should be fairly light, but strong, about ⅞in. hexagon steel. If the bar were used more most people would have fewer rabbits, as I find a warren that has been well barred up in the summer time is seldom opened, and is quite safe for the horses to go over. There is not much use for the pick, except in tank-making. The mattock is useful for shoot-cutting, trimming the sides of tank walls, &c. We need at least two hay forks, one long and the other short. A manure fork is also useful. A very good chaff fork can be made out of a piece of 3in. x 2in. oregon and a few pieces of deal for prongs, and a pine handle; this is invaluable where the cocky chaff is saved. A few carpenter's tools are a great help. Hammers, saw, wood chisel, brace and bits, and plane will be found most necessary. A pair of plyers, snips, and a leather punch are very useful. The last-named will save the harness from going to pieces, as it is useful when mending. When funds will permit a small forge, grindstone, and a few blacksmith's tools can be bought. A cheap portable forge can be had for £2 10s., small, but very useful for sharpening tools, &c. A small vice is necessary. A set of stocks and dies and soldering tools are also invaluable to the man who knows how to use them."

Scrub-Rolling.—Mr. W. S. O'Grady read a paper. He regarded the axe as a primitive and time-wasting method of clearing scrub, and said—"The surest and cheapest means of getting a good lump of scrub down in the right time is a good scrub roller. I prefer an old steam boiler, which should be at least 4ft. 6in. or 5ft. in diameter and 8ft. or 10ft. wide, mounted by a good solid frame, strongly iron bound. Care should be taken to see that the pole is of good length. Such a roller should not cost more than £40 or £50, and be a first-class investment on a scrub block, and quite as important as a stripper or plough. Eight horses, two abreast, or nine, three abreast would work it comfortably, and roll from 10 to 20 acres per day. Timber up to 4in. or 5in. in diameter can be rolled with the assistance of one good axeman easing or nicking the biggest trees. Larger stuff can be rolled, in fact anything that the horses and roller can comfortably be got over when down if a sufficient amount of nicking is done. Average sized scrub is not very troublesome to get over with a team, as a good heavy roller crushes it flat. Some people have an impression that rolled scrub is difficult to burn. Such is not my experience, in fact quite the contrary. This is also borne out by the experience of others who practise rolling, and whom I have questioned on the matter. The earlier in the winter that the scrub can be got down the better will be the ensuing crop; early rolling or chopping the scrub acts something like fallow to the land. Providing it would burn as well, I should prefer scrub cut or rolled for two seasons before being burned. The fire would then kill a lot of the shoots and also burn out a lot of stumps. The land would also improve by lying under the dead scrub. There are thousands of acres of scrub on the coast that can be rolled, even if in some places it is necessary to dodge the heaviest patches and the fringe of plains. One acre of cleared scrub land—on the coast—is worth two or three of the plain for growing either grain or feed. I would strongly advise anyone with a scrub block to procure a roller and give it a trial, commencing on the smallest stuff. Care should be exercised to get the scrub burned before the best of the burning season is over, during February for preference.

ROBERTS AND VERRAN.

February 10th.—Present: nine members and one visitor.

Sheep-Farming.—Mr. J. A. Buttfield read a paper on this subject. In this district he would select ewes locally and cross them with well-bred rams, Lincoln or Shropshire. Ewes should be sold before they lost value through age or loss of teeth. When teeth were missing they could not chew the food properly, and the digestion and assimilation were imperfectly performed. This rendered feeding an expensive matter, and the animal was unprofitable. When purchasing ewes, it should be seen that they were two, four, or six-toothed. Small farmers could sell all their sheep when fat and purchase fresh stock between the middle of September and the end of October, and mate these five months before the lambs were desired. On arable land, the flock should be folded off with hurdles or netted upon such crops as clover, vetches, rape, mustard, turnips, swedes, and sometimes rye and other growing corn. On mixed farms sheep should have constant change of pasture, and the pasture should from time to time be chain harrowed. In the spring the sheep should be fed on the young grass. In summer, vetches and clover might be used and cabbages in the autumn. The flock should be fed liberally, but never to excess. By the constant change of pasture the animals' health and appetite, and power to assimilate food, were kept at their best, while the change was beneficial to the pasture itself. The feeding and care of animals had not reached a final stage, and improvement in this matter, as in others, was to be looked for. When buying a sheep, the purchaser should be satisfied on three points, viz.—(1) That the age given by the seller was correct; (2) that the feet were sound; and (3) that the skin was healthy. In the discussion which followed, Mr. F. Masters thought no farm was complete without sheep, but in this district it was necessary to wait a year or two to get enough feed to carry a large flock. For wool and mutton he advocated the half-bred Merino. The capital laid out in buying sheep could always be realised. Mr. McCallum had kept pure Merino for wool, but suggested a cross for lamb-raising. Young ewes for breeding and export lambs for freezing, if dropped in May, required most feed at the time when it was most plentiful. Ewes fattened more quickly on dry feed, if in lamb. Lambs should be fit for market in five months.

KOPPIO, February 12th.—Manurial Tests.—Mr. J. Newell supplied the results of some experiments he had conducted. Three plots, each a quarter of an acre in area, were fallowed about the middle of September, 1912, and cultivated before the drill; 2bush. of Calcutta Cape oats per acre were drilled in on April 29th, 1913, and the land harrowed after the drill. On plot 1, 210lbs. of mineral super. per acre were drilled in immediately after fallowing, and 90lbs. per acre with the seed. Result—124 sheaves of hay, averaging 8lbs. each. On plot 2, 90lbs. of mineral super. per acre was drilled in with the seed. Result—119 sheaves hay. On plot 3, 300lbs. of mineral super. per acre was drilled in with the seed. Result—133 sheaves hay. Valuing super. at £4 10s. per ton, seed at 2s. per bushel, and hay at 70s. per ton, the results per acre were as follows:—Plot 1, £4 16s.; plot 2, £4 19s. 4d.; plot 3, £5 5s.

MILTALIE, February 7th.—Best Wheats for District.—The Chairman (Mr. P. G. Wilson) had secured best returns from Yandilla King and J4 varieties. Mr. W. G. Smith did best with Gluyas and Federation, and Mr. J. P. Storey with Federation and Marshall's No. 3. Mr. H. R. Jacobs obtained the heaviest grain returns from Silver King and Golden Drop, and Le Huguenot yielded 2 tons of hay per acre.

UTERA PLAINS, February 14th.—Handling Wheat in Bulk.—Mr. M. Abrook read a paper on this subject, written by Mr. H. Dolling, of the Pine Forest Branch, and printed on page 686 of the January issue. After discussing this paper it was decided that the elevator system was not workable in South Australia.

YABMANA, February 7th.—Farm Management.—A paper read before the Inman Valley Branch on this subject was read by Mr. A. Robertson, and discussed by members. Mr. Beinke said a good income could be secured from such sidelines as sheep, pigs, cows, and poultry, if they were properly managed. Labor was too expensive to employ on the farm.

Co-operative Ownership of Stallions.—The advisableness of purchasing a stallion for the use of members was discussed. It was thought that better all-round satisfaction would be secured from a privately-owned animal. A little work was necessary for a stallion, but he should be allowed time in which to pick up condition before commencing the season.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

COOMANDOOK (Average annual rainfall, 18·01in.).
February 7th.—Present: 10 members.

Destroying Mallee Shoots.—Mr. W. Brown read a paper. He advised ploughing out the roots and burning the stubble. A four-furrow implement, high enough to clear stumps, and with plenty of room between the mouldboards and the land wheel should be used. Fallowing should be commenced immediately after seeding was completed, every advantage being taken of the saturated condition of the land during winter The ploughing should be to a depth of 4in. A disc implement was very good for working back, as it would cut off a large number of shoots. The stubble should be fired immediately after the stripper. A better burn was secured in oat stubble than in wheat.

Mr. Williams also read a paper. Rolling should be done, he said, about October. A fire could then be started early in February, which would destroy the dry mallee, and any shoots that had developed in the meantime If two good stubble burns followed on the scrub burn, 95 per cent. of the shoots would be destroyed. Another method was to drag out the roots with a four-furrow plough; the success of this depended largely on the nature of the ground. Members generally preferred the latter method; and advised "dragging" the stubble before fire-raking.

MONTEITH (Average annual rainfall, 14in. to 15in.).

February 13th.—Present: 12 members and six visitors.

Irrigating Reclaimed Swamps.—The Chairman (Mr. D. Travers) contributed the following paper on this subject:—"All water should be put over the surface. The land is very porous, and the faster the watering is done the less waste will occur. The main channel must be deep enough to carry the whole of the water supplied by the sluice through the higher portion of the land. Weeds must not be allowed to grow in this. The land should be graded. Levels should be taken by putting holes down to the water level 2 chains apart each way. Pegs should be marked with a saw cut an equal distance from the top and pressed into the holes until the saw cut reaches the water. The tops of the pegs will then correspond with the water level. Should more pegs be required, they may be driven in and sighted along those previously put into position. Then proceed to measure from the tops of the pegs to the ground. Add all measurements together and divide by the number of pegs used. This will give the average of the paddock. The buckscraper is the best implement to use. A wooden drag, not less than 16ft. in length, should be put over the land to give it a smooth surface. When grading is finished, the paddock should be divided into small areas. Checkbanks should be put across the piece to hold the water back. These should be not more than 3 chains apart, as one can water much more quickly in small pieces. Inexpensive but effective gates should be erected at each of the stops, and on no account should any banks be on the channel, as the water should overflow the channel the whole distance of the piece being watered. The greater the outlet given the faster the water will come down through the higher portion. By this system the land can be flooded at the rate of 2 acres per hour with a fair river, and the desired results can be accomplished with one-third of the water used by any other system which I have yet seen. It behoves each settler to make the best use of the water, as it has all to be pumped, which is costly. The careless use of water makes it difficult to keep it down on the flat. There is nothing more detrimental than to allow the water to rise too close to the surface. In all cases drainage should be the first consideration." Members agreed with the views expressed in the paper.

WILKAWATT (Average annual rainfall, 16in. to 17in.).

February 7th.—Present: 17 members and four visitors.

Oats.—A short paper on this subject was read by Mr. A. J. McAvaney. Whilst there was more trouble involved in harvesting this crop, he said, it would pay farmers in this district to grow more oats. The stubble made good feed, and oats with chaffed hay fed to horses provided an excellent ration. They should be sown early in April. The Algerian variety was the best. The land should be worked well. Mr. M. Neville found that Cape oats stood up better than Algerian, and grew just as heavy a crop. He had secured up to 30bush. per acre.

BERRI.—**Demonstration Plots.**—A committee, consisting of Messrs. F. Arndt, T. L. Hughes, A. P. Wishart, R. Staehling, and W. R. Lewis, was appointed to supervise experimental and demonstration plots to be carried out by the Branch.

COONALPYN, February 6th.—**Miscellaneous Evening.**—The evening was devoted to the consideration of miscellaneous items of interest. Mr. Gurner thought it a mistake to put rock salt in the horses' mangers; it should be placed in a separate box in the yard. Mr R. F. Venning said an old bag hung on a barbed wire panel might frequently prevent an accident. Mr. G. E. Venning recommended an application of equal parts of vinegar and salt to snake bites. Horses which had eaten wheat should be given two dessert-spoonfuls of carbonate of soda, in the opinion of Mr. Bone. Mr. Pitman said eucalyptus applied to old bolts would be of considerable assistance in removing the nuts.

MONARTO SOUTH, February 7th.—Wheat Samples.—Members tabled a number of samples of wheat, which were found to vary in weight between 54lbs. and 68lbs. per bushel.

WAIKERIE, February 9th.—Harvest, Etc—Weather during the month of January had been hot and windy, the rainfall being 18 points. Washington Navel oranges fell badly, hence the crop was poor. There was promise of a fair average crop of common oranges, but mandarins were light. The crop of stone fruits had been very good, but the fruit, especially peaches, was on the small side. The vines promised a record yield. Wheat was brought on well by the late rains, but results were considerably affected by the hot winds.

SOUTH AND HILLS DISTRICT.

MEADOWS (Average annual rainfall, 35·32in.)

January 13th.—Present: 10 members and one visitor.

Working Light Soils in Meadows District.—Mr. W. Phillips read the following paper on this subject:—"In working the lighter soil of this district, that which is commonly called the 'poorer soil,' I have found that it is a mistake to bring it to too fine a tilth. When we get heavy winter rains the soil runs together and becomes waterlogged, and in the summer it becomes hard. The best plan is to plough the land as soon as the crop is off the field. If it is intended to grow another crop of hay on the same land, the first crop of hay should be cut on the green side. If land is summer-ploughed and allowed to lie open, fully 60 per cent. of the sorrel thereon will be destroyed. After a crop of peas, and when the land is clean, it is advisable to cultivate it both ways and allow it to remain until the last week in April, then cultivate, drill across it, and harrow. I advise ploughing deep (5in.) for peas and shallow (3½in. or 4in.) for hay. Our holdings are too small for us to allow the land to lie idle in fallow for 12 months. Crops on the lighter soils will stand a wet winter better if the land is ploughed early in January and left in the furrow. This will allow the subsoil to dry and crack, and when the heavy winter rains fall the land will absorb more water without becoming waterlogged. Decaying roots also assist in drainage. I have a small paddock near the homestead in which, three years ago, I put 3bush. of peas and 2cwts. of bonedust to the acre. After the peas were cut and carted off I put the cultivator over the land twice, and allowed it to lie out for three months. Then I cultivated it again before the drill and sowed 3bush. of White Tuscan wheat on one and a half acres, and 6½bush. of Algerian oats on two and a half acres, two bags of super. B. being put on the four acres. I cut the lot for hay on the green side and carted 15 loads of hay out of the paddock. I ploughed the land as soon as the hay was out of the paddock, let it lie till the end of April, then cultivated it and drilled in the same quantity of seed on the same ground. I put 150lbs. of wheat manure with the wheat and two bags of super. B. with the oats. It cut 16 two-horse trolley loads of hay. Three years ago this paddock was badly infested with sorrel, and now it is the cleanest on the farm. I attribute this to summer ploughing. If we keep putting the same manures in the ground year after year, we will find the land becoming stale or sick, and deficient in other plant food. I consider bonedust the best all-round manure. This will last longer in the ground than any other. Of course, stable manure must have the pride of place, but the trouble is, we cannot get enough of it. I have tried bonedust, bone super., bone manure. super. B., guano super., and S.A. super., and got good results from all, except S.A. super., which, in my opinion, leaches too quickly in this district." In the discussion which followed, the Chairman (Mr. Geo. Ellis) said that a paddock in which sorrel was troublesome should lie out for a year or two, and be fed down with sheep before being ploughed. He cultivated a paddock last year after a pea crop, but the subsequent crop was not a success, the hay being light and patchy. He considered that the land in this district needed ploughing each time a crop was sown. Mr. G. T. Griggs was also of the opinion that it was best to feed the sorrel down with sheep. Mr. A. L. Ellis said that if new ground were only cultivated chips and sticks would be brought to the surface, which made binding difficult. These were buried by the plough.

MORPHETT VALE (Average annual rainfall, 23·32in.).

February 17th.—Present: 12 members and three visitors.

Fodder Crops and Stock.—Mr. H. V. Sprigg read the following paper:—"The production of meat on the farm is not receiving the attention it deserves. It is certainly the best paying 'crop' we can grow; it pays not only in cash, but also by the improvement it makes to the soil. Of all farm products, meat is the one for which the demand is steadily and surely gaining on the supply. Countries like North America, from being large exporters, are becoming importers; Germany and other European countries are being forced by the demand for meat to import. This all goes to show that in the future there will be a strong market, at good prices, for all the meat we can raise—modern freezing methods of export putting it on the world's markets in excellent condition. Our climatic conditions and soil are pre-eminently fitted for mixed farming; yet up to the present we have practically devoted the whole of our energies and cultivation to hay and cereal production. Hay has been a paying crop, but it must be remembered, this has been due to the export trade, and now all the States, except Queensland, are prepared, and probably always will be, to export. The position is changed. Even on top of three indifferent harvests, the price is not great; what then will be the position on top of good harvests? Again, at the price of our land I doubt if we can produce cereals only at a profit. The present price of barley and oats, for instance, is not cheering, and yet we must grow them as rotation crops if we wish to give our land a chance. With prospects of over production in the hay market, and selling our cereals in the world's markets, in open competition with the product of countries of higher yields, or cheaper production, the right course for us to adopt is to turn as much as possible of our farm products into meat, thereby selling them at a higher price in a form that our climatic conditions enable us to produce at a cheaper cost than any other country. These advantages are not fully realised. In Northern Europe and North America, for instance, the stock have to be stabled and hand fed during the winter in most parts, and a larger proportion of the food is consumed in animal heat. Yet we find, then, that farmers devote a large part of their labor and land to growing in rotation fodder, root, and grain crops, and also buy concentrated stock food for producing meat. Here, if our stock is given good natural shelter and plenty of food and water, we can fatten them in the open all the year round. It is not necessary for us to expend capital and labor in housing and hand-feeding, but it is necessary for us to devote labor and land to growing feeding crops in rotation for fattening purposes, if we are to get the best return from our farms. The foregoing remarks apply equally to all classes of meat-producing stock, and the particular class a farmer utilises will depend on his individual preference, and on the climatic and soil conditions of his holding. I intend to restrict my remarks to sheep, as I consider them best fitted, both to mixed farming and climate in this district, as they poach or puddle the land less in wet weather, and are easier to manage and market. The principal factors to be considered in mixed farming with sheep as a leading line, are good fences, small paddocks, water, shelter, and a rotation of fodder crops; these will now be discussed in turn. Good sheep-proof fencing is essential. All our old wire fences are useless for sheep; even a good so-called sheep-proof wire fence only makes rogues of the sheep. Wire netting makes the most effective fencing. The cost is much over-estimated, heavy gauge netting and rabbit-proof mesh are quite unnecessary here. No. 18 gauge, 2ft. wide and 3in. mesh, is ample. but it is absolutely necessary to have a wire top and bottom and the netting well secured to them. This netting costs £8 per mile. A good new fence can be erected as follows:—Posts 5ft. 3in. long, half a chain apart, with three T iron standards 4ft. 9in. long. The hole for the top wire for the netting is punched 1ft. 3in. from the top and the two holes above 7in. apart. This leaves the top hole 1in. from the top of the standard, which is notched to take barb wire. In the posts the hole for the top wire for netting is bored 2ft. 4in. from the ground; the next 7in. above, and for fastening barb wire, 3in. below the top. The bottom wire is not put through the posts or standards, being simply laid along the ground and tied to them. No. 10 wire is sufficient for the top and bottom of the netting, No. 8 for intermediate, and a barb for the top. This gives a fence 3ft. 6in. high, with 8in. and 7in. between the top wires, which prevents large stock feeding between them, that being the cause of the most serious damage to fences. When the netting is stretched and tied between the two wires it will cover 2ft. 3in., leaving the bottom about 1in. from the ground. Old four and five-wire fences can be made sheep-proof by running the netting along them, but a wire must be put at the bottom and tied to the posts at intervals. It is essential that the netting is only tied at the top and bottom, if tied in between it will twist and crumple. This will cost about £11 per 80-acre section. *Small Paddocks.*—By small is meant paddocks proportionate to the flock and farm from, say, a seventh to a twelfth of the total area. This is necessary to allow a rotation of crops and to get the highest feeding value from the land. A given area of grass land will, if divided into three or four parts, carry about a third more sheep than if they are given the run of the whole. When feed is plentiful they simply pick the tit-bits and let the rest grow rank and unpalatable; whereas if it is fed in sections in rotation they will clean up each paddock, and have constant change and fresh growth. There will be more growth, the grass will be longer running to seed, and the pastures will be clean. *Water.*—Good clean healthy stock water is one of the most important factors in fattening. The stomachs of the sheep are much better judges of when they require water than the head of the owner. One of the greatest difficulties is to so arrange the paddocks that water is available in each. On stubbles and dry feed, especially peas, sheep will drink several times a day, and to fatten they must have it; the moral is to have plenty of troughing and keep it full. Shelter, especially shade in summer, is worth a lot of feed and water. When they have it they will camp contentedly during the heat, chewing the cud and putting on flesh, otherwise they will be panting, blowing, restless, and wasting. Where there is natural shelter of trees and undulating ground, this is quite sufficient, but where these are absent it will pay every sheepowner to erect artificial shelter. It may be assumed that all farmers theoretically admit the value of rotation of crops, even those who, for various reasons, give no practical expression to it. The main reason for its omission is the custom of selling the whole of the produce off the farm, consequently cultivation has been restricted to hay, and those grains for which a ready market has been found. That is probably the reason practically nothing but cereals has been produced here for the last 60 or 70 years. We really know little of the possibilities in other directions, and that little resting on sporadic experiments, which have often been classed as failures, without inquiring into the why and wherefore, or even the conditions necessary to ensure success. Similar failures take place every year in our cereal crops, but we do not argue that the district is unsuitable for cereals. The time has now come when we should make a strong, resolute, and united effort to solve this question, and prove, as I am sure we will, that this district can grow fodders all the year round. The value of peas as a feeding crop is so well known that little need be said about them. The only disadvantage is that early summer rains cause them to shoot, making it advisable to feed them quickly. Last season I mixed 1bush. peas, ½bush. each oats and barley, 4lbs. rape, and 1lb. mustard. I have already fattened 10 sheep to the acre on this, the rape has been fed off twice, and with early rains I expect to have good winter feed from it. Dwarf Essex rape is best on the lighter soils, and the tall variety, or thousand headed kale, for heavy lands. The best way to sow small seeds is to mix them with the manure. They should be mixed in the drill as required, not any length of time before using. Next month I intend disking some barley and hay stubble and sowing it with a mixture of rape, kale, mustard, clover, lucerne, melilotus, and grass seed. As to what grasses will give the best results we have very little knowledge, but the best guide is to take those that are now growing here. Although I have had little success with lucerne, I think it is due to the method of treatment rather than climatic or soil conditions. The sample tabled shows what can be done without irrigation, and in a railway cutting the roots are down over 15ft. Other fodder plants that should be tried are field beans, cow peas, soya bean, lupins, and vetches. At Wagga Wagga cow peas, sown in November, give good green feed during the summer. They must be sown after the frosts. They stand the dry weather well. This crop and Japanese millet both do well here. There are, of course, maize and sorghum, but I am only dealing with plants capable of being fed off in the green state or harvested by sheep. Another scheme I intend to try is fattening sheep on pasture with barley and chaff. A recognised ration for fattening sheep on pasture is ½lb. of cotton cake and ½lb. of linseed cake. The feeding value of cotton cake and barley is about the same; linseed cake we can take at, say, double the value of hay chaff. Consequently a ration of ½lb. of barley and 2lbs. chaff will be about 30 per cent. higher than the standard ration. Barley at 2s. 1d. per bushel is ½d. per pound, and hay at £2 6s. 8d. is ¼d. per pound, so the cost of the ration is 1d. Sheep will put on ½lb. to ¾lb. per day; this, at present market price, is 2d., equalling 100 per cent. on cost of ration, for pasture, marketing, and profit. There is no reason why we should not turn our grain and hay into meat when the prices are low. I am confident that if farmers devoted a portion of the land they have under bare fallow to fodder crops it would net a higher cash return, besides improving the fertility, enhancing the value of the farms, and increasing the production of the district. Now, great as are the benefits we derive from the Bureau, I feel we are not making the most of them. We want more practical work in testing and putting theories into practice. Remember that the theories of to-day may be the practice of tomorrow, so let each of us do his little towards solving some agricultural problem. Let us each decide to make some test, some experiment, it does not matter how small, under ordinary farm conditions. Although no general deduction can be drawn from an individual case, yet much useful information may be gained, and a way discovered, each case being laid before this Branch and discussed as it matures. Let us show that we have confidence in our district, and set an example to other Branches in this matter of fodder-growing for meat production."

BLACKWOOD, February 9th.—Poultry Housing and Feeding.—An interesting and instructive lecture on poultry housing and feeding was delivered by the Poultry Expert, Mr. D. F. Laurie. The lecture was illustrated by means of models and diagrams, and at the conclusion numerous questions were answered by the speaker.

CHERRY GARDENS, February 10th—Mr. L. C. Dobbie delivered a lecture and exhibited a collection of lantern views of Queensland, prepared by the Tourist Bureau of that State.

HARTLEY, February 11th.—Harvest Results.—Members exhibited samples of this season's crops. In many cases the grain was somewhat pinched, on account of rust and dry weather. Two or three hot days when the wheat was filling caused the wheat to dry off quickly. The average returns of wheat were from 3bush. to 16bush. per acre. Oats were of a very good sample in most cases. The yield averaged from 10bush. to 30bush. per acre.

IRONBANK, February 5th.—The Horse.—A short paper dealing with the horse and its management was read by the Hon. Secretary (Mr. W. H. R. Coats). The animal should be well fed and stabled, he said, and the driver should carefully study its temper On no account should it be forced when tired. The whip was unnecessary. Mr. W. Slater disagreed with the last statement.

Demonstration Work.—Mr. Slater undertook to test the effect of applications of nitrate of soda to land.

LONGWOOD, February 7th.—The meeting was held at the homestead of Mr. H. Winter. The orchard was inspected, and a striking tribute was paid to the value of thorough cultivation by the clean and healthy appearance of the fruit trees.

Government Experimental Orchard.—The Hon. Secretary (Mr. J. R. Coles) reported on the Branch's visit to the Coromandel Valley Experimental Orchard. He paid a tribute to the good work being done there.

MOUNT BARKER, February 11th.—Annual Social Gathering.—Fifty-five members and about 100 visitors sat down to a banquet arranged in the Town Hall by the ladies. After necessary Branch business had been dealt with and justice done to the excellent fare, several toasts were honored. The speakers were the Chairman (Mr. Harry Bell) Mr. A. M. Dawkins (ex-Chairman of the Advisory Board), Mr. G. G. Nicholls (Secretary), Mr. Bert Fidler, Messrs. Scrymgour and Dumas. Several new members were enrolled. A high tribute was paid to the fine work of the Secretary, Mr. J. E. Smith, B.Sc. The function proved a thorough success, and was in itself striking evidence of the popularity and worth of the Bureau in the Mount Barker district.

MOUNT PLEASANT, February 14th.—Crop and Stock Reports—The crops were reported to have been disappointing in this district, owing to the prevalence of red rust and hot winds. Stock were falling away in condition.

Camel Team, Oodnadatta.

AGRICULTURAL PUBLICATIONS.

The following publications have been issued by the Department, and are available for distribution at prices mentioned:—

Vinegrowers' Manual, by A. Sutherland, 6d.; posted, 7d.

Reports of Conferences of Australasian Fruitgrowers held at Brisbane and Wellington, 1s. each, or 1s. 1d. if posted.

Journal of Department of Agriculture of South Australia, 1s. per annum in advance; 3d. per single copy to residents of South Australia; 2s. 6d. per annum to other places.

Any of the following Bulletins and Leaflets may be obtained by sending a penny stamp for postage:—

Agriculture, Miscellaneous: Agricultural Bureau Congress Reports; Amount of Spirits to be Extracted from a Ton of Raisins; Depth of Sowing some Agricultural Seeds; Digestibility and Handling of Wheaten Hay; Dry-Farming Conference Reports; Feeding-Off Experiments with Sheep; Housebuilding in New Districts; Irish Potato Blight; Lucerne Cultivation and Management; Lucerne Leaf-Spot Disease; Milling Experiments; Reclamation of Land; Roseworthy College Farm Flocks; Roseworthy College Harvest Reports; Roseworthy College Experimental Field Reports; Sheep on the Farm; Spraying against Potato Blight; Stage to Cut Wheaten Hay; Trial of Stone-Gathering Machines.

Horticulture: Banded Pumpkin Beetle; Bordeaux Mixture; Curculio Beetle; Codlin Moth; Currant Industry; Fertilisation of Orchard Lands; Fruit Drying; Fruit Flies; Fruit Preserving; Grape Vine Mildews; Gumming Disease of Peach and Almond Trees; Selection and Planting of Fruit Trees; Peach Leaf Curl Fungus; Plums and Prunes; Preserving, Canning, and Drying of Fruits; Production of Early Tomatoes; Remedies for Diseases of Fruit Trees and Vines; Some Notes on Almonds.

Dairy: Milking of Cows; Spaying of Cows: Taints and Flavors of Dairy Produce; Taints in Milk and its Product; Testing Milk and Cream.

Stock: Branding of Stock; Bot Flies and Bots; Castration of Colts and Spaying of Cows.

Poultry: Diseases of Poultry; Parasites of Poultry; Poultry Tick; Reports of the Egg-Laying Competitions; Single Testing for Egg Production.

Beekeeping Notes.

[Every farmer and fruitgrower should join the Agricultural Bureau. Write to Department of Agriculture for particulars.]

POINTS FOR PRODUCERS.

Farmers' Conference.

The Annual Conference of the Northern Yorke Peninsula Branches of the Agricultural Bureau is to be held at Kadina Town Hall on Friday, April 17th. The speakers include the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), who will open the Conference, the Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.), Mr. F. E. Place, B.V.Sc., M.R.C.V.S. (Government Veterinary Lecturer), members of the Advisory Board, and others. Sessions will be at 11 a.m., 3 p.m., and 8 p.m. Papers from district Branches will be read and discussions will follow each. The meetings are open to the public, and it is anticipated that a large number of farmers will attend.

African Box Thorn.

The attention of landholders is directed to the fact that in certain parts of the south the African box thorn (*Lycium chinense*, Mill.) is liable to cause considerable trouble. The district council of Port Elliot applied to have the plant proclaimed under the Noxious Weeds Act, and stated, *inter alia*, that in that district a great deal of land had been appropriated by the box thorn, and it was now the worst of all weeds. Birds carried the seeds all over the country, and the result now was that thousands of acres of land would be utterly useless to stockbreeders unless much money was spent in rooting the box thorn up. According to a paragraph appearing in a Western Australian paper the Government of that State have recently gazetted the box-thorn as a noxious weed.

Pruning Almond and Prune Trees.

A writer in the *Pacific Rural Press* discusses the question of pruning or non-pruning of almond and prune trees. He gives some interesting information as to the results obtained from cutting back almonds of the Hatch varieties for the purpose of grafting in other varieties. In some cases the grafts failed to take, but the shoots from the stub, which were, of course, from the Hatch varieties, bore finely in a way that left all the old wood out of the running. Apparently the advantages were not with the grafting in of new varieties, but the sending out of new wood. The writer concludes—"In almost every instance prune or almond growers who have reason for dissatisfaction could well experiment in a little more vigorous pruning and shortening back; if they have lots of water sprouts in their orchard and not even an excuse for them, they are hopeless if they do not even cut them out."

Feeding Value of Grain Sorghums.

In the course of some interesting comment on the growing of sorghums Professor O. O. Churchill, Agronomist of the Oklahoma College of Agriculture, states—" In feeding value the grain of the different grain sorghums will run about nine-tenths of that of corn. Ten bushels of Kafir, milo, or feterita is equal to 9bush. of corn for fattening purposes. If the grain is ground there is probably very little, if any, difference in feeding value between the different varieties. There is, however, a difference in the hardness of the different seeds, and hence there may be a slight difference in the feeding value when the grain is fed without grinding. It is just as easy to put stock in good condition for the market by feeding Kafir and milo as it is by feeding corn. Such feed, if fed exclusively and in large quantities, may produce harmful effects on the animal's digestive system. It is well, therefore, to feed a mixed ration."

Migration from English Rural Districts.

Giving evidence before the Dominions Royal Commission, Mr. R. H. Rew, C.B., Assistant Secretary to the British Board of Agriculture, said that some of the board's correspondents in the country had complained of the activity of the emigration agents, and he declared that if the present rate of emigration continues it will not be a good thing for English agriculture. There was, he said, no surplus of agricultural laborers—certainly none to spare for emigration ; and he agreed that it was not in the interests of the Mother Country to be stripped of its workers for the benefit of the Colonies in this way. Referring, says the *Agricultural Gazette*, to the report of the board on migration from rural districts, he stated that its general tenor was that there was a moderate deficiency of labor in agricultural districts, which was undesirable from the point of view of the farmer. On the other hand, an over-supply was, of course, not good for the laborer. If emigration to the colonies did not exist, it was probable that there would have been a larger migration from the country to the towns. The board's correspondents had put it almost as a complaint that the emigration agents had been particularly active in endeavoring to persuade farm laborers to accept the rather tempting offers made to them to emigrate.

Rural Education.

Dr. E. J. Russell (Rothamsted Experimental Station), speaking on the question of rural education at a Conference of the Teachers' Guild of Great Britain and Ireland, said that it should be remembered by the educationalist that the countryman's outlook on life was essentially different from that of the townsman. The average town boy grew up to be very much of a specialist and was drilled more or less into obedience to a system, the country boy had specially to develop self-reliance and to learn how to see a thing through once it was begun. This self-sufficiency made the country boy a magnificent colonist, but it also made him wholly averse from submitting himself to a system. Another distinction lay in the nature of relaxations possible after a day's work. In the day the countryman could entertain himself satisfactorily, but his ingenuity in this respect often vanished with the daylight. Education should enable him to do for his leisured hours what the training at his work enabled him to do during his hours of labor. The system of rural education must also recognise that the boy's life would be spent in the most intimate contact with nature, and it must admit of variation.

Siberian Butter and Cheese.

In the course of an interesting despatch on the growing importance of the Siberian Dairy Industry, the St. Petersburg correspondent of the *Daily Telegraph* states that the turnover of the union of West Siberian butter-farming artels, which in 1912 was 7,000,000 roubles, was more than doubled last year (1913) to 14,500,000 roubles. It embraces 563 different butter-making associations, with 502 depôts. The net profits of the union amount to 120,000 roubles. It is interesting to note that the first experiment of producing Siberian " Cheddar " cheese for the English market was made in 1912, but the result was not brilliant. The cheese turned out rather coarse, and not like the genuine article. The union promptly sent an expert to England to study cheese-making processes on the spot, and last year the result was so far satisfactory that about 65 tons of Siberian Cheddar cheese were sent to England. Siberian dairy and peasant farmers find that while there appears to be an over-production of butter for the European markets, there is a great want of cheese, and therefore they propose to devote particular attention to the development of this branch for the benefit of the British markets. The union has already acquired its own steamers and barges on the River Obi, and expects to receive considerable financial assistance from London.

Effect of Metals on Flavor of Butter.

The effect which the presence of minute quantities of iron or copper may have on the flavor of butter has been the subject of investigation by the experts of the Dairy Section of the United States Agricultural Department. "According to their report," says the *Mark Lane Express*, "very small amounts of these metals in the cream cause certain undesirable flavors to increase in intensity during storage. These flavors are often designated as 'metallic,' 'oily,' or 'fishy.' Experiments were carried out using known quantities varying from 1 to 500 parts to a million parts of cream. The butter was stored and examined at intervals varying from 20 to 187 days. The most noticeable feature was the rapid development of bad flavors in the butter containing the iron. Butter made from cream which had stood in rusty cans developed a peculiar taste easily picked out. The influence of copper was even more marked than that of iron. The work shows that if cream is kept in rusty cans or comes in contact with iron or copper during the process of butter making, it may take up iron or copper from rusty cans, exposed bolt heads, or other metal parts of pasteurisers or churns, in sufficient quantity to affect the flavor of storage butter. While there is nothing to show that the nature of the flavor is appreciably changed, it does demonstrate very clearly that the rate of development of the undesirable flavor is greatly accelerated during storage by very small quantities of iron or copper."

Intensive Cultivation.

The problem of successful farming nowadays, and particularly the problem of small holdings, must depend for its solution on intensive culture; which means that the crops grown one after the other in quick succession must be sown in soil worked into a condition as perfect as possible, and must be regularly nourished with ample supplies of available plant food. If horses are put to extra hard work they are supplied with extra rations, including energy-producing grain ; similarly the soil, if expected to produce a quick succession of exhausting crops, must be supplied with the nourishing material to enable it to bear with success the strain.—*Agricultural Gazette.*

Selling Crops or Keeping Stock.

Of course the farmer must sell something to make his profits, but is it better for him to dispose of his products in the shape of hay, straw, corn, and roots as they are, or in the form of beef, mutton, pork, milk, &c., produced by the crops grown on the land ? It is a question of selling the crops to the stock on the farm rather than to an outside purchaser, and the point is, which will pay the best price in the long run ? The unmistakable cry to the farmer this year is, get more stock, more stock ; and there are signs which indicate there will be a demand for some time. Very well then, the stock will want feeding, and shall the farmer try to do this, or aim to grow the food or a good portion of it and sell the crop, as it were, in the flesh ? And while we are on the subject, do not let us forget that while crops are sold off as such the land stands to suffer, but when they go to market through stock there remains the manure to keep up the fertility of the land, add to its value, and increase its yielding capacity.—*Mark Lane Express.*

Pig Breeding.

In a lecture recently given by Professor Grisdale, one of the greatest living authorities on pig breeding and feeding, he is reported, says the *Live Stock Journal*, to have given the following expression to his views :—"As to the future, a world-wide survey of conditions, not only as regards hogs, but other lines of livestock as well, justifies the belief that profitable returns from hog-raising may be counted on for several months to come, at least. Even if prices do go down, there is money in hogs. Our own records at Ottawa for 15 years past show that in none of those years did we fail to make a profit, and in some years a very handsome profit, on hog-feeding."

Pollination of Prunes.

The question of what variety would best pollinise the Tragedy prune was brought up in a recent issue of the *Pacific Rural Press*, and it is stated, a little light on the matter can be gained from experience in Contra Costa county. On a ranch in the Alhambra Valley, near Martinez, there are a number of Tragedy prunes which had never borne well. Acting on the advice of another fruit grower, the owner grafted in some Clyman scions on a number of trees, and after these had blossomed a decided increase in yield was noted, the trees near the Clyman wood also bearing more uniformly. On the subject of pollination, the effect of Silver prunes on Robe de Sargeant has been seen on an orchard near Linden, San Joaquin county. The owner has about 450 Robe de Sargeants planted in alternate rows with Silver prunes, which have produced fine yields and large sizes. Neighbors with Robe de Sargeants alone have had smaller yields and smaller sizes, other things being approximately the same, and the men make replantings with French prunes or the Prune d'Agen. The fruitgrower in question considers the Robe de Sargeant the best of all. The Wickson also has the reputation of being an irregular bearer under some conditions. It is reported that in the Vaca Valley and elsewhere grafting in scions of the apple plum has made a great improvement in productivity.

Consumption of Tobacco in Germany.

The average yearly consumption of tobacco in Germany is estimated at 98,000 tons, valued at £6,500,000. Over two-thirds of the total quantity used is imported, the home production in recent years averaging about 30,000 tons, of the value of about £1,500,000. The net income from the taxation of tobacco amounted to £5,000,000 in 1911.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"C. B.," Riverton, lost two cows; an examination showed the bible dry and hard. Cows were in fair condition and 24 hours before death showed no loss of appetite; they were on stubble, with brackish water. He asks if disease is catching.

Reply—The disease is not catching, but more cows may die, because they want variety in food. As a preventive give bonemeal licks (*see* back numbers of *Journal*), with ½oz. of saltpetre in lick per cow daily. To affected ones give a pint or more of yeast, or 2lbs. currants, and tincture bryonia 15 drops four times daily in a quart of milk or beer.

"A. J. H.," Coonawarra, has a four-year-old draught mare which is often troubled with swelling behind the jaws; the swellings are intermittent. She also has small lumps like peas on the body, especially the shoulders. The mare is in good condition and thriving well.

Reply—The symptoms are produced by the blood being out of order. It would be well to give her bran mashes only for two days and then a 6 dram aloes ball, which will purge her; a week later give her daily in food ½oz. of flowers of sulphur for 15 or 20 days.

A member of the McNamara Bore Branch, Agricultural Bureau, inquires the cause of a horse, while feeding, ejecting food from mouth; and at different times something has broken in the back of the mouth or nostrils and pus passes from nostrils. Another member has a horse which is more frequent in passing dung than the other horses, and before each dropping passes a small quantity of water. He cannot get the horse in good condition.

Reply—(1) Probably there is an abscess at the root of the upper molar tooth. Have teeth well examined; syringe nostril with potash permanganate

(Condy's crystals), as much as will lie on threepenny bit to quart of warm water, daily, and occasionally give pinch of snuff. (2) The trouble is intestinal indigestion. Feed on bran mashes only for a few days and then give 6 dram aloes ball, which will purge; after this is over, feed less chaff and plenty of bran, and give 10 drops tincture nux vomica in sugar or bran twice daily for a fortnight.

"J. O." asks the cause of a swelling on six-year-old mare's belly, from udder forward, which came and went at intervals.

Reply—Lymphangitis, very possibly connected with bloodworms. Give sulphur ½oz. and saltpetre ¼oz. once daily in food for 10 days.

"S. E. M." has a colt, three years, which has gone very poor and weak in back; it cannot rise without help and sits like a dog. He asks—Is it bloodworms? What is the remedy? The horses drink from a well in low swampy ground, the water being raised by a windmill to iron tank. He also asks whether kerosine will kill insects raised by the pump from the well.

Reply—The symptoms are those of an acute attack of bloodworms (*Sclerotomata*). Give once daily in a little chaff or bran Fowler's solution of arsenic, two tablespoonfuls every day for a fortnight, stop for a fortnight, and repeat for third (*see* back numbers of *Journal*). Also give in bran, if the colt will eat it, if not, mixed with a little molasses in the mouth twice daily 20grs., roughly a teaspoonful, of sulphate of quinine for the first fortnight, once daily for the second, and twice weekly for the third. Kerosine would put the horses off the water. Make a rough filter of bits of limestone and charcoal in a bag at the intake of the mill, do not fill the bag too full. Put sulphate of iron (copperas) in the tank, 1lb. per 1,000galls., or chlorinated lime (bleaching powder), 4ozs. per 1,000galls.

"H. S.," Charlton, inquires the cause of heavy draught horse continually lying down and pawing ground. The animal is losing condition and has little appetite.

Reply—The symptoms seem to point to trouble in the large bowels in which bloodworms are at work, and it is more than probable that the horse will die. Give a dessertspoonful of Fowler's solution of arsenic and a teaspoonful of sulphate of quinine twice daily, mix with a little molasses or sugar and put on the teeth if the horse is not eating, if he is, put it in the food. Rub the flanks vigorously for 10 minutes twice a day. Soft or green food, and encourage to drink as much as possible.

"A. H. S.," Eastern Well, asks cure for horse suffering from stoppage. Two hard balls can be felt in the bowels. The animal was dosed with fresh milk and also strong coffee, but with no effect.

Reply—As the hard balls of dung can be felt give copious enemas of soapsuds at body heat, and, if possible, put in one of them eight tablespoonfuls of glycerine. Rub the belly and flanks well for several minutes two or three times a day. Give 10 drops of tincture nux vomica in a little bran or molasses in the mouth four times a day. Bran mashes or greenfeed only till bowels are working loosely.

The Port Germein Agricultural Bureau asks for advice concerning a colt, rising four years, unbroken, which has been ill for eight days ; not eaten any food. Swelling on both sides of mouth, which broke three or four days ago, in a manner somewhat similar to strangles. The tongue is protruding about 1½in. from the mouth, is black and coated with a substance that peels off like a skin. Does not appear able to swallow. Wherever you put your hand on its body, the feeling is that of placing your hand on a sponge. The sheath also began swelling. There does not appear to be any stoppage in the bowels or water.

Reply—Most probably strangles, complicated by grass seeds at root of tongue ; these should be looked for and tongue treated with Condy. Give in drinking water twice daily for a few days 1oz. hyposulphite of soda, then for a few days tr. arsenicum, 10 drops twice daily. The spongy feel is due to the air getting under the skin, and will gradually disappear.

" W. B.," Pinnaroo, had a horse which had prolonged sub-acute stoppage of both water and dung, and eventually died. *Post mortem* showed lining of bowels completely rotten, liver black, and in gut ball of sand was found. He asks the cause of death and remedy for sand.

Reply—From the symptoms it is probable that the horse died of peritonitis, and probably there was a puncture of the bowel unnoticed. The sand had something to do with it. Sand remedy—1 pint milk, 1lb. honey, or 1 quart coffee, follow with tincture nux vomica 10 drops twice daily. Stoppage of water—gin ½ pint, essence peppermint 20 drops, water ½ pint.

" C. A. R." had a five-year-old horse which died after a fortnight's illness with intermittent colic. It was treated with coffee, sweet nitre, and rubbing for sand. The dung was alternately hard or scouring. He asks what should the treatment have been.

Reply—The symptoms in a five-year-old rather point to an internal abscess either in the bowels or liver, and probably no treatment would have been of any avail; but in a sandy country it is always well to treat for sand occasionally, either with coffee or milk and honey, and give a teaspoonfull of powdered nux vomica in the feed two or three times a week.

" F. A. M." has been trying for some months to cure a young mare of swelling on fetlock which exudes fluid. He has used a preparation five times, but with little effect. He asks—(1) Would it be advisable to continue treatment ; (2) should mare be stabled or paddocked ; (3) what best treatment.

Reply—After five applications of the remedy it is not much good going on with it ; the animal would be better in the paddock. Put a good pitch plaster on half an inch thick, or better, write to chemist for a "charge bandage" and apply tightly round fetlock and leave on for some months; this will reduce the swelling somewhat, but it will always recur with work.

"J. E. F. M.," Karoonda, seeks a remedy for sore shoulders on horses which have to be worked.

Reply—Try white lead 2ozs., neatsfoot oil 1 pint, tincutre arnica ½oz. Apply to sore and collar in the morning and noon, and on the sore at night. Horses can generally be kept working with this; beat out collars well and use branbag numdahs.

"A. J.," Rudall, has a mare which was cut with barbed wire two years ago; 18 months later the strained the same leg; the lump hardened and the mare is now very lame.

Reply—The hock joint is evidently involved in the series of accidents, and treatment is not likely to be of much good. If in foal it would be well to put on a good pitch plaster and turn the mare out. Work is out of the question.

A member of the Morphett Vale Agricultural Bureau inquires cause of horse eating dirt whenever it gets opportunity.

Reply—This is a symptom of indigestion, and is often relieved by the following powder once daily in the food:—Bicarbonate of soda, gentian root, of each 1 dram; flowers of sulphur, common salt, of each ½oz. The indigestion most often arises from irritation of small worms in the stomach.

"J. E. F.," Karoonda, has a horse which developed sudden lameness. At first there was a slight swelling above fetlock, which subsequently spread over and up leg.

Reply.—As the animal was in the fire rake it is possible it has been staked. If not that, a snake bit it, or it may be a strain of a tendon. The following lotion applied once or twice daily will be of use:—Tinct. arnica, 1oz; methylated spirit, ½ pint; glycerine, ½ pint.

"A. L. V.," Brentwood, asks treatment for mare attacked with colic pains. She passes dung lying down, and is worse after drinking.

Reply.—Probably due to sand, for which the coffee already given should prove effective. Give tinct. nux vomica, 10 drops, three times daily in the mouth for a few days, then twice daily for a week; after which a tablespoonful of sulphur and a teaspoonful of baking soda mixed once a day in food for a week.

"J. A. H.," seeks advice concerning pigs which have a disease causing them to lose power in front legs.

Reply.—Due probably to worms. Give daily in food a teaspoonful of flowers of sulphur and a similar amount of Epsom salts; continue for several days until recovery is well established. The mixture is preventive as well as curative. As a regular thing give cinders or charcoal in the food.

ROSEWORTHY AGRICULTURAL COLLEGE.

Harvest Report, 1913-14.

By ARTHUR J. PERKINS, Principal Roseworthy Agricultural College.

(Continued from page 811.)

WHEAT CROPS.

FIELD "EBSARY'S" B.

The past history of this field may be summarised as follows :—1899, purchased and fallowed ; 1900, wheat ; 1901, bare fallow ; 1902, wheat ; 1903, bare fallow ; 1904, oats ; 1905, pasture ; 1906, bare fallow ; 1907, oats ; 1908-9, pasture ; 1910, bare fallow ; 1911, wheat and barley ; 1912, bare fallow ; 1913, wheat.

This field never made very good growth, and was very badly affected with red rust ; portion of it was cut for hay ; the balance was allowed to ripen and cut subsequently for grain, with results that are indicated below in Table XI.

TABLE XI.—*Showing* 1913 *Wheat Yields in Field "Ebsary's" B.*

Variety.	Selection.	Date Sown.	Area Sown. Acres.	Yield per Acre. Bush.	lbs.
Queen Fan	2nd	May 17–20	10·500	8	5
Queen Fan	3rd	May 20–21	3·095	8	0
Gluyas	6th	May 22	0·749	6	19
College Eclipse	5th	May 21–22	5·491	5	48
Late Gluyas	7th	May 20–21	1·748	4	45
King's Red	7th	May 22	4·169	4	23
King's White	7th	May 21–22	3·421	4	14
Beardless King	2nd	May 21	1·919	2	38
College Comeback	5th	May 21	1·735	1	55

Thus, then, about 33 acres of wheat of various varieties, sown on carefully fallowed land, barely averaged 6bush. to the acre. These are results that I did not think the district capable of.

FIELD "DALY'S."

This field was purchased for the College in 1912, and fallowed by us in the same year. The 1913 crops represented, therefore, the first crops raised by us in this field. Growth was very irregular in this field, and red rust quite as bad as in the preceding one. Portion of the field was cut out for hay, the balance being harvested for grain with results that are shown in Table XII.

TABLE XII.—*Showing* 1913 *Wheat Yields in Field "Daly's."*

Federation	3rd	May 16–17	5·026	3	48
King Fan	4th	April 29–30	2·839	3	18

In this field, then, about 47¼ acres were cut out for grain and yielded a little over 6¼bush. to the acre.

FIELD NO. 5 B.

The past history of this field may be summarised as follows :—1897, bare fallow ; 1898, wheat ; 1899, wheat ; 1900, bare fallow ; 1901, wheat and oats ; 1902, pasture ; 1903, bare fallow ; 1904, wheat ; 1905, pasture ; 1906, bare fallow ; 1907, wheat ; 1908, bare fallow ; 1909, wheat ; 1910-11, pasture ; 1912, bare fallow ; and 1913, wheat.

This field is 76 acres in area and was sown to various varieties of wheat, the whole of which, with the exception of the headlands, was cut out for grain. Details concerning the various plots are shown below in Table XIII.

TABLE XIII.—*Showing* 1913 *Wheat Yields in Field No.* 5 *B.*

Variety.	Selection.	Date Sown.	Area Sown. Acres.	Yield per Acre Bush.	lbs.
Gluyas	7th	May 27	3·603	9	55
Gluyas	4th	May 27–29	29·884	8	7
Gluyas	6th	May 27	1·072	8	0
Petatz Surprise	2nd	May 27	3·842	6	21
Queen Fan	1st	May 23–26	27·427	5	49
Late Gluyas	6th	May 26	2·248	5	14
Late Gluyas	5th	May 26	9·381	5	13

In this field about 77½ acres yielded slightly under 7bush. to the acre. All the varieties were dressed with superphosphate at the rate of 2cwts. to the acre.

FIELD "FLETT'S."

The past history of this field may be summarised as follows :—1902, purchased and fallowed ; 1903, wheat ; 1904, bare fallow ; 1905, wheat ; 1906, pasture ; 1907, bare fallow ; 1908, wheat ; 1909, pasture ; 1910, bare fallow ; 1911, wheat, barley, and oats ; 1912, bare fallow ; and 1913, wheat, barley, oats, and rye.

This field is 176 acres in area, and portion of it was cut for hay, as has already been indicated. About 14 acres were taken up with hand selection seed plots, the balance of the field being under various varieties of wheats, many of which are new ones of our breeding.

Full details concerning these various wheats are shown below in Table XIV.

All the wheats in Tables XIV., XV., and XVI. were sown during the month of May, but did not show above ground before the 28th of July. All plots were dressed with 2cwts. of superphosphate to the acre. The total area under wheat in "Flett's" was close on 73 acres, and yielded 7bush. 14lbs. to the acre.

GRAINGER CULTIVATION PLOTS.

These plots were established in 1911 with the object of testing the influence on wheat crops of various methods of treatment of bare fallow. There are 12 plots in all, each one a little over four acres in area; and alternately in each successive year one half of the plots are treated as bare fallow, whilst the other half comes under wheat.

Of these plots four pairs illustrate what may be termed early fallow, *i.e.*, they are ploughed up in early July; whilst the remaining two pairs illustrate late fallow, *i.e.*, land ploughed up after the 1st of September. In the early fallow plots the value of the following practices is under observation:—(1) Heavy rolling immediately after ploughing (Plot 1); (2) harrowing immediately after ploughing (Plot 2); (3) leaving the ploughed land in the rough state until spring (Plot 3); and (4) giving the land a second shallow ploughing with the skim-plough. In the late fallow plots the following two practices are being tested:—(1) Comparatively deep ploughing followed immediately by heavy rolling (Plot 5); and comparatively shallow ploughing on land that is only cultivated and harrowed according to requirements (Plot 6).

In 1913, as was indeed the case in 1912, these plots were sown to College Comeback wheat at the rate of 100lbs. to the acre with 2cwts. of superphosphate. Seeding took place between May 9th and 15th, but the crop did not show above ground until the last days of July.

The treatment, in the several plots, of the bare fallow that carried the 1913 crops, was as follows :—

EARLY FALLOW PLOTS.

Plot 1.—1912—July 4-6, ploughed 7in. deep ; July 16, rolled ; August 23, cultivated ; October 3, cultivated ; October 7, harrowed ; November 7, harrowed 1913—January 29-31, cultivated ; February 27-28, cultivated ; April 2, harrowed ; and May 8, cultivated before the drill.

Plot 2.—1912—July 8-10, ploughed 7in. deep ; July 17, harrowed ; August 23, cultivated ; October 3, cultivated ; October 7, harrowed ; November 7, harrowed. 1913—January 29-31, cultivated ; February 27-28, cultivated ; April 2, harrowed ; and May 9, cultivated before the drill.

Plot 3.—1912—July 10-12, ploughed 7in. deep ; October 1, cultivated ; November 6, cultivated. 1913—January 29-31, cultivated ; May 9, cultivated before the drill.

Plot 4.—1912—July 12-16, ploughed 7in. deep ; August 24, cross skim-ploughed ; October 3, cultivated ; October 7, harrowed ; November 8, harrowed. 1913—January 29-31, cultivated ; February 27-28, cultivated ; April 2, harrowed ; and May 10, cultivated before the drill.

LATE FALLOW PLOTS.

Plot 5.—1912—September 19-24, ploughed 7in. deep, and whatever area was ploughed was always rolled on the same day ; October 2, cultivated, rolled and harrowed ; November 8, harrowed. 1913—January 29-31, cultivated ; February 27-28, cultivated ; April 2, harrowed ; and May 13, cultivated before the drill.

Plot 6.—1912—September 25-27, ploughed 4in. deep ; October 7, cultivated ; November 8, harrowed. 1913—January 29-31, cultivated ; February 27-28, cultivated ; April 2, harrowed ; and May 13. cultivated before the drill.

I append below in Table XVII. the 1913 yields of these plots comparatively with the yields of the preceding year.

TABLE XVII.—*Showing 1913 Yields of Grainger Cultivation Plots Comparatively with Yields of the Preceding Year.*

Plots.	Grain per Acre.			Total Produce per Acre.		
	1913. B. lbs.	1912. B. lbs.	Means. B. lbs.	1913. T. c. l.	1912. T. c. l.	Means. T. c l.

4	6 36	22 16	14 26	0 14 14	1 17 40	1 5 83
Means of early fallow	7 2	21 34	14 18	0 14 104	1 16 16	1 5 60
Late fallow—						
5	5 4	22 45	13 55	0 12 7	1 19 19	1 5 69
6	3 23	16 27	9 55	0 9 60	1 6 88	0 18 18
Means of late fallow	4 14	19 36	11 55	0 10 90	1 12 110	1 1 100

These experiments on the handling of bare fallow I propose continuing in future years; in the meanwhile, however, we may note the following conclusions that may be drawn from the results of two seasons:—

1. Both in a relatively favorable season—1912—and in a very unfavorable one—1913—the yields of the early fallow plots were superior to those of the late fallow plots, both in grain and in total produce, or hay. This superiority of the early fallow plots was, however, far more pronounced in 1913 than in 1912, being represented by close on 40 per cent. for grain and 28 per cent. for total produce; whilst in 1912 it was only a little above 9 per cent. for grain and not quite 9 per cent. for total produce. And if we take the mean of the two seasons' returns we find that early fallow proved itself superior to late fallow by close on 17 per cent. in the matter of grain, and over 14 per cent. in the matter of total produce or hay.

2. In the matter of the handling of early fallow, the more thorough tillage given to Plots 1, 2, and 3, which carried with it a certain amount of winter after-working, appears to have resulted in yields somewhat superior to those obtained on the less frequently tilled Plot 3.

3. It may be remarked that the rolling given to Plot 1 appears to have favored both the growth and yield of Plot 1 in a bad season like 1913.

4. In both 1912 and 1913 the practice of leaving fallow land untilled until the spring months appears to have resulted unfavorably relatively to land worked over in the winter months of the year.

5. In the matter of late fallow, deep ploughing, followed immediately by heavy rolling, has yielded far better results than shallow ploughing without rolling. Indeed, in 1912, the yields on this late fallowed plot were quite equal to the best of the early fallow plots.

THE GRAINGER DEPTH OF PLOUGHING TESTS.

These tests consist of a series of 12 plots, one half of which are treated in alternate years as bare fallow, whilst the other half comes under wheat. Each plot is one acre in area. When these plots are fallowed, Plots 1 and 2 are always ploughed to a depth of 2in.; Plots 3 and 4 to a depth of 4in.; and so on with intervals of 2in. until we reach Plots 11 and 12, which are ploughed to a depth of 12in. The object in view, therefore, is to ascertain the influence of depth of ploughing on the growth of wheat crops.

The 1913 crops, which were the third crops in these tests of which we have any record, were sown on May 16th with King's White at the rate of 90lbs. of seed to the acre and 2cwts. of superphosphate.

The 1913 yields, together with the mean yields for the three years (1911-1913), are shown below in Table XVIII.

Table XVIII.—*Showing* 1913 *Yields of Depth of Ploughing Plots, together with the Means for* 1911-1913.

Plots.	Depth of Ploughing.	Grain per Acre.				Total Produce per Ac.					
		1913.		Means for 1911-13.		1913.			Means for 1911-13.		
		B.	lbs.	B.	lbs.	T.	c.	l.	T.	c.	l.
1 and 2	2in.	11	55	16	53	0	19	32	1	10	63
3 and 4	4in.	7	31	18	43	0	13	94	1	11	41
5 and 6	6in.	7	48	18	19	0	14	23	1	10	83
7 and 8	8in.	8	34	19	26	0	15	20	1	11	48
9 and 10	10in.	9	11	19	25	0	16	43	1	11	88
11 and 12	12in.	8	32	19	20	0	12	86	1	11	0

We have as yet, in connection with these depth of ploughing experiments, the results of only three seasons; and we are not in a position, therefore, to set out any very definite conclusions on the subject. We may, however, note in the meanwhile the following points:—

1. In 1913, the highest yield, both of grain and total produce, was secured from the plot that had been fallowed to a depth of only 2in. This result is certainly remarkable, and must be set down to the infinitely better germination which took place in this plot when compared with those that had received deeper ploughing. For the rest, the yields were heavier in those plots ploughed between 8in. and 12in. than in those ploughed 4in. to 6in. deep.

2. If we average the two seasons, the heaviest yields are shown to the credit of plots ploughed 8in., 10in., and 12in. deep, all of them averaging approximately 19¼bush. to the acre. Plots ploughed 4in. and 6in. deep averaged about 1bush. less, and the plot ploughed 2in. deep about 2bush. less than the latter.

THE GRAINGER SUPERPHOSPHATE PLOTS.

These plots were set going in 1909, the year in which we acquired the farm known as "Grainger's." The object in view was to test the relative value of light and heavy dressings of phosphatic manures both on the yield of wheat crops and on the carrying capacity of the land when left out of crop. And for this purpose the Grainger farm was admirably suited, since it had been dressed with superphosphate in the past only very slightly, if at all. These plots consist of 15 plots, 2·82 acres in area each, and arranged in five series of three plots each. In each season one of these plots is treated as bare fallow, another comes under wheat, and a third is grazed over with sheep. The first series of three plots is to remain permanently unmanured, whilst the second series receives ¼cwt. of superphosphate every time it is under wheat; the third 1cwt. of superphosphate; the fourth 2cwts. of superphosphate; and the fifth 3cwts. of superphosphate.

I have summarised below in Table XIX. the 1913 yields of these plots, together with the means of the results since 1910.

Table XIX.—*Showing* 1913 *Yields of Grainger Superphosphate Plots, together with the Mean Yields since their Inception,* 1910-1913.

Plots.	Treatment.	Grain per Acre.				Total Produce per Ac.					
		1913.		Means. 1910-13.		1913.			Means 1910-13.		
		B.	lbs.	B.	lbs.	T.	C.	L.	T.	C.	L.
1–3	No manure	2	26	9	43	0	5	78	1	0	10
4–6	½cwt. superphosphate	4	49	15	42	0	8	97	1	6	38
7–9	1cwt. superphosphate	5	47	17	10	0	11	98	1	11	83
10–12	2cwts. superphosphate	6	14	16	51	0	12	82	1	12	80
13–15	3cwts. superphosphate	5	26	17	18	0	14	45	1	15	7

We may note from the above table that whilst each additional quantity of manure used would appear to lead to improvement in yields, at the same time the law of diminishing returns comes fairly early into action. Thus, taking the mean results of four seasons, ½cwt. of superphosphate added 6bush. to the yield of the no-manure plots, whilst an additional ½cwt. of superphosphate only added 1½bush. to the ½cwt. plots ; and with still heavier dressings the improvement in grain yield, if any, is barely perceptible. It is, on the other hand, a little more marked in the case of total produce or hay. In favor of heavy dressings of superphosphate I have also repeatedly pointed out elsewhere that we have always noted a very marked improvement in the sheep-carrying capacity of the land whenever it happened to be left out of cultivation.

THE PERMANENT EXPERIMENT FIELD.

Full details concerning the manure and rotation plots in this field are published from time to time in separate reports. In the general harvest report I shall content myself with stating that in this field there were 58·029 acres under wheat, variously treated and manured, which, in 1913, yielded 5bush. 55lbs.

1913 GENERAL FARM AVERAGE OF WHEAT.

We are now in a position to determine what has been the general farm wheat average for the 1913-14 season. We had under wheat 333·07 acres which returned us 2,175bush. 5lbs., or an average yield of 6bush. 32lbs. to the acre ; unquestionably the lowest average ever reaped on the College Farm, at all events within my recollection. In my view, this extremely low average can be accounted for only by the very unfavorable distribution of the rainfall indicated in the earlier part of this report, together with unseasonably early hot north winds and a virulent attack of red rust. How this average compares with those of recent years is shown below in Table XX.

TABLE XX.—*Showing the Average Yield of Wheat on the College Farm, 1904-1913.*

Season.	Rainfall. "Useful." Inches.	Rainfall. Total. Inches.	Area under Wheat. Acres.	Average Yield per Acre. Bush.	Average Yield per Acre. lbs.
1904	11·60	14·70	330·00	18	3
1905	14·23	16·71	212·00	24	11
1906	16·30	19·72	318·00	14	30
1907	13·81	15·05	178·00	13	20
1908	15·53	17·74	258·52	22	14
1909	21·15	23·05	328·47	25	5

Wheat Stacks Port Wakefield.

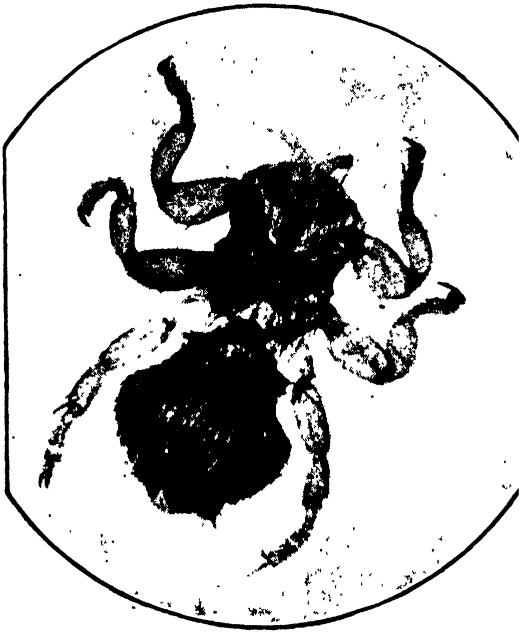
THE SHEEP TICK.

LIFE HISTORY.

(By F. E. Place, B.V.Sc., M.R.C.V.S., Government Veterinary Lecturer.)

The sheep tick, according to Dr. J. Fiebiger, belongs to the class *Hexapoda*, order *Diptera*, sub-order *Pupipara*, species *Malophagus ovinus*, sometimes called the sheep louse fly.

Length 3-5mm., hairy, reddish-yellow body with irregular striping on the back, antennæ naked, eyes small, wingless, double claws on feet; the female is the larger, and produces 4-5 larvæ in a year; these are 5·7mm. long, whitish, smooth and flattish, with small roundish projections in front, bearing at the apex two small suckers. Pupation and development appear to take place in the ground.



Sheep Tick (*Malophagus Ovinus*—Lat.). × 14.

Habitat.—On sheep among the wool, they suck blood, and their excrement stains the wool greenish, their bite is only slightly painful, and causes a dark spot with lighter surrounding ring. Their presence and mode of life tend to

[Microphotographs by Mr. D. F. Laurie, Poultry Expert.]

destroy the staple of the wool, and when they are present in large numbers the sheep lose flesh.

Neumann describes it as " One of the only two species of *Pupipara* of interest, which, being wingless, is a permanent parasite, generally responsible for lousiness in the sheep." This, in my opinion, is a loose statement, and not accurate as far as South Australia is concerned. It is nourished on the yolk of the wool and the blood caused by its bites ; thus living like a louse, although really a fly.

Macquart describes it—Head disengaged from thorax, palps elongated, antennæ nude and tuberculated, eyes small and very close, no occelli, thorax somewhat narrow, abdomen oval, feet downy, tarsal claws bidentated, wings null, generally rusty colored and irregularly spotted, length of body 3-5mm. These particulars are excellently brought into prominence in the photos herewith.

Neumann further states—" The presence of the *Malophagus* is indicated by the pupæ which are attached to the individual fibres of the wool, and appear as shining oval bodies, not unlike small apple pips in color and shape. On separating the wool, the parasites are found close to the skin, and when they are numerous the fleece is entangled (pointy), and sometimes absent in places." The *Malophagus* emigrates from ewes to lambs, which it sometimes torments so much as to cause serious emaciation. If the fleece is short, in order to avoid the teeth of the animal, the parasite takes refuge in front of the shoulders, on the neck, and particularly about the ears and horns. By biting they produce great itching, which makes the sheep gnaw themselves, scratch, and rub. The *Malophagus* species are at times so abundant as to constitute a veritable scourge, and yet they are not prolific, for the female lays only one larva at a time, and only four or five in the course of a year.

EFFECT ON SHEEP.

(By Henshaw Jackson, Wool Instructor, School of Mines and Industries.)

The loss to a sheepbreeder by reason of his animals being tick-infested is more real than apparent, for the reason that tick-stained wool sells just as readily on a price per pound basis as that which is not so affected, and in consequence the owner cannot see how ticks can discount his wool cheque. To all intents and purposes a ticky sheep is a sick sheep and cannot produce a robust staple, but invariably brings to the shearing-board a fine, thin-haired fleece, very suitable for the production of certain superfine materials, and consequently, from a quality standpoint, of considerable value per pound. Price per pound, however, is not the criterion of value so much as return per head, and 5lbs. of ticky wool per sheep is not to be compared with 8lbs.

to 10lbs. of robust, bright, clean fibre, so far as the actual money return is in question. Again, apart from the wool, there is the carcass to be considered, and a ticky sheep is never fat; so that where meat is concerned we are up against another loss. The tick is a blood sucker, and saps the vitality of sheep, to a very large extent rendering its existence miserable and preventing it from fulfilling its functions as a source of profit on the farm.

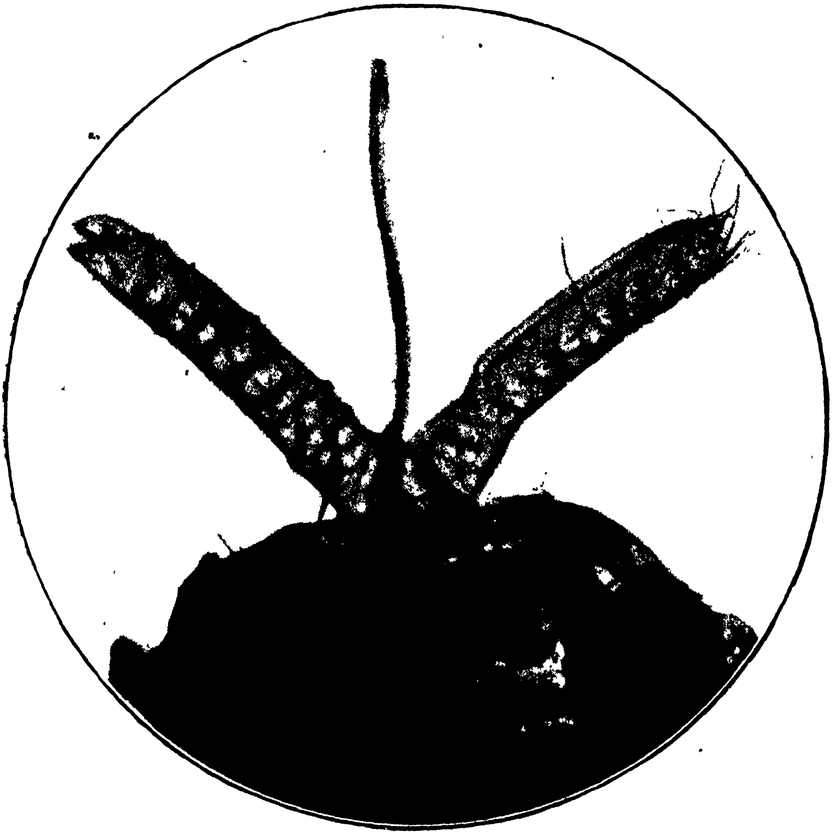
SHEEP TICK (*Malophagus Ovinus*—Lat.).
Dissected Head. Shews Palpi and Proboscis (Stained Eosin). × 80.

From an economical sense, then, apart from any humanitarian aspect, the eradication of sheep tick is a necessity. Prevention is easy enough. By using a reputable poisonous dipping preparation and putting the sheep through a bath of the same about four weeks after shearing in the case of Merinos, and six to eight weeks after shearing with Longwools or Crossbreds, it will be found that the sheep will remain immune to and free from ticks throughout the year, and produce both a heavier fleece and better carcass, and in the case of ewes a better and thriftier lamb.

THE TICK IN SOUTH AUSTRALIA.

(By T. H. Williams, Chief Inspector of Stock.)

This parasite was, no doubt, introduced on sheep imported from Great Britain. They were numerous on sheep in the South-East and on Yorke's Peninsula over 50 years ago. Little appears to have been done to check their spread till 1890, when regulations were issued under the Stock Diseases Act compelling owners to dip tick-infested sheep.



Sheep Tick (*Malophagus Ovinus*—Lat.).
Head, Palpi, and Proboscis. × 95.

Their Present Distribution.

The South-East and South, the ranges east of Adelaide, Yorke's Peninsula, the Lower and Middle North, the West Coast, and Kangaroo Island.

The Annual Loss Caused by Ticks.

It is quite within the mark to say that £100,000 worth of wool and condition is annually lost to owners who neglect to keep their sheep and lambs free of this pest. Over 300 clips, large and small, recently examined, were found weak and badly stained. It was estimated by experts that the loss on one small clip alone, which netted the owner about £100, was £20—due to the presence of ticks. All breeders of lambs are aware of their unthrifty, stunted state when infested with parasites ; few, however, appear to realise what the annual loss really means. Thousands are reduced in value from 2s. 6d. to 5s. per head.

THE REMEDY.

Dip the sheep and lambs in some of the best known poisonous dips on the market. Examine frequently, and should parasites be discovered, dip again. It only costs about 1d. per head to increase the value of the animal from 2s. 6d. to 5s. Do not overlook the fact that the parasites quickly spread from infected ewes to their lambs.

SHEEP TICK (*Malophaqus Ovinus*—Lat.).
Tarsi, Hooklets, &c. × 94.

Some Fallacies.

There are many sheepowners to-day who will glibly assert that "poverty breeds parasites on sheep." This absurd fallacy has long been exploded. Many thousands of our Far Northern sheep, which become poor (poverty-stricken), are not infested with parasites, while on the other hand, sheep in from good to fair condition in tick-infested districts rapidly fall off if the parasites are allowed to increase on them. It would be quite as logical to assert that poverty-stricken pastures bred sheep, as to argue that poverty breeds ticks on the sheep. Do not lose sight of the fact that male and female parasites are both present to complete their life cycle on the sheep and that they live on their host's blood, and thus become one of the chief factors in reducing them to a poverty-stricken state.

The Legal Side.

Tick was declared to be an infections and contagious disease under the provisions of the Stock Diseases Act in 1890, and under clause 19 of the Act owners are compelled to report to the Chief Inspector of Stock, Adelaide, and the Inspector of Stock for the district, when their sheep are infected with parasites. The penalty for neglecting to comply with this provision is £20 per day.

The regulations provide that sheep infected at time for shearing must be dipped within one month. If one sheep in a flock is infected, the whole flock is deemed to be infected. No person, drover, or owner shall permit infected sheep to stray on public roads, lands, commons, or reserves, nor travel infected sheep from place to place, or on roads, commons, or reserves. No person shall move any infected sheep from the land on which they are kept or depastured without permission from an Inspector of Stock. No owner or other person shall expose infected sheep in any market or saleyard, whether public or private.

The penalties for breaches of the above regulations are from £5 to £100.

Camel Team, Oodnadatta.

RELATION OF IN-BREEDING AND CROSSING IN PRODUCING A TYPE OF SHEEP.

(By Henshaw Jackson, Wool Instructor,. School of Mines and Industries.)

The present is particularly the day of small breeders, and the establishment of small flocks is becoming a marked feature in connection with the advance of mixed farming. Such being the case, it may be useful to discuss some of the questions which arise in connection with the foundation and continuance of a type of sheep that will be at once profitable and creditable to the owner. When commencing to breed with pure-blooded stock it is a cardinal point with such animals that " like will beget like," and with a sire and dam perfect in any one direction we may safely expect the offspring to be the " living image " of its parents in this respect. If, on the other hand, either ram or ewe be defective, the progeny, subject to a natural law, will be half-way between the two. With both parents defective in the same direction their progeny will be so more than either, having in effect inherited the sum of their weakness, which is added together in the body of the latest born. The number of perfect animals being comparatively small, the art of breeding lies in a system of counterbalancing, or breeding out of the offspring, the defects of one parent by the distinguishing superiority of the other in the same points. To the parent possessing the highest strain of purity belongs the greatest power of stamping its individual characteristics on its progeny; but if blood be equal the ram possesses greater power in this respect than the ewe.

The Ram.

When commencing to breed it is open for us to begin on ewes that may have any defects short of cardinal ones, always providing that we use the proper ram, and gradually throw out as we progress all ewes showing considerable fault, every year becoming more vigorous in culling. There must be no mistake in our choice of a ram at the beginning ; then is the time to exercise the utmost care in his selection, never losing sight of the fact that whatever weaknesses he may exhibit will be stamped upon the whole of the future flock. Should the defects be material ones, such as hollow back, thin or hairy or uneven fleece, the future descendants will be of poor quality and small value. If the ram closely approaches perfection, or as near as may be, the defectiveness of the ewes will be decreased and gradually bred out. It is, however, practically impossible to obtain perfect rams, so we must choose those having the least material faults, and which can be met and counterbalanced as breeding progresses by the decided excellence of the ewes in the same points. Should one ram be rather long in the leg, then give him short-legged ewes; if his fleece is too yolky, mate him with the driest-woolled ewes, and so on.

Where it is possible to draw upon choice rams as required, this system of counterbalancing calls for little skill did each parent possess but one fault. If the ewe is a trifle light in the wool but good in every other respect, not much judgment would be needed to decide that she be bred to an extra heavy-fleeced ram. Generally speaking, however, most animals have several defects in greater or less degree, and to mate in such a way that every fault in the dam shall be met with its opposite in the sire, and *vice versa*, requires not only ample material for selection, but the keenest discrimination and experience.

IN-BREEDING.

Let us suppose that we have already established our flock successfully on good lines of breeding which provide excellent character. To continue means that we must go on breeding in and in, or seek fresh blood from other flocks at the risk of losing the distinctive characteristics we have now obtained. The question at once arises as to which is the policy to pursue, so I shall now endeavor to place the matter in shape to form a conclusion.

Opponents of in-and-in breeding contend that diseases and all other defects are thereby rendered hereditary, and that there is a tendency to decrease in size, with debilitation and general break up of the constitution. Apologists for the system, on the other hand, say that if the parent stock is healthy, inter-breeding does not of itself diminish healthiness or weaken the constitution of the offspring. They also aver, with a great degree of truth, that by no other means can the skilful breeder arrive so rapidly at the desired standard, and unless it be true that time works for debility, keep to that standard much more easily.

So far as constitution is concerned the above arguments may be to some extent true, for it is probably difficult to always decide exactly when an animal is free from disease and likewise has no predisposing tendency to it. A peculiarity of constitution may manifest itself under given circumstances in a brother and sister apparently and actually healthy, and in the absence of the necessary conditions for its development they may live on till old age apparently robust. Should they be bred together they transmit by natural law in a double degree this same peculiarity which, supposing the ram to be interbred with his closest female relations for a few generations, predisposes the particular evil, whatever it may be, to pervade and become ingrained into the constitution of the whole flock. All this time it has gained strength with each generation at a compound rate, and, when the cause arises that will excite the disease, we are faced with it in a peculiarly severe and malignant form, having practically bred up to it. Should such an outbreak be of a fatal nature, away goes our flock as with a plague. If not fatal, then chronic indisposition or periodical sickness is the result. Regarding defects of the outward form the same remarks apply with equal force. Slight blemishes which are hardly noticeable at first rapidly increase until the value of the animals becomes greatly depreciated.

Most breeders who have given attention to this subject will probably agree that such are the effects to be feared from closely in-breeding, and generally will not favor such a system.

CROSSING.

How, then, can the bad effects of inter-breeding be avoided, and the character of our flock still be maintained ? The answer seems to be that we must select rams of the same breed, but different family, which possess as closely as may be those characteristics which we desire to perpetuate in our own sheep, exercising the greatest care in choosing and seeing to it that we do not draw indiscriminately on every different variety of the breed. That is to say, we must not allow of a hotch-potch mixture of broad-haired and fine wool, long and short staple, leggy and round bodied, yolky and dry woolled, etc., or we shall never attain that uniformity at which we are aiming. A fusion of many varieties cannot take place for generations, and in some cases it is impossible to get different strains of blood to mix at all.

Many men just starting to breed will experience a difficulty in reaching a satisfactory base from which to proceed, and find their sheep continue deficient in the points striven for. We may take it as an axiom that, if what is aimed at is characteristic of the particular breed gone in for, it is correct to stick to that breed if it is proved to be the right one in any given district, and keep on looking for better stock that will lift the flock on to the desired plane.

To put the question as simply as possible, suppose a man has acquired a poor rubbishy lot of Shropshire sheep and desires to obtain the quality of the best of that variety, he must get superior rams of that breed. Again, say that he wants sheep with Lincoln or Leicester characteristics, then he must necessarily go for rams of those breeds. If, on the other hand, he wishes to breed up to fine wool he must pick Merino sires, and in each case continue steadily coming on the breed he intends to predominate, increasing its blood and diminishing that which he wants to leave behind. Natural law applies all through the piece, and continuity of purpose, with care in mating, will go a long way in helping to reach the desired goal, be it wool or mutton.

Most of the finest varieties of our domestic animals are all more or less the result of judicious crossing, and with care and perseverance, there is no reason why in this country any man with natural aptitude should not achieve success from very small beginnings. Ewes of decent size and fair shape with good constitutions are readily obtainable, and with the points they lack provided for in the sire, our farmers should be able to establish flocks which, though of no great size, will be profitable to them and in no way discreditable to the sheep and wool industry of the State.

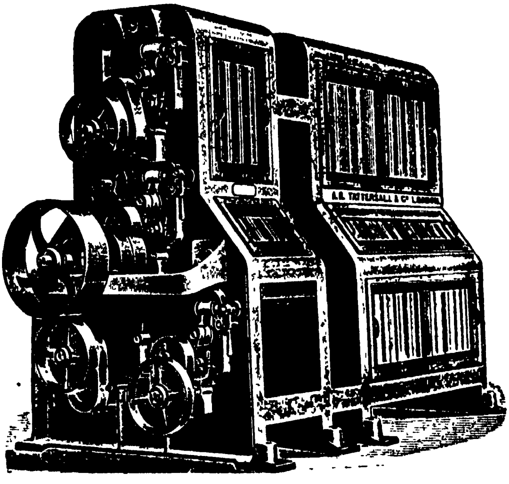
WHEATS AT THE MARCH SHOW.

MILLING AND BAKING TESTS.

By G. H. Stevens, Departmental Miller.

At the recent Autumn Show of the Royal Agricultural and Horticultural Society an innovation was introduced in the agricultural produce section, in that in four classes the wheats entered for competition were judged on the results of actually baked bread in addition to the usual points for milling, weight per bushel, and general appearance of the sample.

There were in all 18 entries in the four classes referred to, nine in the class for champion milling wheats, four in the ordinary soft wheats, one entry for medium hard wheats, and four entries in the class for general wheats. Samples of all these wheats (3bush. lots) were milled in the new Midget roller mill just recently erected at the Turretfield Experimental Farm by Mr. J. McKell (representative for A. R. Tattersall & Co., London). This mill has a capacity of 165lbs. of flour per hour. It is a great improvement on the small experimental mill previously used by the Department of Agriculture, and, when the conditioning plant which it is intended to erect is in position, the wheat treated will, in all respects, pass through the same processes as in the case of a large commercial mill. This was the first occasion on which the new milling plant was put to a practical test, and the work performed by it was highly satisfactory, the flour, bran, and pollard being in every instance quite equal to the commercial article.



A. R. TATTERSALL & Cº LONDON

Midget Roller Flour Mill Erected at Turretfield.

The department hopes, by means of this mill, to carry out some very interesting experiments in connection with the work of wheat-breeding and selection at Turretfield, and from the results already obtained it is expected that the plant will in every way fulfil the purpose for which it was installed.

In the following table we have included the points awarded for weight per bushel and general appearance in addition to those gained for milling and baking qualities, as the weight, plumpness, and general excellence of the sample have usually a direct bearing on the milling and baking tests.

TABLE I.

Variety.	Weight per Bushel.	General Appearance.	Percentage of Flour.	Ease of Milling.	Color.	Total Milling Points.	Quantity of Bread.	Quality of Bread.	Total Baking Points.	Grand Total.

General Wheats.										
1 Bunyip	21·74	23·5	19·9	3	3	25·9	10	8	18	89·14
2 Florence	23·44	24	18·8	1	2	21·8	9	6	15	84·24
3 Florence	22·44	21	18·9	1	2	21·9	10	7·5	17·5	82·84
4 Crossbred 53......	21·97	21	16·5	2	4	22·5	11·5	—	11·5	76·97

The figures in the above table speak for themselves, and there is no need to further comment on same so far as the milling is concerned.

In the baking tests the chief points for consideration were the amount of mixed liquor (viz., yeast, salt, and water) absorbed, and the weight and quality of the resultant bread.

In Table II. will be found the figures for the various flours tested.

TABLE II.

Class.	Entry.	Variety.	Weight of Flour.	Mixed Liquor Added.		Weight of Bread.	
			Lbs.	Lbs.	ozs.	Lbs.	ozs.
		Champion Milling Wheats.					
1	1	1 Comeback	25½	17	0	36	2
1	5	2 Cedar	25	16	12	36	6
1	3	3 Bunyip	25	16	2	35	0
1	9	4 Crossbred No. 53	25	16	14	35	8
1	6	5 Comeback	25	17	0	35	4
1	2	6 Walker's	25	16	2	35	12
1	4	7 Florence	25	16	9	35	14
1	8	8 Florence	25	15	6	35	6
1	7	9 Crossbred No. 53	25	15	10	35	4
		Ordinary Soft Wheats.					
2	1	1 Bunyip	25	15	15	34	12
2	3	2 Dart's Imperial	25	15	7	36	6
2	2	3 King's White	25	15	12	35	6
2	4	4 Crossbred No. 53	25	15	6	34	8
		Medium Hard Wheats.					
3	1	1 Bayah	25	15	14	35	4
		General Wheat.					
4	1	1 Bunyip	25	15	15	34	8
4	2	2 Florence	5	15	8	33	10
4	3	3 Florence	25	17	2	36	0
4	4	4 Crossbred No. 53	25	16	9	34	12

It will possibly be noted with some surprise that Dart's Imperial has shown up so well in the baker's hands. This variety as a rule is not considered a strong milling wheat, yet the baker was unable to separate it from Cedar in regard to points, both these varieties being awarded the maximum for baking qualities.

It would be a difficult matter to venture a definite opinion as to the reasons for this, especially as Comeback, which is looked upon as one of our best and strongest wheats, gained two points less in this test. A possible explanation, however, lies in the fact that a strong flour need not necessarily make the best commercial flour; in fact, it is recognised in milling circles that the best commercial flour is obtained by blending two or more varieties of wheat of different strength and characteristics. A "straight" flour, that is, flour from a single variety of wheat, does not behave so well in the oven as a blended flour, especially if it be obtained from a strong wheat, and it is probable that Dart's Imperial produces a better "straight" flour than Comeback, and this would account for the latter wheat having to take second place to it in the baking test.

Generally speaking, the above tests must be regarded as satisfactory; but there are one or two directions in which they could, in my opinion, be considerably improved and rendered even more reliable.

The present system of attaching only a cardboard tag to the bags is unsatisfactory, as in a fair number of cases the tags are lost during transit, and there are afterwards no means of identification. The number of the class and the entry should in every instance be clearly branded on the bags. Further, the present practice is to keep the miller and baker in the dark as regards the names of the wheats they are dealing with. This fact has the doubtful recommendation of ensuring impartiality in treatment, but it is a well known fact to all connected with the milling and baking trades that different varieties of wheat and flour require different treatment in order to get the best results, and for this reason it is advisable that the information referred to should be given.

The various competitors have nothing to fear from this practice, as their names need not be disclosed.

Then again, in order to ensure the best results in the baking test it is essential that the flours should have a reasonable time to cool off between milling and baking, and the longer time that can be granted between the two operations the more satisfactory are the results likely to be.

THE BAKER'S REPORT.

The department was fortunate in securing the services of a practical baker of standing so well known as Mr. Eldridge to conduct and report on the tests. The baking was conducted with the greatest care and exactitude throughout. The following is Mr. Eldridge's report :—

" In accordance with our arrangement the test of baking bread from flour supplied by Mr. Stevens, from the Government mill at Turretfield, was carried out on Tuesday and Wednesday, the 3rd and 4th of March. I have already handed you a list of the variations of the dough and bread weights, together with my marked list of the quantity and quality of the respective lots tested.

" The bread made from the class 1, entry 5, lot and the bread from the class 2, entry 3, lot were splendid samples when we consider the flour was absolutely new, all of it having been milled less than a week before the baking test. I could not separate the class 1, entry 5, from the class 2, entry 3, consequently I bracketed them equal first.

" The bread from the Bunyip variety was excellent, as also that of the Florence and Comeback varieties ; in fact, I was astonished to find that nearly all these flours—with no chance of maturing—should make such good samples of bread as they did.

" I would particularly emphasize the class 1, entry 5, variety as a very strong flour with fair color, and should say that with the advent of machinery in the baking trade bakers will have to get stronger flours to get the best results in the finished article—our daily bread. This has been borne out by the experience of the Sydney bakers. The leading bakers there are always after the strongest brands of flour for blending purposes, so much so that they have paid from £1 to £3 per ton above the ordinary market price."

SPEECH DAY AT ROSEWORTHY.

ANNUAL DISTRIBUTION OF PRIZES.

Roseworthy College was visited by a large number of parents of students and friends on Monday, March 9th, the occasion being the annual Speech Day and distribution of prizes. The Minister of Agriculture (Hon. T. Pascoe, M.L.C.) was unable to attend, and in his absence Mr. S. B. Rudall, M.P., presided. Others present included the Director of Agriculture (Mr. W. Lowrie, M.A., B.Sc.), Messrs. G. R. Laffer, M.P. (chairman), C. E. Birks, and T. Coleman, of the Advisory Board, the Secretary to the Minister of Agriculture (Mr. W. L. Summers), Professor Osborne, and Dr. W. Ramsay Smith.

The Principal's Report.

The Principal of the College (Professor Perkins), in presenting his report, said—" On an occasion such as this, it is, I am afraid, rather difficult to avoid a 'thrice told tale,' and after some consideration, I have thought that I might perhaps, with some advantage to the institution, draw your attention to a few points bearing on the general training that we have here to offer to students. I do not disguise from myself the fact that the subject of general agricultural education is a very vexed one, concerning which the most widely divergent views are held, and which cannot very well be handled without challenging hostile criticism. In my present position, however, I must accept full responsibility for the line of training that has been adopted here ; and in the circumstances, I shall perhaps be permitted to sketch out the ideals that I have endeavored to aim at.

" Those who have given any attention to the question of agricultural education may be roughly grouped together in several sections. In the first place, there are those who are quite satisfied that the agriculturist, unlike the rest of mankind, stands in no need of special training ; that the mental operations involved in the handling of land, and its fruit, and its livestock, are so elementary in character as to be intuitively within the reach of all those who have aspirations towards a rural career. Everyday facts and ordinary common sense are so much in opposition to views of this kind that they may almost be said to carry their own refutation on the face of them, and I shall assume that the great majority of us are prepared to admit that in rural avocations, like in any other, training of some kind or other is essential to success. General agreement as to the necessity of special training does not imply, however, unanimity as to the character of the training that is to be imparted ; and in this connection it may be said that there are those who pin their faith to the purely theoretical side of the training, whilst others hold fast by what they are pleased to call 'practical training.' Now, however simple the mental effort may appear, it is no easy matter to convince partisans that both sides of the medal are essentially part and parcel of one and the same thing; or in other words, that complete training includes both theoretical and practical training, and that one cannot with advantage be separated from the other. The attempt has been made at this institution—and I believe with some degree of success—to combine both the theoretical and the practical training in those rural pursuits that appear to be best adapted to our special conditions. The credit of initiating this form of training, which has been very largely copied in other Australian agricultural colleges, is due to the present Director of Agriculture, who was for 13 years principal of the institution; and during the past 10 years I have endeavored, to the best of my abilities, to foster the original scheme, and extend its scope.

"This happy marriage of apparently divergent views appears so rational, both in principle and in the recorded facts of the institution, that it would appear almost unnecessary to dwell upon it at any further length. Unfortunately there are still many who will persist in seeing but one side to the medal, and who continue to deny all value to theoretical training; who, for instance, cannot see any connection between a knowledge of the sciences and the routine work of the average rural worker. I may be pardoned for thinking it almost incredible that such should be the case in our times. I can affirm from personal experience, and there are many who can support me in the matter, that a very appreciable proportion of those who are to-day fighting their way on the land are very keenly alive to the helping hand that is being extended to them by the sciences. They may not have had, it is true, the personal advantages of special training, but there is scarcely a day that passes that does not bring to us requests for solutions to problems that are baffling them in their everyday work. Waters, soils, manures, &c., are constantly being sent up for analysis; advice is sought as to drainage, the use of manures, tillage, diseases of crops, &c. All this is encouraging, and should weigh with those who imagine that the whole art of the agriculturist is summarised in the driving of teams and in the handling of simple implements. Nobody expects an engineer to be proficient in his art who is ignorant of the theoretical basis of his profession; why then should it be expected that ignorance and competence should walk linked together in the various agricultural pursuits?

"So much for the purely utilitarian aspect of this question, which rightly, perhaps, carries most weight with the average mind; but in the training of the mind of the rising generation there are other issues at stake of equal importance to be considered. A study of the 'why' and the 'wherefore' in the routine of daily operations, of the principles which underlie practice, besides opening the road to improvement in inherited routine, reacts on the mind, broadens it, and extends the horizon of our thoughts to a degree that can be appreciated in after life only by those who have had the privilege of early training. It is generally recognised that throughout the civilised world one of the most difficult problems of modern times is represented by the gradual desertion of rural districts and the corresponding congestion of urban areas; and in Australia this problem is quite as acute as elsewhere. I must freely admit that at times—and particularly in the old world—economic conditions are mainly responsible for this abnormal condition of affairs; in Australia, however, I am inclined to think that educational factors, or rather the neglect of them, control the position. We are possessed of enormous tracts of unoccupied or only sparsely occupied country; we are very far yet from the stage of gigantic industrial operations; indeed, in spite of the astonishing progress of recent times, we are not yet out of the stage of early settlement; and yet we know that there is unrest in the country districts, and that the city throws off its unemployed units most grudgingly. I know that it is often stated that it is the drab monotony of country life which is the deterrent, whilst the sociability and amusements of the city form the magnet which continue to lead to this modern patch-work settlement of a country. And by whom is it that country life is deemed so monotonous? Solely by those, I think—the majority, perhaps, at the present time—who can see in country work nothing more than a series of routine operations repeated year after year without change. Is it necessary to add that this need, indeed should not, be so? If the man on the land were educated on the lines that I have indicated, he would realise that his work is as interesting, as intellectual as that of the most exalted of professions. He would have open to him the pleasures of the imagination, of the intellect compelling matter; and the glamour of the city would be powerless against the attractions of saner and healthier occupations. With particular force does this apply to the smart country lad who has become conscious of natural ability, and who chafes at the prospect of seeing it wasted in the dull routine of manual operations. Let him but understand that behind this apparent routine there is scope for the play of as much intellect as in any other occupation, and in the majority of cases he will remain true to his early surroundings.

"We are celebrating to-day the thirtieth occasion on which College diplomas have been distributed—and I have pleasure in thinking that I have taken part in 23 similar functions. During the 32 years of its existence the College has seen 596 students on its rolls; and of these, after to-day, 217 will have been awarded the College diploma. I suppose it would be idle to expect that all alike have benefited to the full by the training we have to offer. Many, we know, have in their after careers done exceedingly well; they are now scattered all over the States; and we entertain the hope that they may prove effective missionaries of the advantages of agricultural training.

"I may now pass on to the immediate objects of this meeting. I must, in the first place, extend my heartiest congratulations to the gold medallist of the year, Mr. H. A. Follett. He has done exceptionally well; his general average, 90·3, is three decimals better than that of Mr. C. F. Stephens, whose own average represented a record in 1913. Mr. Follett has also taken honors in every subject, and won every prize but one that was open to him. I trust he may prove equally successful in after life. I must also congratulate Mr. L. J. Clark, who is to be awarded a diploma of the first class. Third-year students, as a whole, are also to be congratulated on their mean diploma average, which is 70·7 per cent.

"The thanks of the institution as a whole are due to those gentlemen who have very generously presented prizes for competition; I can assure them that their generosity is highly appreciated by staff and students alike.

"To those who are leaving us, I would say that they carry with them my best wishes for their future welfare and success. I hope they leave us well equipped for the battle of life; we have done our best for them, and trust they will prove a credit to the institution."

Diploma and Prize List.

The diploma and prize list was as follows:—

Diplomas (in Order of Merit).

Diplomas of the First Class.

Henry Arthur Follett, with honors in agriculture, viticulture, œnology, fruit culture, wool-classing, surveying, chemistry, bookkeeping, aviculture, and dairying.

Leslie James Clark, with honors in agriculture, viticulture, and dairying.

Diplomas of the Second Class.

Morris Hains, with honors in surveying.
Alfred Frank Harper, with honors in surveying and wool-classing.
Howard George Mortimer.
George Rolfe Webb.
Philip Anstruther Tod, with honors in wool-classing.
Robert Cyril Hardy, with honors in wool-classing.
David Hatton Killicoat, with honors in wool-classing.
Leslie Durnell Tillotson Jarman, with honors in wool-classing.
Sophus Carl Vohr.
Robert Reid Bartholomaeus.

Diploma of the Third Class.

John Tinline Murray.

Prize List.

Third Year Students.

Gold medal (presented by the Royal Agricultural and Horticultural Society for the highest aggregate in all diploma subjects), Henry Arthur Follett.

College second prize, Leslie James Clark.

Old Student's Cup (presented by the Old Students' Association for highest aggregate in agriculture and veterinary science), Henry Arthur Follett.

Fruit culture prize (presented by the Albert Molineux Memorial Trust), Henry Arthur Follett.

Special prize (presented by the members of the Advisory Board of Agriculture for the highest aggregate in all practical examinations), Henry Arthur Follett.

Ploughing—Special prize (presented by Professor Lowrie for the best ploughman), Leslie Durnell Tillotson Jarman.

Oenology prize (presented by Professor Perkins), Henry Arthur Follett.

Chemistry prize (presented by Mr. J. H. Phillips, B.Sc.), Henry Arthur Follett.

Viticulture prize (presented by Mr. H. E. Laffer), Henry Arthur Follett.

Veterinary science prize (presented by Mr. F. E. Place, M.R.C.V.S.), Henry Arthur Follett.

College prize for best outside work, Henry Arthur Follett.

Sports prize for highest batting average, J. T. Murray.

Second Year Students.

Silver medal (presented by Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S.), Oscar Sturt Symon.

College second prize, Francis Henry Ough Dealy.

Agriculture and Farm Diaries (prize presented by Professor Perkins), Oscar Sturt Symon.

Viticulture (prize presented by H. Buring, Esq.), Oscar Sturt Symon.

Fruit culture (prize presented by Mr. H. E. Laffer), Oscar Sturt Symon.

College prize for best outside work, Herbert Henry Orchard.

Veterinary science (prizes presented by J. P. Richardson, Esq.)—(1) Oscar Sturt Symon; (2) Herbert Henry Orchard.

First Year Students.

Silver medal (presented by A. L. Brunkhorst, Esq.), Thomas Sydney Ough Dealy.

College second prize, Stuart Gawler King.

Agriculture and Farm Diaries (prize presented by Professor Perkins), Thomas Sydney Ough Dealy.

Botany (presented by Mr. A. J. Adams), Thomas Sydney Ough Dealy.

Bookkeeping (prize presented by Mr. H. C. Pritchard), Thomas Sydney Ough Dealy.

English (prize presented by Mr. A. J. Adams), Thomas Sydney Ough Dealy.

College prize for best outside work, Bryant Charles Hamilton.

THE SPEECHES.

Speeches appreciative of the work of the College were delivered by the Chairman, Mr. Laffer, M.P., and Mr. A. J. Follett, after which Mrs. Rudall distributed the prizes.

EXTRACTS FROM TRADE COMMISSIONER'S REPORT.

Under date London, February 6th, the Trade Commissioner reports, *inter alia*—

BRITISH DAIRY FARMERS' ASSOCIATION.

As I previously advised you, there were several matters that I intended bringing before the council of this association when they were discussing the arrangements for the next dairy show. I am pleased to report that each of the lines that I proposed were considered yesterday at the committee and council meetings, and each one went through satisfactorily.

Bacon.—I pointed out that while the industry was only in its infancy it was hardly fair to expect the colonies to compete with the United Kingdom in this line. I have now arranged that there will be a distinct class for bacon produced in the dominions beyond the seas, apart from the class for that produced within the United Kingdom. There will be three awards in each class, and, of course, the colonial will still have an opportunity of competing for the trophy, which will be considered as a sort of champion prize.

Butter.—In the past there was only one class for both Australian and New Zealand butters. This we have now made into two separate classes—one for Australia and one for New Zealand—so that the Australian will not now have to compete with New Zealand. The chief object in bringing this before the council was that in previous years the New Zealand butter has been staged in the original boxes which, as you are aware, are of a different shape from the Australian, and, while I have no reason or desire to cast any reflection on the judges or on the New Zealand butter, at the same time it was not fair competition that the judges should know by the boxes beforehand where the butter came from. This difficulty will now be obviated by the fact of having two distinct classes.

Honey.—I have also arranged to have two distinct classes for honey—one for honey produced within the United Kingdom, and one for honey produced in the dominions beyond the seas. The competition will be open to *bona fide* producers only, and not to merchants or associations; and in order to prevent the prize being taken by mere "pot-hunters," each exhibitor must produce a Government certificate to the effect that he has a commercial quantity (say 5 tons). I was prompted to have this clause inserted in order to prevent anyone who might have a small patch of clover, or something of that kind, competing, and who at the same time would not be likely to have any sort of a commercial quantity. I sincerely trust some of the leading apiarists in South Australia will enter for this competition at the next show. Full particulars will be forwarded later.

The majority in the first instance were opposed to creating any further classes. As a matter of fact, some of the principal members of the council are beginning to eye with a certain amount of suspicion the continual increase in colonial classes. Although this is the British Dairy Farmers' Association, it is not British in the full sense of the word, and I am afraid the average farmer in the United Kingdom is not altogether imbued with the imperialistic spirit.

For some years past I have called attention to what I have considered an impossible feat on the part of the judges. There has only been one judge for the salted class and one for the unsalted, and I have maintained that it is a physical impossibility for one man, single-handed, to properly judge such a large number of boxes and keep his palate to the last. This question is to be brought up at the next council meeting, when I have every reason to believe the number will be added to. I intend proposing that there be three to each class.

AMERICAN VINES AND THEIR HYBRIDS.

By H. E. Laffer, Lecturer on Viticulture and Fruit Culture, Roseworthy Agricultural College.

Throughout North America there are a great number of wild species of Vitis, whose value lies in their greater or less degree of resistance to phylloxera. In their own country certain of these have been improved by cultivation as regards their fruit, but not sufficient to seriously challenge the position of the European vine (*Vitis vinifera*).

PHYLLOXERA-RESISTANT VINES.

Consequent upon the outbreak of phylloxera in France, about 1860, once the origin of the mysterious malady was established, investigation proved that it had been introduced upon American vines, and also that these same vines were resistant to the effects of the attack. The natural outcome of this discovery, failing eradication of the disease, was to establish or reconstitute vineyards upon resistant American stocks.

In an undertaking of this description it was only natural that many errors were committed at the outset, and it may safely be said that France is only now overcoming the results of those early mistakes. At the present day it is recognised that there are two controlling factors which make for success in grafting phylloxera-resistant vines. First, there is the adaptability of the stock to local conditions of soil and climate, and, secondly, the amount of affinity existing between the stock and the scion, and upon which the success of the union depends. On the former will depend the vigor and strength of the vine, and on the latter its health and length of life in a profitable condition. It is an established rule that the nearer the stock and scion are akin in botanical and physical characters the healthier and longer lived will the plants be.

It was mainly owing to lack of attention to these details in the early years of reconstitution that many costly mistakes were made. The fact of a vine exhibiting a sufficient degree of resistance, coupled with a successful graft, was considered sufficient, and it was not until some years later that the need for other qualifications was realised.

In the meantime considerable attention was being paid to the question in various directions, and the number of stocks at the disposal of the vigneron was enlarged. Probably the two American species of Vitis most universally employed at this period were Riparia and Rupestris. Although they were readily grafted with Vinifera they did not adapt themselves to soil conditions, and so ultimately failed as graft-bearers. Needless to say, these mistakes were exceedingly costly to those concerned, as it entailed the replanting of large areas for a second time within a comparatively short period. Other stocks of pure American species were tried with but little permanent success, and of these *Vitis berlandiere* may be instanced. This vine appeared to be of very great value, as representing a species which flourishes in soils containing high percentages of lime, characteristic of a great deal of the northern districts of France. Unfortunately it was grafted only with difficulty and struck root badly from cuttings.

A VALUABLE DISCOVERY.

During this period of experimental work another factor established itself, and proved to be one which was to go a long way towards solving the difficulties previously experienced. This was the production of hybrid vines and their extensive propagation. There can be little doubt that the benefits derived from these hybrids were indirect to the original object of their production. That is to say, the first idea of artificial hybridisation was to create a vine of European-American parentage which would combine the chief characteristics of both parents—resistance to phylloxera and production of fruit of good quality and value.

That this object was at any rate partially achieved is evidenced to-day by certain types of resistant vines known as direct producers. The indirect outcome of the practice is, however, the most important, for we have a number of graft-bearers possessing ample resistance to the disease, and which through their partly European parentage unite more readily with the Vinifera scion.

Success in this respect opened up further fields for experiment, and hybrids of chosen American species, and in some cases double hybrids, were established in addition to those of Vinifera-American parentage. The outcome has been that many of these vines at the present day promise to very largely eliminate the original difficulties. One can hardly maintain that the problem is solved, but the fact remains that the solution is very much nearer at the present day than ever it has been. The creation of hybrid stocks is carried out on scientific lines, choosing parents adapted to certain conditions of climate and soil, and endeavoring to transmit these characteristics through the progeny. Thus we find that instead of taking one or two stocks and adapting them to all soils, conditions, and scions, there are now a number, each of which displays some qualities of special value for certain conditions under which it is to be utilised.

With the spread of the disease throughout the world, the field of experiment has been enlarged by the inclusion of results from South Africa and the eastern States of Australia. An examination of the collective experience of these countries demonstrates how few of the pure American species are giving satisfaction at the present time, and how the propagation of the hybrids has extended.

We must not lose sight of the fact that probably no grafted resistant vine will prove so long-lived as the old Vinifera under good conditions, as the effect of the graft is to create a weakness in the compound plant. The life of such a plant depends largely upon the success with which the stock and scion unite, and experience goes to prove that in most cases the hybrid vines graft more readily than the pure species. Therefore it would appear, apart from the question of adaptability to soil, that scions grafted upon these hybrid stocks may reasonably be expected to give better and more lasting results.

As in the early years of reconstitution, Europe, and particularly France, did the main part of the work, those countries which became infected at a later date were enabled to reap the benefit of what had already been done. Thus we find South Africa, Victoria, and New South Wales drawing supplies of the various tested stocks from France, and propagating them according to their adaptability to conditions in these countries.

A UNIQUE POSITION.

South Australia is in a unique position in so far that for some thirty odd years the disease has been devastating the neighboring State, and assuming, as is only reasonable, that at some time it will be found within our own borders, the work being done by the Viticultural Department of Victoria will be of inestimable value as a guide to our proceedings.

Although from time to time we have arguments advanced as to the introduction and propagation of resistant vines into South Australia in order to be prepared, yet, for reasons which will be referred to later, such a procedure may be characterised as exceedingly unwise and unnecessary.

EXPERIENCE OF OTHER COUNTRIES.

Looking at the experience of South Africa and Victoria we find how few stocks have proved really effective over a general range of conditions. Further, we find that, taking the conditions of Europe in conjunction with these others, the stocks which find greatest favor are more or less identical in all three. Such a condition only limits the field of experiment to a further extent and emphasizes the fact that the way is being smoothed for countries which may become infected in the future.

In South Africa we have the country with longest experience of phylloxera in the Southern Hemisphere, and its experience should serve somewhat as a guide to Australia. The qualifications of the various resistant stocks has been exhaustively dealt with in a bulletin published by the Viticultural Department under Messrs. Perold and Tribolet, and, taken on the whole, similar results have been obtained by the Victorian department under Mr. F. de Castella.

South African experience tends to show that no matter what the degree of resistance may be, if the vines are permitted to become weak by excessive cropping they will succumb to the attacks of the disease. This is a possibility which must be guarded against, as, at the present time, the young reconstituted vineyards bearing in Victoria are fruiting very heavily in comparison to the old vineyards. This, however, may not be a true comparison, as these young vineyards are being planted under far better conditions as regards preparation of the soil than were the old ones, a factor which should materially increase the vigor and fruit production. However, in view of the possibility of over-bearing, a proper ratio must be preserved between wood production and fruit production.

GRAFT-BEARING STOCKS.

In examining the various graft-bearing stocks, we may for convenience divide them into—(1) Pure American species of Vitis. (2) Hybrids of two American species. (3) Hybrids of Vinifera and American.

In the first place, what constitutes a hybrid vine ? The vine is included botanically in the natural order of *Ampelideæ.* This natural order is divided into a number of genera, and the one which is of interest to us is the genus Vitis. The genus Vitis is again divided into numerous species, which include all the wild types of vine in different portions of the globe. Thus we say that the European vine is of the genus Vitis and species Vinifera (*Vitis vinifera*). Of the American species we have *Vitis riparia, V. rupestris,* &c. All these species in their native state preserve their distinctive features, but may be artificially cross-fertilised, producing in the progeny or hybrid a combination of the characters peculiar to both parents. The characters of one or the other may predominate according to circumstance.

PURE AMERICAN SPECIES.

Of these the first to be utilised to any extent were the Riparias, of which there are two main types or varieties.

1. *Riparia Grand Glabre.*—This vine was resistant to a high degree, but failed in the reconstituted vineyards owing to lack of durability in the graft, usually shown by the scion growing away from the stock and exhibiting an appearance somewhat like an inverted bottle. It has now been generally discarded in Europe, South Africa, and Victoria.

2. *Riparia Gloire de Montpellier.*—Like the former, this stock lacks durability, and has been abandoned in Europe and Victoria. In South Africa it is still used to a certain extent in some of the deep, rich soils, but, in view of the fact that there are several more durable stocks available for like conditions, it is a question as to whether there is any justification for retaining this one.

The next species in importance was *Vitis rupestris,* and the two varieties gave but little better results than did *V. riparia.*

1. *Rupestris du Lot.*—This stock is giving fair satisfaction on the better class of soils in Victoria, but is not used to any extent in South Africa, giving place to those which have proved more suitable.

2. *Rupestris Metallica Cape* was at one time well favored, but is giving way before the better varieties of stock. *Vitis berlandiere*, which has already been referred to, had to be discarded owing to difficulty of grafting and rooting cuttings.

These vines represent the main species, and it will be seen that in no case have they proved satisfactory. Yet these same vines hybridised have given some most promising stocks, as instanced by the following examples.

AMERICAN HYBRIDS.

As is usual in such circumstances where great numbers of seedlings have to be dealt with, numbers are made use of to distinguish one from another. The names in brackets indicate the parentage.

Nos. 3306 and 3309 (Riparia x Rupestris). These two stocks appear to be of considerable value in the reconstitution of European vineyards. In Victoria they are giving general satisfaction in a variety of soils. In South Africa there is no mention of them unless under an obscure name.

No. 3306 does best in the heavier types of land and, in addition, adapts itself to irrigated soils, exhibiting considerable resistance to root-destroying fungi as well as phylloxera.

No. 3309 appears better suited to hill slopes and sandy soils, and for these conditions is a valuable stock.

Nos. 420A and 420B (Berlandiere x Riparia). These are said to be excellent stocks; hardy, drought-resistant, and heavy fruit producers.

Nos. 301A and 301–64 (Rupestris x Berlandiere) are also stocks which give much promise.

Among other promising hybrids which are being tested, the following may be mentioned:—No. 34E (Riparia x Berlandiere), No. 601 (Bourrisquou x Rupestris), No. 125-1 (Cordifolia x Riparia), No. 106-8 (Riparia x (Cordifolia x Rupestris), a double hybrid. These two last, through their Cordifolia parentage, adapt themselves to the heavy clay lands.

VINIFERA-AMERICAN HYBRIDS.

Among this section of graft-bearing resistant stocks we find many which are most popular, being readily rooted and grafted, as well as being resistant to phylloxera. One group of these hybrids worthy of special consideration is that known as A.R.G., the vines being a hybrid of Aramon (Vinifera) with Rupestris Gangin (American), and there are three of them (A.R.G. 1, 2, and 9). In South Africa these stocks are referred to as Aramon, but must not be confused with their Vinifera parent so largely grown in the South of France, All these stocks are hardy, but No. 1 most so, proving of great utility under a variety of conditions of soil and climate; in fact, with the exception of dry hill slopes it appears to adapt itself to almost any locality or soil. It is most popular in Europe, and particularly in Spain. It appears to suit the strong-growing scions, such as table grapes. In Victoria it is highly spoken of, being hardy, resistant to phylloxera, and adapts itself to irrigated land or soil with defective drainage. The remaining members of the group are not so good as No. 1, though they have a certain popularity.

No. 1202 (Mataro x Rupestris).—This vine shares with A.R.G.1 and 3306 the resistance to defective drainage, and adapts itself to irrigated lands. It is, however, more drought-resistant than either of these, as might naturally be expected from its origin. It is found to be a good stock for bad scions such as Mataro and Doradillo. There can be little doubt that for much of our South Australian vine country this should prove a most useful stock.

No. 41B (Chasselas x Berlandiere) represents that type of the American vine thriving in soils of a limestone nature. It is hardy and drought-resistant, grafts and strikes root readily. It is strong and vigorous, and should prove one of the most suitable stocks for South Australia in event of the necessity arising for its propagation.

In addition to these stocks, there are others which promise to be of great use, but at the present time they have not been sufficiently tested to give any conclusive results. It is sufficient for the time that there are a number of stocks, tested under a diversity of conditions, and which up to the present are proving to be all that was expected of them.

AN UNWISE SUGGESTION.

It serves to impress the fact that for South Australia to repeal the existing Phylloxera Act and undertake propagation of resistant stocks at the present time is both unwise and unnecessary. Unwise, in that to temper with existing laws opens the door for the promicsuous introduction of vines, a danger which cannot be too carefully avoided. Unnecessary, because Victoria is forced to do the work and is in a position, not circumscribed by quarantine laws, to do it properly. Such an undertaking would necessitate an increase in the phylloxera tax to meet expense, and all for no compensating advantage. At present the serious propagation of stocks is confined to Victoria, and South Australia desires nothing better than that the existing conditions may continue.

In conclusion, I must acknowledge my indebtedness to Mr. F. de Castella for the opportunity of inspecting the propagation nurseries at various times, and also for general information regarding the respective stocks.

POULTRY NOTES.

By D. F. Laurie, Poultry Expert and Lecturer.

OPERATIONS FOR APRIL.

We are now at the turn of the season. Theoretically we have the four conventional seasons, but actually we have warm weather, and from April to, say, September we have cool weather with more or less rain. Except for the production of green fodders, regular rainfall is not of vital interest to the poultry breeder—that is directly. The advent of cold, wet weather, which we all hope soon to experience, should warn all poutry-breeders of the need for providing adequate housing accommodation. Housing is an absolute essential. The average man, in town or country, can afford to erect proper yards and houses. He need be in no doubt as to what to build, because he can write and ascertain.

Modern Stock.

At this time of the year our breeders have large numbers of high-class utility poultry to dispose of. Now is the time to buy. If you delay you will get the residue—the best will have been sold—or you will get none. It may save time and trouble if this fact be noted. Good utility stock, which alone is profitable, is the result of hard work and brains. There is a demand for this, and you cannot purchase such poultry at the price of farm "scrubs." For egg-production only there is but one breed which has stood the test, and that is the laying strain White Leghorn.

All-Round Breeds.

The generally inferior quality of the table poultry available for our markets warrants greater attention to the all-round breeds. These, which include Wyandottes, Orpingtons, Plymouth Rocks, Rhode Island Reds, &c., are all good average layers, and the chickens, if sold young and in prime condition, will afford a supply of superior table birds. If we are able to boast a little about our egg-production and the large sum paid to us for our surplus eggs we must certainly hold back when table poultry is the theme. There is an excellent and profitable market, and breeders should take note.

Early Breeding.

Out of season—very early—table poultry, young and fat, will command high prices until about Christmas. To get the best prices you must hatch early. Autumn hatching has been recommended by me for years, and those who follow my advice find it very profitable. There is ample scope for all breeders.

VERMIN.

During the winter on many farms there will be need of firewood during the cold weather. Let every owner of tick and vermin (generally) infested stables and fowlhouses burn these plague spots and erect new sanitary houses. It is a marvel to me to note the complacent attitude of owners of vermin-infested premises. Much might be said that must remain in thought alone.

ARTIFICIAL INCUBATION.

Although there are thousands of incubators used in this State there are still many people who are in doubt as to their utility. You can buy either imported or well-made reliable locally-made incubators. In breeding for egg-production a gradual process of selective breeding is making the supply of "broody" hens very short. To make poultry-breeding profitable you must be in the position to hatch at a given date, so that you can have birds of a certain age at the time desired. This you cannot rely upon if you depend on broody hens. I cannot, of course, recommend any particular make of incubator, but as a rule it is wise to select well-known and well-proved makes.

THE MARCH SHOW.

I was disappointed at not seeing a number of country friends interested in poultry-breeding. The poultry exhibit in the departmental court was full of interest, and I should have welcomed more country friends. The chief point of interest was the mammoth incubator of 5,200 eggs capacity, which the Hon. Minister of Agriculture has authorised for Parafield Poultry Station. This machine is built up of six sections which are double, and each holding some 800 odd eggs. The heat is supplied by a coke oven furnace which heats a water-pipe service. The heat of the oven is automatically controlled by the expansion of water. Each section of the incubator is also automatically controlled by an ether capsule actuating a rod and valve, thus controlling the hot water heating supply. Each unit has four egg trays, which are reversible and interchangeable. There are two sets of egg trays for each unit, and the turning of the eggs is done in a few seconds by these means. The cost of running these mammoth machines is less than a seventh the cost of kerosine-heated machines, and there is no danger from fire, nor are there any objectionable fumes as from kerosine. To Mr. D. Lanyon, the well-known incubator manufacturer of Kent Town, was entrusted the task of building what is the first of its kind in the State. The general appearance and workmanship are most creditable, and show what can be done in the

State. The machine will be housed in a special room to be built at the Parafield Poultry Station, where visitors can, after June, inspect this modern method. A large part of the plant there is heated by air gas, and I shall also run a few small machines by kerosine to demonstrate the three methods. Here one will find brooders of several types suitable for small or large operations. Mr. Buchan, of Renmark, who is erecting a large poultry plant, is installing a 1,200 egg mammoth incubator, also a mammoth brooder 40ft. long, worked on the same principle.

PARAFIELD POULTRY STATION.

There are two public visiting days at Parafield each month, and large numbers avail themselves of the opportunity to inspect the plant, stock, &c., and learn the methods adopted. On March 28th over 100 persons, including several ladies, paid a visit and spent an interesting afternoon. The public single testing to be carried out this year is attracting much attention, and will prove a great help to our breeders. The work of building is going ahead, and there is much of interest to show each month. Parafield is an observation school to hundreds who wish to house and treat their birds to the best advantage.

PARAFIELD LAYING COMPETITION, 1913-14.

FINAL REPORT (Abridged).

By D. F. LAURIE, Government Poultry Expert and Lecturer.

The abridged report now presented refers to the tenth competition held in this State. The first was held at Magill, the following eight at Roseworthy, and the tenth at Parafield. In the first test there were 156 pullets competing, in the tenth there were 900. There were also three competitions held at the Kybybolite Poultry Station, and some excellent results were obtained. As usual, a full report will be issued in due course. This will contain several special paragraphs of practical and scientific interest; also a complete table showing the monthly and total egg production of each pen. The full report may be had later on application to the Poultry Expert, Adelaide.

How the Birds are Fed.

Only grain of the best quality, as well as bran and pollard, are used. It is a mistaken policy to buy inferior or damaged foodstuffs. Where standard quality is concerned, one may accurately gauge the quantities required and the results to be expected. All foods are purchased at current market rates. No condiments of any sort are used.

Morning.—At 7 a.m. the first meal of the day is served out. This is fed in earthenware pans. Never throw mash on the ground. The average proportions of the morning mash are pollard two parts, bran one part (by bulk), and lucerne hay chaff. Meat meal at the rate of ¾lb. per 100 hens is made into soup which is used for scalding the bran and lucerne chaff. These are then dried off with pollard until a crumbly mass results. Hot soup is only used during cold weather. In the hot months—from September to March—the meal may be mixed with cold water. A handful of salt per 100 hens is added to the liquid used in moistening the mash. The quantity of mash averages from 4ozs. to 5ozs. per bird, according to appetite. The food is mixed by hand. I have not yet seen a mechanical mixer that would suit the purpose. A proper consistency of mash is of the utmost importance. Slovenly methods soon tell their tale in the unthrifty appearance of the stock. The exact amount of food required by a pen of birds depends on circumstances. Observation alone will show this. If the food is not all eaten, say, within a quarter of an hour, the balance should be removed. Should the birds require more food they should have it. As the yards are floored with straw in which the grain is scattered, there are no idle moments for hungry fowls. As soon as it is light enough in the morning for the birds to see they leave their sleeping quarters, and are soon busily scratching in the litter for grain left over from the previous day. This exercise promotes digestion and keeps the birds warm in cold weather. When the morning feed arrives they are ready for it, but there is no rushing and excitement.

Noon.—At midday green food, chaffed, is fed at the rate of about 2ozs. per bird. The amount may be increased so that the birds have as much as they will eat. Green food is of the utmost importance as a food. It has also important functions in assisting various processes of digestion, and reactions on the blood. Grains and seeds generally are deficient in salts and minerals. These valuable food constituents are well represented in green foods. Green food for poultry should be fresh and succulent. Stale green food, or old, tough, fibrous growths are of little value, and may even be harmful. For Australian conditions lucerne is the most valuable of all green foods. It grows readily in most localities, and under good conditions of soil and treatment will give enormous yields. Berseem (Egyptian clover) introduced to this State by the Principal of the Roseworthy College, is a most valuable green fodder for poultry. As a rule lucerne yields little after

April. Berseem sown in March and well irrigated will give a succession of cuts yielding enormous quantities of succulent green food highly relished by the birds. With the advent of the warm weather it is advisable to plough in the remains of the berseem, and prepare the ground for other crops. Barley, oats, and rye all make good winter crops, but must be cut young, not when tough and stringy. Kail, including thousand-headed, Jersey tree, and French (chou moellier), are exceedingly valuable. They should be planted out in rich soil and irrigated. The thick stalks of the French kail are hollowed out by the birds. Silver beet affords a large supply of excellent food in spring and summer, and is much appreciated, especially by young stock. Sprouted oats have been tried, but many of the birds did not approve of them. Sprouting grain, *i.e.*, just germinating, contains various proteins of considerable food value, but must be used with discretion. Succulent green food can be grown by most South Australian breeders. If green food is not available, or the supply is short, the birds should have a little grain thrown into the litter at midday. On the whole, the system of feeding chaffed green food is preferable to giving it loose as cut from the plot. The birds eat practically all the green chaff. Lucerne hay which has been well made, if chaffed and scalded, adding a little salt to the water, makes a splendid substitute for green food. All breeders should stock lucerne hay chaff. Our fodder merchants do not stock this valuable food as a rule. If, however, breeders made a persistent demand, no doubt arrangements for regular supplies would be made. One-third of the bulk of a fowl's food may be vegetable—green or cured—and with ducks the proportion may be one-half. Not only are better results obtained, but at a lower cost. Green food and lucerne hay chaff are cheaper than grain and mill by-products.

Evening.—According to the time of the year, from 4·30 to 5 p.m. witnesses the feeding of the third and last meal. This is always in the form of grain, generally wheat. In cold weather peas, maize, and short, stout oats may be fed with great advantage. The average quantity is 2ozs. per hen. The grain should always, as at the poultry station, be well scattered in the scratching litter. This prevents the birds overloading their crops, because they have to scratch and hunt for the grain and eat slowly. As a rule there is enough left in the litter to tempt the birds to early activity next morning. When other grains—oats, peas, maize, &c., and a little barley occasionally—are obtainable at reasonable rates, it is policy to feed them, because variety of food is most desirable.

Other Essentials.—I maintain that a good supply of clean scratching litter in the yards, and where possible also in the houses, is the keynote to success. Busy birds are generally healthy, contented, and productive. Birds must have exercise, and they get more under these conditions in small yards than they do where the range is unlimited but with no scratching litter.

Water.—In cool weather the drinking vessels, after careful cleansing, are filled daily. In hot weather the supply is renewed as required. This point is regarded as of great importance. The body, as well as the egg of a hen, contains a large percentage of water. Fowls require a large amount of water, especially on hot days. Particular attention must be paid to the cleansing of the water vessels. These must be scrubbed—a mere rinse out may leave the trouble behind in the vessel. The water vessels should be shaded from the sun ; sun-heated water leads to trouble.

Grit.—Three kinds are used—hard quartz and shell grit—both of these are much sought after by the birds ; the third is charcoal grit. I have used charcoal grit for 30 years, and have advocated its use from the newly-hatched chicks onwards. It is invaluable as an antacid. Where used sickness is rarely encountered. The grit should be kept in a hopper or trough in the house and sheltered from the wet. Wet charcoal loses much of its absorptive power.

Medicating the Water.—Sulphate of iron in the form of Douglas mixture is commonly recommended. One writer after another has copied the instructions, and I also did. Some years ago the fact struck me that the amount of iron in the organism is so small that the administration of large quantities was a mistake, because, beyond an infinitesimal amount, none would be absorbed. Then it seemed that organic iron would be far more suitable to use, and I am not convinced at all by those experimenters who claim that inorganic iron is as effective as that of organic origin. Douglas mixture—ferrous sulphate and sulphuric acid—may be used sparingly in either the drinking water or for mixing in the mash. The sulphates of soda and magnesia—Glauber and Epsom salts—are of very great value for poultry. In both these sulphur is held in chemical combination, but in the system splits up and performs valuable offices. The sodium sulphate (Glauber salts) is more expensive than the Epsom, but it is a more valuable substance. In laying hens the action on the intestines is gentler, and the influence on the oviduct is most beneficial. The blood is alkalinated also. It is a good plan to mix a stock solution—4ozs. to 1 pint of hot water. Of this use a teaspoonful to each quart of drinking water. Epsom salts has its value also, and may occasionally be used; its use is indicated in hot weather as a cooling agent. One ounce dissolved in the water used for mixing the mash of 20 hens, once a week, is sufficient. These salts are useful in outbreaks of chickenpox. After the morning meal is eaten all pens are cleaned and turned over ready for next day. Great care is exercised in regard to cleanliness. Success in poultry-keeping depends largely upon the power of observation on the part of the attendant. The various processes in connection with feeding should be carried out quickly, but not perfunctorily. A quick glance should note the appearance of each bird at feeding time. A bird "off its feed" needs examination.

THE GENERAL AVERAGE.

The average egg-production for the three sections, equal 900 hens, is 178·48. Last year the general average for 804 birds was 182 per hen.

The cost of feeding each hen was 5s. 3·8d. this year, as compared with 5s. 7·8d. last year—a difference of 4d. a bird.

The profit over cost of feeding per bird is 9s. 2·9d. compared with 10s.10·2d. last year. The contributing causes are as follows:—An abnormal season, which resulted in a long period of moulting. During March the heavy moult caused a great reduction in the number of eggs laid. For the period April 1st, 1913, to March 31st, 1914, the average price of eggs per dozen in the Adelaide market was only 11·74d., compared with 13·08d. last year. This considerable fall in the average price of our eggs points strongly to the fact that, despite interested statements to the contrary, we must soon send part of our surplus to oversea markets, where the price is higher than in Adelaide at the glut season. Another factor to be reckoned with is that 19 pens were for a considerable period one bird short, and two pens had two birds short, and one had three birds short. The total shortage can be best expressed as 1,420 egg days, *i.e.*, that a maximum addition of 1,420 eggs could have been made, thus largely increasing the general average. These shortages were due to deaths and incapacitated birds occurring at a period when the scores were so far behind that there was no hope of winning a prize; still, the effect on the averages is considerable.

BREED AVERAGES.

The average production of 750 White Leghorn hens is 184·4. Last year the average production of 618 White Leghorns was 191·3. The next highest breed score is that of the White Wyandottes, viz., 181·5. This variety of Wyandotte I have recommended as a fine all-round fowl for farmers and others.

BREEDS AND AVERAGES.

No. Pens.	Breed.	No. Birds.	Eggs Laid.	Aver. per Hen.	Aver. per Pen.
125	White Leghorns	750	138,306	184·4	1,106·4
1	Brown Leghorns	6	724	120·66	724
14	Black Orpingtons	84	12,992	154·66	928
3	Silver Wyandottes	18	2,574	143	858
2	Black Langshans	12	1,901	158·41	950·5
1	Buff Orpingsons	6	799	133·16	799
1	White Wyandottes	6	1,089	181·5	1,089
1	Black Minorcas	6	819	136·5	819
1	Faverolles	6	731	121·83	731
1	Dorkings	6	704	117·33	704

SUMMARY OF RESULTS.

Number of pens	150
Number of hens	900
Total number of eggs laid	160,639
Total value of eggs laid	£655 7s. 2d.
Total cost of feeding	£239 9s. 6d.
Profit over feeding	£415 17s. 8d.
Average market price of eggs per dozen	11·74d.
Average number of eggs laid per hen	178·48
Average number of eggs laid per pen	1,070·9
Average cost of food per pen of six hens	£1 11s. 11d.
Average cost of food per hen	5s. 3·8d.
Eggs laid by winning pen, Section I.	1,444
Eggs laid by winning pen, Section II.	1,222
Eggs laid by winning pen, Section III.	1,330
Highest average per hen	240·66
Highest score per pen	1,444
Profit over cost of food per pen	£2 15s. 5¼d.
Profit over cost of food per hen	9s. 2·9d.

FOOD USED.

The following quantities, varieties, with cost of each, will show the expenditure incurred during the year:—

			£	s.	d.
Wheat	688¾ bush.	at average price 3s. 6d. per bush.	120	10	7
Pollard	950½ bush.	at average price 1s. 1¼d. per bush.	52	9	6
Bran	433¾ bush.	at average price 1s. 1¼d. per bush.	23	18	11
Lucerne chaff	14¼ cwts.	at average price 4s. per cwt.	2	17	0
Meat meal	40¾ cwts.	at average price 18s. 6d. per cwt.	37	13	10
Grit (including hard grit, shell grit, charcoal, &c.).	9½ tons		1	19	8
			£239	9	6

Average cost per bird for year, 5s. 3·8d

PRIZE WINNERS.

Section I.

			£	s.	d.
1.	E. McKenzie	1,444 eggs	10	0	0
2.	Moritz Bros.	1,361 "	5	0	0
3.	Indra Poultry Farm	1,340 "	3	0	0
4.	W. G. Swift	1,337 "	2	0	0
5.	J. E. Bradley	1,335 "	1	0	0

Section II.

1.	D. Kenway	Black Orpingtons	1,222 eggs	10	0	0
2.	T. W. Cote	"	1,149 "	5	0	0
3.	J. E. Bradley	White Wyandottes	1,089 "	3	0	0
4.	Cowan Bros.	Black Orpingtons	1,079 "	2	0	0
5.	B. P. Martin	"	1,057 "	1	0	0

Section III.

1.	R. Carling	1,330 eggs	10	0	0
2.	C. Sampson	1,273 "	5	0	0
3.	" Herdsfield "	1,270 "	3	0	0
4.	J. Rowe	1,193 "	2	0	0
5.	R. Kerr	1,192 "	1	0	0

In section I. the winner, E. McKenzie, is a Victorian breeder; second and third places are occupied by South Australians, viz., Moritz Bros, Kalangadoo, and Indra Poultry Farm, Freeling; fourth and fifth prizes go to Victorian breeders. In section II. (heavy breeds), the first four prizes go to breeders in the other States, and fifth prize to B. P. Martin, Unley Park.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1913-14.

[Started April 1st, 1913, terminated March 31st, 1914.]

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, March 11th, there being present Mr. G. R. Laffer, M.P. (Chairman), Professor Perkins, Col. Rowell, Messrs. C. J. Valentine, C. H. Tuckwell, J. Miller, G. Jeffrey, F. Coleman, A. M. Dawkins, and the Secretary (G. G. Nicholls).

Bulk Handling Wheat.

The Secretary reported that the Minister of Agriculture (Hon. T. Pascoe) had intimated that he did not think anything would be gained at the present juncture by holding a conference, such as had been proposed by the Council of Agriculture of Victoria, on the question of handling wheat in bulk. A further letter from Melbourne had been received, stating that in the opinion of the committee of the Farmers' and Settlers' Association of New South Wales no good purpose would be served by holding the suggested conference at present. It had, therefore, been decided to postpone the conference indefinitely, unless it should be particularly desired by Queensland or South Australian organisations. As a prompt reply was desired he therefore had transmitted the views expressed by the Minister, and the matter had been postponed indefinitely.

It was resolved to inform the Goode Branch of the Bureau that at present it was not intended to take any action in the direction of establishing wheat elevators at Decres Bay or elsewhere.

African Box.

A letter addressed to the Commissioner of Crown Lands by the District Council of Port Elliot, and sent on to the Board for an opinion, directed attention to the great appropriation of land in that district by the African boxthorn; explained that birds carried the seeds all over the country: emphasised that thousands of acres of land would be rendered utterly useless for stock grazing and other purposes unless large sums of money were expended in eradicating the pest; and urged that it should be declared a noxious weed. Professor Perkins saw no good purpose served by declaring any weed noxious, since the Act was inoperative as it stood. Mr. Coleman said that when weeds were declared to be noxious a large number of farmers endeavored to eradicate them. At the same time many of the district councils were very lax in the performance of their duties in connection with the destruction of such growths. Regarding this African box, he was not prepared to speak, but believed it was extensively used in some parts to form hedges. Mr. Dawkins—In sandy country the box spreads very rapidly and overruns good land. Mr. Birks—North of Adelaide it has not become a pest, and when it gets away it can be easily destroyed. Apparently, however, it grows much more vigorously in the south, and is a pest there. Seeing that it possesses useful qualities as a hedge-making plant, I doubt whether it would be advisable to proscribe it. Col. Rowell—In the earlier days of the State some high prices were paid for plants. Mr. Jeffrey—I think, seeing that the plant is appreciated in many localities, it would be dangerous to declare it a noxious weed, and that it will be sufficient merely to give publicity to the letter from Port Elliot, so that the landholders will be made fully alive to the objectionable possibilities of the plant. This suggestion was then adopted (see "Points for Producers,'' this issue).

VETERINARY SURGEON WANTED.

A resolution from the Lucindale Branch to the following effect was tabled :—"That the Government be requested to appoint a qualified veterinary surgeon to be stationed in this district." It was mentioned that the mover of the motion had lost two valuable horses through inability to secure the advice of a man thoroughly competent to treat them. Mr. Coleman said this was still an important question in several of the rural districts. Only recently he was asked why the scheme for the appointment of veterinary surgeons to different districts had been dropped. Stockowners were at a great disadvantage under existing conditions when any of their animals required skilled treatment. At the instance of Col. Rowell it was determined to send the communication on to the Minister of Agriculture without comment.

WHEATS AT THE SHOW.

Mr. Coleman suggested that the Director of Agriculture, who was one of the judges of the wheats exhibited at the March Show, should be asked to furnish a report for publication respecting the results of the milling and other tests. The information, he was certain, would be very interesting and helpful to the farmers. The milling was done with the new one-sack mill—imported by the department and established at Turretfield—which, according to the miller (Mr. G. H. Stevens), had acquitted itself admirably. He understood, however, that to enable milling tests to be conducted on absolutely the same lines as were followed by the commercial millers, it would be necessary to install a conditioning plant which, no doubt, would be obtained. With the aid of this the grain could be properly toughened, and the process of milling would be made easier. Without such a plant the bran was crushed up rather fine, and the flour was not so white as it would otherwise be. Mr. Coleman's idea was heartily indorsed.

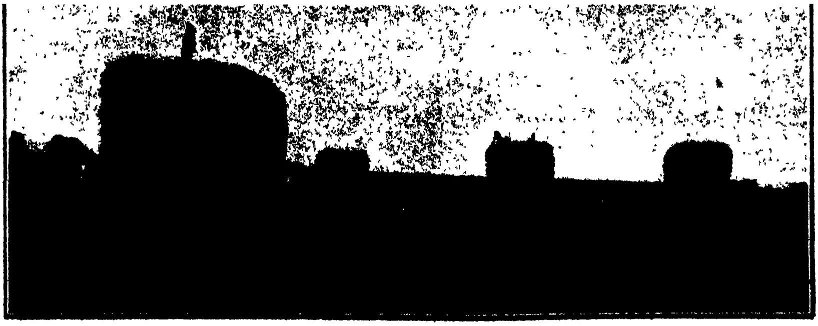
BUREAU BRANCHES AND MEMBERSHIP.

Bandon.—Owing to a local dispute in the Bandon Branch, which had prevented any effective work since the formation of same some months ago, it was decided, after careful consideration, to close the Branch.

Badge of Membership.—The Longwood Branch suggested that a badge or token of membership should be supplied to members of the Bureau. It was decided to give the Longwood Branch an opportunity to bring this matter forward for consideration at the Congress to be held in Adelaide in September next.

Life Member.—Mr. A. Goodall, a valued member of the Paskeville Branch, was duly approved as a life member of the Bureau in recognition of his services to the institution and the producing interests of the State.

New Members.—The following gentlemen were approved as members of the Branches shown, viz.:—Monarto South—A. Daly; Berri—A. V. Mills; Paskeville—M. Liddy, S. Pontifex, F. Couzner, J. C. Price, J. Petherick; Wilkawatt—J. L. Ottoway, J. Dunn, J. Oram, J. Cushion; Strathalbyn—H. L. Tucker, R. Halliday, C. L. Taylor; Two Wells—H. J. Webb; McNamara Bore—D. Bicknell; Millicent—E. J. F. Altschwager; Kanmantoo—L. Wooley, R. Shepherd, C. J. Downing; Mount Barker—L. Patrick, A. Paterson, F. Daddow, C. M. R. Dumas, A. Cornish, W. E. Pyne, S. Waters, E. G. A. Tyrie; Mundoora—H. H. Stephenson, J. R. Noble, W. Bates, E. Button; Hartley—H. Simcock, F. Pope; Wirrabara—H. S. Heathersy, J. H. Jeske; Laura—V. Walter, J. Bowman, J. Shuttleworth, A. Holland, H. McDonald, B. J. Crocker, T. P. Winter, W. H. Sellick, J. Spicer, R. F. Cox, G. G. Maywald; Spalding—W. Frost, J. J. Dowd, J. McLean, R. Dunden; Morphett Vale—R. Morrow, C. Duval, D. Whittington; Riverton—J. McInerny, J.P., W. J. George; Clare—J. Sincock; Tatiara—C. Saxon, W. A. Johnston, A. Brown; Naracoorte—P. Heffermann; Orroroo—J. Markham, F. Macdonald, W. C. Fogden, A. C. Moody; Pine Forest—W. C. Hewett; Roberts and Verran—L. E. Cowley.



Haymaking.

THE AGRICULTURAL BUREAU.

CONFERENCE OF UPPER NORTHERN BRANCHES.

The Annual Conference of Upper Northern Branches of the Agricultural Bureau was held at Orroroo on March 20th, 1914.

The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), the Director of Agriculture (Professor W. Lowrie, M.A., B.Sc.), the Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) represented the department, and Messrs. C. E. Birks and C. J. Tuckwell, and G. G. Nicholls (Secretary), the Advisory Board of Agriculture. The undermentioned Branches were represented by delegates, as follows :—Arden Vale and Wyacca—O. E. Hannemann, J. H. Williss; Carrieton—F. Kaerger; Coomooroo—W. Robertson, E. Berryman, A. H. Tilbrook, E. W. Brice, R. G. Polden; Julia—T. H. Carter; Morchard—E. J. Kitto, J. Scriven, J. W. Reichstein; Orroroo—T. H. P. Tapscott, W. C. Fogden, L. R. Cottrell, J. C. Hagger, M. W. Forrester, J. G. Shackleford, J. R. Chapman, H. Chapman, H. J. Cottrell, J. J. Dennis, J. McNaughton, A. L. Brice, E. J. Turley; Quorn—C. Patten; Tarcowie—W. S. Bennett, H. Dempster, A. W. Muller, J. Breuer, W. Travers; Wepowie—J. Chrystall, J. Crocker; Willowie—D. McCallum; Wilmington—D. S. George, A. H. Noll, P. H. Pickering, B. Jericho, J. F. A. Zimmermann. A large number of visitors also attended.

CHAIRMAN'S WELCOME.

The President of the local Branch, Mr. J. B. McDougall, in extending a hearty welcome to the Minister, the officers of the department, and visiting delegates, mentioned that on the previous day a show had been held under the auspices of the Branch. This had been successful, far in excess of expectations, and there was every reason to expect that it would become an annual feature. He asked the Minister of Agriculture to declare the Conference open.

MINISTER'S ADDRESS.

The Hon. T. Pascoe said he was very pleased to see that the farmers had not lost hope because of the bad seasons through which they had passed. In country like that represented by the various Branches included in the Upper Northern Conference district, they must expect every now and then to be faced with conditions similar to those that had obtained during the past few years. He only hoped that the coming season would turn out better, as many people seemed to think it would. Men who were, perhaps, worse off than those in this district were farmers who had gone into country that had been boomed, and had given £12 per acre for £3 and £4 land. They entered into it with a millstone of mortgage and debt round their necks. These men paid in interest much more than the farmers in some parts of the North paid in rent.

THE TURN OF THE TIDE.

South Australian farmers were in a much better position to take advantage of the good seasons when they came than they were when the tide turned in the 90's. They had made mistakes in the past, and they had suffered for them, but all their experiences could be turned to advantage when the good seasons came. One lesson which they did not appear to have learned thoroughly yet was that of making preparation in the fat years for the lean ones. If they made £1,000 in a good year, they should put aside a certain amount to carry them over the bad years. When they had a growth equal to two tons of hay per acre, they should cut more than would meet their season's requirements. A heap of cocky chaff was an excellent standby. By the addition of something of a more concentrated nature, they could make this carry their stock through dry times.

He sympathised with them, as a farmer who had gone through, and was going through the mill at the present time, and hoped that they would have a successful and profitable Conference.

SILAGE.

Mr. P. Pickering, of the Wilmington Branch, read a paper, as follows :—

"The term ensilage generally applies to a special process of preserving green fodder. Unfortunately it is little known in South Australia, but no doubt in time it will be looked upon as essential as a stack of hay. When green stuff is heaped together, either in a pit or in a stack, the most apparent change is a rise in temperature. The rise in temperature is due to the fact that cells of the plants thrown together are alive, and as such continue to breathe for awhile. As breathing is a form of combustion, it simply means a rise in temperature. When a great number of these cells are thrown together the whole mass rises in temperature until all the cells are killed by excessive heat, as no living cell can stand a temperature much above 150° F. Before the cells are killed chemical changes take place in the composition of the green forage. If these are allowed to go on unchecked acids are formed, and finally the whole mass becomes putrified. Therefore the art of making good silage consists in knowing how to use these chemical changes to the best advantage and how to check decay. The object is to exclude the air, and so prevent oxidation, which brings about fermentation, decay, and loss. The more thoroughly the air is excluded the greater the success. According to the stage of decomposition to which the silage has reached it is known as either 'sour' or 'sweet.' This depends mainly on the temperature at which fermentation takes place. Sweet silage is that in which the chemical changes have been checked more or less and the temperature allowed to go above 120° F., while in sour silage the changes have been allowed to go farther and the temperature kept below 120° F. There is no question that sweet silage has greater feeding value than sour, because the farther those chemical changes go the greater the waste of substance. To completely check the formation of acids on a large scale is practically impossible. The best method of making is to keep whatever is to be ensiled in shallow layers and allow it to heat. New layers should be put on until the average temperature is between 135° and 140° F. That temperature is sufficient to check the formation of acids. If the temperature rises much higher the silage assumes a dark, burnt appearance, and is not relished much by stock. As soon as weight is added to heated herbage a further rise in temperature is checked. If a pit or stack is filled without reference to the thermometer the silage will most likely be sour, because the temperature will not rise sufficiently to check the formation of acids.

"Maize stands out above all other greenstuff for making silage, because of its fleshy leaves and stems, which are neither too succulent nor too dry. Both are rich in sugar. Besides maize, sorghums, millets, peas, beans, and cereals can be used; in fact almost any green herbage is suitable. Because a plant will ensile well, however, it does not follow that it will always pay to use it in that way. One has always to study one's own requirements and conditions. Some people want ensilage for the winter, while others require it for the summer and autumn. There will be no advantage to ensile anything that can be used in the green state. We generally make silage from growths in spring that are in excess of what can then be used, and which can be profitably ensiled. Parts of the crops may be too dirty for grain or hay, and these can be profitably used. If we sow an area especially for ensilage it is as well to mix with a cereal (wheat or oats) peas, beans, or vetches, and always sow thickly. The best and most reliable method of dealing with it is to chaff it into 3in. or 4in. lengths. It then packs better, leaves less waste of space, and more effectively excludes the air when the weight is put on. One disadvantage in chaffing is the difficulty in handling, unless one is using the overhead silo. One condition that must be observed is that more stuff should not be cut than can be used immediately. It is a mistake to cut a great amount and let it lie about, because when the stuff wilts it is difficult to secure the necessary rise in temperature. Not more than three days should elapse before adding more material, as the top will go mouldy. Salt sprinkled on occasionally is an advantage. As the pit is being filled great care should be taken to tramp down the mass firmly, especially around the edges, because in settling down it has a tendency to leave the walls and settle in the middle. The pit should be filled a few feet above the top and allowed to settle; filled again, and allowed to settle, and so on. There will then be very little waste space on the top of the pit. Finally, it must be weighted down. On top of the greenstuff place 6in. or so of chaff or straw to exclude the air, cover with boards, and distribute weights evenly over the surface at the rate of 1cwt. per square foot. The pit is then finished, and if made properly it will remain good for years. With 'stack' ensilage, the main advantage is that it does away with the expense of a pit or overhead silo. The chief objection to this is the loss around the edges, which may extend from 12in. to 18in. inwards around the stack. If it is intended to make only a small quantity the stack is not to be recommended, on account of the greater loss compared with the pit. The stack is built like a haystack, with vertical sides. When the stack is finished the edges should be higher than the middle. When the required height is reached it should be weighted. Considerably more weight should be used than in the pit, from 2½cwts. to 3cwts. per square foot being required. The overhead silo has an advantage over both of the methods described, in that when it is filled it can be emptied by means of gravitation. Chaffed forage can be used to advantage in this form, as it can be elevated into the silo.

Comparison with Hay.

" In comparison with hay, silage always represents a bigger weight, going from 50lbs. to 60lbs. per cubic foot. Roughly speaking, five tons of green forage will make one ton of hay, whereas it will make four tons of ensilage. Is does not follow, however, that the ensilage is four times more valuable than the hay. The main difference lies in the amount of water retained. Silage will hold about 70 per cent. of its own weight of water, while hay will not hold more than 10 per cent. to 15 per cent. Ensilage constitutes a foodstuff far more digestible than hay. About three tons of ensilage equal one ton hay made from the same forage. Ensilage is fed almost exclusively to dairy herds; in fact, it is rarely used for any other purpose. In a country like this, where green succulent food is not obtainable for months in the year, it could be fed with advantage to any stock. Probably in the course of time, when it becomes known that stock can be profitably fed with ensilage, it will receive more attention."

Discussion.

Mr. C. J. Kitto (Morchard) said the writer had advised putting in a layer of silage every three days; he would like to know whether it was necessary to weight the stack after each layer was put on.

Mr. Pickering replied that the weighting was only necessary when the stack was completed.

Mr. J. W. Lock (Carrieton) said it had been stated that ensilage had a deleterious effect on the milk when fed to dairy cows. Was that so ?

Mr. Pickering said that would not happen if small quantities were fed to the animals at first.

Mr. R. Phillis (Wepowie) asked whether wild mustard would be suitable for ensilage.

Mr. Pickering said that if it were put in with other stuff it would not affect the silage.

The Chairman asked whether it would be safe to use sweet ensilage for feeding young horses.

Mr. Place (Government Veterinary Lecturer) said from experience he could say that silage, whether sweet or sour, fed under commonsense conditions, was practically safe for any class of stock. He had fed horses on practically nothing else for months. However, stock of all classes could not be constantly changed from one class of feed to another without upsetting their digestive arrangements. If they were going in for ensilage, they should begin to feed it before they got their stock off the other feed, gradually accustoming them to it. They could not get away from the fact, however, that with silage in the stack or in the silo, they allowed in a great deal of air, with the result that a number of moulds grew, and these upset the animals. If this stuff were fed with cocky chaff, or some such dry material, it would be safe. Practically any greenstuff could be made into ensilage. Whilst it was best to chaff the material being ensiled, this meant a certain amount of labor and expense. They could construct very cheap silos if they had a hillside on the farm. These could be filled from the top and emptied from the bottom, which would save a considerable amount of labor. In India they constructed silos of bamboos and mud—a capacity of about 100 tons being built for from £15 to £20. If they fed the silage to cows after milking there would be no trouble on account of the milk being tainted. They could safely feed a horse on up to 40lbs. of silage per day, but 10lbs. was enough to begin with; 60lbs. per day would not be too much for a cow, 15lbs. being sufficient at the beginning.

Mr. T. H. P. Tapscott (Orroroo) asked whether wild oats cut for silage should be allowed to stand in the paddock.

Mr. Pickering said it should be stacked immediately.

The Director of Agriculture said silage was a means of storing feed and still retaining a percentage of its succulence. In this respect it was of value. However, in country where they could grow a small area of lucerne, for example, to keep the stock from stomachic troubles, personally, he would not make the feed into silage, but would give a small percentage of greenstuff with the ration. A great deal of labor was entailed both in putting in and taking out the silage. He strongly opposed underground silos. As a matter of thriftiness in making a definite weight of food go further—and this was the critical test—he was of the opinion that they got more out of it by making it into hay than by making it into silage. When feeding silage they should not give it to cows near the place where they were milking; they would then find that it would improve the quality of the produce rather than deteriorate it. Instead of putting money into the construction of a silo, he preferred to spend it in the purchase of a windmill and distributing pipes. Silage was certainly particularly suitable for cows; the same advantage did not obtain with sheep, and with horses his experience generally was that they did not take to it very well, although some horses ate it ravenously. The method of making recommended by Mr. Pickering was sound.

Mr. C. E. Birks (Advisory Board) had found it a decided advantage to chaff fodder intended for ensilage. Long stuff entailed considerably more trampling, and there was more likelihood of it turning out mouldy. Taking into consideration the extra trampling and spreading, it took just as long to get it into the silo as when it was chaffed. In New South Wales, he had noticed, they scooped out a channel about 6ft. or 8ft. deep, carried the fodder into this, and covered it with earth. At Junee they were now using fodder that had been held for three years in this way.

SORGHUM FOR HAY.

Mr. C. E. Birks tabled samples of sorghum cured for hay and chaffed. It had been grown at Wandearah. He contributed the following notes:—"There is no doubt that sorghum would be more largely grown in suitable places, such as river flats and lowlying land, and as a chance crop on ordinary wheat-growing land if it were generally recognised that the crop could be profitably cut, stooked, and cured. That such is the case is proved beyond doubt by actual experience. What the feeding value of the chaff actually is can only be determined by use and analysis. The sample exhibited is from a crop of three acres grown under irrigation, which consisted of one flooding just after the crop was sown. It grew to a height of 6ft. and not receiving another watering, seeded profusely, and at the same time was remarkably green down to the bottom of the stalks. At this stage the binder was put into it. It was cut and stooked and left for four to five weeks before carting. This curing, or drying, is the one weak point, as in the case of irrigable land it is important to get the crop off quickly; and it would necessitate the crop being watered two weeks before cutting, and then before the hay was fit to cart the second crop would be anything from 2ft. to 5ft. high again. The rows being 20in. to 24in. apart, the stooks would need to be made in the spaces and as flat as possible, to lessen the time of drying. On non-irrigated land this trouble would be much less, if it existed at all; the carting might have to be done through a growth of 2ft. of sorghum, but as this would in all probability be fed off, no harm would be done unless the stooks were put on top of the rows. In cutting the crop it is as well not to take a full cut at a time, as two rows give the machine plenty to do. It would then be covering 3ft. 4in. to 4ft. It is as well, if the land is fairly dry on top, to let the sheaves lie for a few days before stooking, and when this is done, with three weeks' good hot weather, it is possible that the crop will be fit to cart. Sorghum seed is one of the most fattening grains I know of, and by this method it is possible to make use of it. There is a large amount of loss when fed long, unless the crop is cut before the seed is ripening. To chaff it economically it must be made into hay, except in establishments where it pays to chaff the greenstuff every day; and that, of course, is a matter of quantity. I fully believe maize could be handled in the same way, only the curing trouble would be the greater. It sometimes happens that a farmer has a far greater amount of greenstuff than he can deal with. For instance, he sows 20 acres of sorghum in the hope of getting some greenstuff on which to turn his stock. If conditions are very favorable the result is a quick growth of, say, 5ft., 6ft., or 7ft. To turn stock into that is not only waste, but it causes a deal of trouble in the way of clearing up land for the succeeding crop. If as much as it is possible to use is cut out, and the balance treated for hay, the next growth can be fed off clean. The latter should not be allowed to grow too much stalk. This plan will work admirably on land adjoining rivers or dams that go dry, for one good soaking on the crop after it is in (and up for preference) will ensure one good cut and fair growth after."

In reply to questions, Mr. Birks said he sowed about 5lbs. or 6lbs. per acre in November, using every third hoe of the drill only. It was cut with the binder. In the particular case under notice the variety used was Early Orange Cane. No manure was used, as the seed was put in on a rich river flat.

The Director of Agriculture mentioned that Early Orange Cane and Early Amber Cane varieties had been proved in this and other countries to be the best.

AFTERNOON SESSION.

ENCOURAGEMENT OF MILLING.

Mr. W. Robertson, of the Coomooroo Branch, read a paper, as follows :—"The marketing and bulk handling of wheat is a subject which is receiving a good deal of attention at the present time, with the object of economising expense and securing to the grower a better return for his labor and outlay. There is one way in which this could be done which has not received as much attention as it might. If our milling trade could be encouraged, and a trade in flour established with the United Kingdom, it would reduce both freight and handling charges by one-third, and be a gain, not only to the farmer, but to the manufacturer and the laborer as well. Mill offal, for which there is a growing demand, would be retained in the country and used for dairying and stock fattening. The trouble in the past has been that the South Australian millers have been unable to compete with the British millers on account of the extra cost of labor. This difficulty might be overcome either by a little help from the Commonwealth, or by some other means, until a trade is established. The British miller buys our wheat chiefly for blending purposes, ours being the superior article. Surely our millers, with all good wheat, can produce a grade of flour that will compete successfully with that made in Great Britain, where they use part good wheat and part inferior."

Mr. J. Scriven (Morchard) said there was difficulty in getting offal from the mills at the present time at a satisfactory price. Possibly the scheme recommended by Mr. Robertson, if adopted, would result in an improvement in this regard.

The Hon. T. Pascoe said it was a difficult matter for the South Australian farmers to comply with the requirements of the British bakers with regard to flour. They not only wanted a flour of even quality, but they even went so far as to want flour made from particular varieties of wheat. So far as South Australian methods of marketing were concerned, this was impracticable. It became a question as to whether they would give the grower better prices when he was marketing his produce as flour than they would give for the wheat. Australian wheats had a special value for blending, because of the dryness of the climate in which they were produced. This put a special price on them over and above that which they would otherwise secure. Some tests made in connection with the Leeds grocers' exhibition last year had proved conclusively that bread made from South Australian flour was equal to bread made from any other flour, but the bakers were not prepared to use it unless there was a regular supply, both of quality and quantity, always available.

THE EASTERN MARKET.

He had been trying during the past two years to arrange with the shipping companies to call here in connection with the Eastern trade. There was a market in the East of which South Australia should be taking a greater share. The demand for offal in this State was greater than it had been before, and it would be used still more largely if supplies were available at more reasonable prices.

The Director of Agriculture said this question had agitated people in South Australia a great deal. The thought as to whether it was practicable that they should grind wheat here and send flour abroad had been encouraged by the practice obtaining in America. There was a time, not so very many years ago, when America's production was sent as wheat, and it was ground in the Old Country. Within the past 12 or 15 years a great change had taken place, and the English milling firms were feeling the competition of the Americans very keenly. Our wheat had a special value to the British miller for blending purposes. It was necessary to understand that a line of flour turned out by a mill should be absolutely regular in quality. Millers in this State had not the opportunity of doing this, because they did not blend to the same extent that the British millers did. South Australia produced a considerable proportion of soft white wheats, but farmers were gradually going in for varieties yielding stronger flour. A stronger wheat would produce more loaves of bread to the bag than a weaker grain. The position was that neither the grower nor the miller nor the baker had the chance of learning enough about the question. However much they might desire to get a footing for their flour in the English market, until they got the constancy referred to above, they would not be successful. What they should strive for was a share of the trade in the East and in South Africa. Australia should have the advantage in these markets, because our flours, when conditioned, kept better than those of England.

Mr. Kelly (Orroroo), who had been a miller for a number of years, said this State could not compete with England and America in the grinding of wheat, not on the score of quality, but on account of the cost.

WATER FOR LIVESTOCK.

The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.), in an address under the title "Water in the Diet of Livestock," said—"At a meeting of farmers there seems to be a fixed idea that a veterinary surgeon should talk disease and all the drugs of Araby. The Chinese are wiser; they pay their doctors, and no doubt their veterinary surgeons, too, as long as the patients under their charge remain healthy, and the subsidy stops when disease appears. The speaker is not prepared to say whether this method would meet with the approval of the veterinarians in this State or not, but in practise it is what the Stock and Brands Department carries out, namely, the control and stamping out of disease; and it appears to the speaker that the prevention of preventible troubles is a matter for farmers to closely consider for themselves; hence, he has chosen for a short talk to-day the importance and the value of water in the everyday diet of the animals of the farm. And in addressing a meeting at Orroroo, the importance of this item of diet will very forcibly impress itself upon his hearers. If the question is raised as to what is to be done if there is no water, then he would say there should be no stock. The striking of the rock by the diamond drill of the borer may produce the miraculous gushing forth of the water so anxiously desired by a thirsty land; but if waterholes without water, dams dry, and creeks crusted with salt are to be offered to thirsty stock, then, surely, the brains of the South Australian farmer must be utilised on the question of dry farming in relation to the vegetable kingdom rather than the animal; because common sense must plead for the necessity of an adequate water supply if animals are to be expected to live, let alone thrive. Paralysis, dry bible, and similar affections are, in a great number of cases, simply fancy names for shortness of water, which fluid forms more than half the body weight of an animal; and yet is often ignored altogether when the matter of building up that body is being discussed. It is the chief medium by which the nourishment of the food is carried into the blood, and the main cleanser of the bowels, and preventer of those forms of stoppage which account for so many deaths among stock in South Australia. Water is of the highest importance in all the processes of change in the animal body which are spoken of as life, and it is especially so in the processes connected with digestion. It helps in chewing; by it the food is rendered fit to be absorbed by the bowels; it is the chief carrier of nutriment to the system, for without a sufficiency the blood is unable to utilise the food offered to it; its evaporation by the skin and lungs is one of the chief means of keeping the body at a suitable temperature; and its presence is absolutely necessary in what is called the metabolism of the food, those intricate changes which transform the vegetable cells into fit food for animal tissues by such marvellous processes that even the balance of the chemist is not able to check the minute alterations that take place. When water is not present in sufficient quantity the processes of digestion are slowed down and those of waste removal checked, so that poisons form in the system which would not otherwise do so, and the products of protein digestion rapidly change into virulent poisons. When the blood is too thick from loss of water the body temperature rises and the system becomes more liable to attack by those poisons, and the young, both before and after birth, are seriously crippled in their struggle for existence, while thirst diminishes the desire for food, and purging, vomiting, paralysis ensue, and death does not loiter on his way. The calf, with tissues of some 65 per cent. moisture, lives upon suction only, while the fat Merino, with less than 35 per cent., does very well upon the stubble paddock; the horse and cow standing midway must have ready access to water as well as feed. Much as the speaker dislikes quoting figures, the following are so striking that he cannot forbear reproducing them:—For every pound of dry food the pig requires 7lbs. to 8lbs. of water, the cow 4lbs. to 6lbs., and the horse 2lbs. to 3lbs. just as a maintenance ration. That is to keep life in the body, without considering such matters as the reproduction of the species, the making of milk for man's use, or the labor and sweat of the team. Now, do they get it? If not, is the shortage responsible for that lack of bloom, that want of roundness and plumpness, that gaunt stretching of skin over prominent bones, which so soon becomes a hide? If experience of thousands of dead and dying beasts in the famine-stricken desert of India counts for aught, the answer would come back unhesitatingly—your cattle die for want of water, your store stock starve for want of water, your show stock is gaunt and light for want of water. The rounded rump is 50 per cent. water, the well-ribbed barrel is 50 per cent. water, the sleek smooth skin is padded out with 50 per cent. water. You pay a shilling a pound for it when you buy juicy English steak, and your canner adds it to the solid meat he has bought from the Australian grazier; he would pay you 2d. or 3d. a pound for it and be glad to do it, because frozen in the tissues of the carcass it would fetch him more on the quality of his export. Water adds weight, and nothing has struck the speaker so forcibly when on meat inspection duty as the low—very low—water content of the meat. Not only does water make weight, but it actually favors the deposit of fat in the tissues; which means all the difference between a poor carcass and prime one. Now, do not think that — like the farmer who found the wheelwright put putty in his wagon to strengthen it, ordered the next to be built all of putty because he wanted that to be extra strong—our beasts should be wrapped in oilskins to conserve the moisture, for even with water, enough is as good as a feast, and excess leads to indigestion, waste of food material, and flabby muscles; but it seems like painting the lily and gilding refined gold to talk about an over supply of water here. However, what is pertinent to the district and conditions is this fact: The water contained in the food is of far greater feeding value to the animal than that taken as drink, and it is of great interest to read the tables so carefully worked by Professor Perkins and his staff, and to note that the water content has a marked influence on the feed value of hay. Australia is deeply indebted to Professor Perkins for the care and accuracy bestowed on those unique observations, as well as for his advocacy of succulent fodders like berseem. It is a fact worth noting that in the country once called the Ninety-Mile Desert, men now put down their 1,000 acres of lucerne with every confidence, and are rewarded with the success they deserve; they are feeding water, and they find it pays. Professor Lowrie insists, in season and out of season, on the preservation of the humus of the soil, and not only so, but tells you it must be got into the soil that has it not; he tells you it is the greatest moisture-conserving agent you can get, and he goes further and tells you how the green crop, be it rape or vetches, lucerne or mixed clovers, will help you to ward off those seasons of drought which hang so ominously over our heads. In one word, he is asking you to feed water. Doubtless many of you know how the beast has been dragged from death's door by copious drenches of pollard gruel, or some other mixture of which water has formed the greater part, and you will not be surprised to hear that life has often been saved by injecting warm water into an animal's veins. Our cereals contain about 12 per cent. water, our green fodders vary from 40 per cent. to 70 per cent., while our bleached straw has been treated by nature much as the chemist would do if he wanted to find out its constituents, without water; it has been kept for hours at a high temperature, and consequently contains very little indeed. If we watch our animals at ease in the paddock when out of work, we shall find that they do not drink often, once or twice a day under ordinary circumstances; but if we could check the observation we should find that they would drink from two to four times the weight of water more than the forage they eat, figures which closely approximate those quoted above if allowance is made for water in the fodder. It may be taken that an idle horse in ordinary weather will take about 7galls. a day, but heat, work, and similar conditions will largely increase the quantity;

for instance, a light horse kept trotting was satisfied with 3galls., but immediately doubled his requirements when trotting with a load. When the horse is at rest and drinking 6galls., he will pass 3galls. in his dung, 1½galls. in his urine, and 1½galls. by his lungs and skin. Work will immediately alter this ratio, and this explains why the attack of stoppage of the water follows a hard day's work. Heat will make the lungs and skin do more than their share, and so explain why congestion of the lungs is likely to follow a very hot day's work. We notice that horses in the army or used by large coaching or carrying firms are generally plumper and in better condition than many on the farm, and we think how nice it is to have a nation's purse or a company's profits with which to feed horses. Armies and carrying firms do not keep horses for the fun of the thing, but they find that it pays to feed water. It runs through the pipes and costs nothing for delivery, and the collar does not gall or the saddle wring the horse that has as much as he wants. Sometimes we are shocked when we see such horses white with sweat going to the trough and drinking at their will. We are even more shocked when we see the hose playing over them. The army has to keep fit, the company has to pay dividends, dead or ill horses will not help in either case, so they get good food little and often, and drink as just described; because physiology shows that a horse should drink before he gets his food, which will take some hours to digest, and so long as he is not kept standing in a keen, cutting wind after, he makes better use of his food and water when he gets the latter first. Cattle, on the other hand, have an arrangement which enables them to make better use of water if they take it on the top of a certain amount of roughage, which will have to be re-chewed as cud. With the working horse, evaporation of water is so rapid that the functions of the various organs of the body are seriously interfered with if they have to draw entirely on the water contained in the caecum or water gut, and, therefore, they will do much better if they have the chance of drinking at reasonable intervals during their work. We carry the water bag with us, but have an unreasoning fear of letting our horse do what we find necessary. He has as much sense as we have, and he will not drink too much if he can get it now and again; but, like ourselves, thirst will drive him to do stupid things, and his digestion will suffer in consequence. The wearied horse should not have too much, any more than a wearied man; but the latter is all the better for a glass of beer or a cup of tea, and so will be the horse for half a bucket of water with a handful of oatmeal or pollard stirred up in it, or a few mouthfuls of lucerne or wetted hay followed by a moderate drink. Food and drink, little and often, for the working horse will keep him fit and free from sores or ailments. Succulent food will supply half the drink a cow needs, and nearly all a sheep wants, while the pig will thrive much faster if he has a liberal supply of wash than he would on dry stuff only; and with them all that is the end and aim of their existence, to give the best return in the shortest time for the least cost."

In reply to questions, Mr. Place said it was a mistake to have the water trough alongside the manger, where the animal would foul the water with chaff, but they should have the trough in the yard, available to the horses at all times. If time and labor were available to malt wheat and warm up mashes, cows would do well fed on these, but they would thrive better on dry feed than on food partially wet at times. No harm would be done if they turned horses in a heated condition into a yard with a trough, so long as they were not exposed to a bleak wind. If the animals were very thirsty, however, they would do better by placing a couple of handfuls of bran or pollard into a bucket of water, and restricting each beast to this for a while before it went to the trough. Generally, water from artesian bores was suitable for stock, but when salt of magnesia were present this was not so. Well water was better; it was generally cleaner than water from dams, in which blood worms found an excellent breeding-ground.

PRESERVATIVES IN CREAM.

Mr. C. J. Tuckwell (Advisory Board), after apologising for the absence of Mr. G. R. Laffer, M.P. (chairman) and Mr. F. Coleman (vice-chairman), advised dairymen not to use preservatives in their cream. If anything were used, however, it should be either small quantities of salt or boracic acid compounds.

FRUIT AND FOWLS.

Mr. J. C. Hagger, of the Orroroo Branch, read a paper entitled "Poultry in the Orchard." He said—"Domestic fowls can be reared in the orchard and gardens with very little damage to the fruit and trees. They do far more good than harm by destroying pests and enriching the soil. In laying out orchard and runs and erecting houses great care should be taken to have each row of trees of the one kind. This will save labor in picking the fruit and also in spraying. For example, take it that we have an acre to lay out in trees and poultry runs: I should make the runs 20ft. wide and plant all the trees on the north side of each run. A 3ft. wide gate should open inside of each on the south side. This will allow 17ft. for the spread of the trees, which should be planted in the centre of the 17ft. and about 12ft. apart in the rows. Most of the shade will then be on the north. No vines should be planted in any of the runs that will be used in the summer months, for the grapes are apt to give the birds diarrhœa. The roosting houses should be made of four 4in. x 2in. or 3in. x 2in. posts, each 4ft. in height; 6in. x 1in. jarrah for bottom boards and 6in. x ⅞in. flooring for top boards, and framed in order to fit 9ft. x 3ft. plain iron for the back and 6ft. x 3ft. plain iron for the sides. Three sheets of 10ft. iron are required for the roof. Use sawn 2in. x 1½in. jarrah or deal for perches. The front can be left open to the north. This class of house will accommodate 40 fowls, is easily and cheaply constructed, provides no cracks or harbors for tick, and is easily shaded by placing it close up to the centre tree in the run. By having apples in one run, early peaches in another, and so on, the fruit will be ready to pick at one time, and the fowls can easily be shifted for a few weeks to one of the other runs at this period. Early peaches and apricots, and late apples and pears are most profitable. Chicks of all ages and fowls should not be allowed to run together. It is better to bring all the chickens out in the one batch, but in these parts the incubator is not in general use. I recommend the incubator for the sake of getting the early chicks. It will well repay the cost. By growing vegetables in some of the runs the ground receives more working, and when one crop is getting done one can fork up the ground and put on the chicks. They will get more worms, &c., and more exercise. Keep a sharp lookout for poultry ticks; eradicate them as soon as they are noticed. Gather the eggs daily. The infertile egg is the commercial egg of the future. There is a loss to this State of £60,000 annually on bad and rotten eggs through neglect. Whatever profit there is in fowls running at large there is double the profit if they are housed properly and kept under control. More labor is involved to start with, certainly, but far less afterwards. Separate the cockerels from the pullets as early as possible. Have the cockerel pens all at one end and out of sight of the pullets, and both will thrive better. Keep the drinking water in the shade. Get all surplus cockerels to the market as soon as possible. Get rid of all hens after two years old. Do not overfeed or underfeed. Give plenty of cut lucerne in the mash, and not too much mash to the breeding pens. Keep breeding stock, if good, for four or five years."

In reply to an inquiry from Mr. Tapscott, Mr. Hagger said the best fowl to keep was not so much a question of breed, but of strain. Of the light breeds, however, he recommended the White Leghorn. This would "rough it" better than any other in the north. Fowls did better in confinement than running free. A run 15ft. by 50ft. would provide ample accommodation for 40 hens. An effective method of dealing with tick was to wash the houses and runs with a mixture of 10galls. of boiling soapsuds and a bottle of kerosine. Grease, oil, and insectibane could be applied to the birds.

BLIGHT IN CABBAGES.

In dealing with this subject in a paper, Mr. J. Crocker (Wepowie) said blight attacked the cabbage plant at any stage of its growth. Turnips were also affected. He had tried dressings of lime, ashes, and sulphur, with the idea of checking the pest, but with little effect. Placing the crop on new land also was ineffective. The practice he was now successfully adopting was to dig in a light application of super. when the cabbages were being planted, and also to sprinkle the plants with super.

The Chairman mentioned that this year was the worst he had experienced with blight. Crops of cabbages and turnips were completely cleared out in the course of a few days.

EVENING SESSION.

NEXT CONFERENCE.

It was decided that the annual gathering should be held at Quorn in 1915.

IRRIGATION ON THE FARM.

Mr. F. Kaerger, of the Carrieton Branch, in a short paper, said—"There are very few farms that are without a well and windmill, or permanent water. All water fit for stock will grow lucerne and some varieties of vegetables. The farmer who possesses a well and windmill should have at least one acre under lucerne. If put in well and attended to properly this will provide enough greenfeed through the summer for six cows and several horses. Where pipes are laid summer vegetables do not require a great deal of attention. If the seeds of some varieties like cucumber and beans are put in in small quantities every 10 or 14 days this will ensure a succession of crops. Tomatoes, sweet or rock melons, water and pie melons can all be grown without much trouble. They require only two thorough waterings per week in very hot days. If a small plot of cabbages, carrots, &c., is put in beside the summer vegetables this will grow well. The cost of the pipes, hose, sprinkler, &c., would be amply repaid."

MANURES.

The Director of Agriculture (Professor Wm. Lowrie, M.A., B.Sc.) delivered an address. He dealt at length with the policy adopted by a number of farmers of purchasing low-grade super. Without imputing even a suggestion of unfair practice on the part of the distributors, he stated that apparently many tillers of the soil were buying superphosphate at a price considerably above that which they need pay for it. Some of the merchants, he added, were charging £3 17s. 6d. a ton for super. containing 30 per cent. of phosphate of lime, and £4 5s. a ton for that known as 36 per cent. quality. Artificial manures were generally valued on the price per unit—1 per cent. of phosphate of lime rendered soluble. The cost of the 36 per cent. on this basis worked out at 2s. 4⅓d. per unit, and that of the 30 per cent. at 2s. 7d. per unit. Those figures, which represented a difference of 2⅔d. per unit, were obtained by dividing the £4 5s. by 36 and the £3 17s. 6d. by 30. That difference did not seem very much, but it amounted to something considerable on, say, 15 tons, the average quantity of super. used by the farmers. It was not surprising to hear agriculturists who used the cheaper grade say that they obtained equally as good returns with it as they had secured by using the 36 per cent., because there might not be much difference apparent in the crop. If, however, the respective grades were used on two accurately measured plots, and the produce therefrom carefully weighed, an appreciable difference would soon be noticeable. Assuming, though, that there was actually no difference between the 36 per cent. and the 30 per cent., there could be no difference between the 30 per cent. and the 24 per cent., or between the 24 per cent. and 18 per cent. Still another 6 per cent. could be deducted, and so on, until they arrived at the point when there would be no phosphoric acid in the mixture. In reality, of course, there was a difference—a difference in the yield obtained, in the fertility of the soil, and in the cash balance in one's pocket, comparing the higher with the lower grade.

He regretted that farmers could be so short-sighted as to pay freight on 6 per cent. of stuff that was absolutely of no use to them, and pay more for the balance which was of value, because they did not trouble to reckon up the intrinsic worth of the fertiliser they were buying. The merchants knew very well the true value of the lower-grade article, but were out to do business. Recently he learned that some of the merchants were importing super. containing 45 per cent., and even as high as 48 per cent. He promptly communicated by telephone with one firm, and inquired what price was being quoted for 46 per cent. super. The reply was, "We cannot quote it, as it has all been broken down." He then asked, "Why has it been broken down?" and was told, "Because the farmers won't buy it. They want cheaper stuff." In a nutshell, that firm undertook the expensive process of mixing and thus lowering the grade for the simple reason that the farmers declined to purchase it at the figure required for the higher grade. A little calculation would show them that those who bought the £4 5s. super. received, on the basis of the £3 17s. 6d. stuff, value to the extent of £4 13s.

POUNDS, SHILLINGS, AND PENCE.

The essential and valuable element in the superphosphate, of course, was the phosphoric acid. In the 36 per cent. article there was 16·47 per cent. of this, but in the 30 per cent. there was only 13·4 per cent. The total disparity in 15 tons of the two grades was more than 900lbs. In other words, for land to receive the same quantity of soluble phosphate of lime as would be contained in 15 tons of the 36 per cent. super. it would be necessary to apply 18 tons of the cheaper material. In pounds, shillings, and pence it meant that whereas 15 tons of 36 per cent. super. at £4 5s. a ton would cost only £63 15s., they would have to pay £69 15s. for 18 tons of the £3 17s. 6d. a ton stuff to get the same amount of soluble phosphate of lime. The man who purchased the latter was therefore throwing away £6 for nothing. Not only was he doing that, he was also paying freight on 3 tons of useless sand. Here was provided a striking illustration of the value of a little technical education to the farmer. If they bought 46 per cent. super. on the basis of 2s. 4½d. per unit, it would be worth £5 8s. 7d. a ton, but purchased on the same unit value as the 30 per cent. its market value would be £5 18s. 10d. a ton. If only that 46 per cent. could be regularly obtained what a big saving the farmers would make in freight, even in a single year. If desirable on account of its stickiness, the farmer could break it down himself. The merchants would prefer to place this high-grade super. on the market, but owing to the penny-wise-and-pound-foolish policy of a large number of the farmers they could not do so.

MANURE FOR THE NORTH.

Regarding the most suitable manure for their requirements he was of the opinion, and believed that their experiences would support him, that it was the soluble phosphate of lime, and that only, that was wanted to reinforce the soils in those drier areas. There was no need for additional potash, and the same remark applied to nitrogenous fertilisers. They had there soils that had almost all their latent fertility in them. Superphosphate was more soluble and better for them than bonedust, guano, basic slag, or any of the other less soluble forms of phosphate. They favored applications of from 45lbs. to 60lbs. to the acre, but he considered that three-quarters of a hundredweight was little enough to apply. A crop of 20bush. to the acre would take out of the soil 9lbs. to 10lbs. of phosphoric acid. In 100lbs. of 36 per cent. super. they would apply about 17lbs. of phosphoric acid, so that when only 56lbs. was used as a dressing they put back into the land only that quantity which they took out. If it was merely a matter of the maintenance of the fertility the need for substantial applications would be patent, but there were other questions even more important. Plenty of phosphate immediately available induced the plants to throw out a large and more vigorous bunch of roots, and enabled them to penetrate well into the subsoil, so that when the hot weather set in the plants were better able to withstand the heat. That deeper and more vigorous rooting, however, could not be secured unless a little more than half a hundredweight of manure were used. Another point to remember was that when there was a good supply of food on hand less water was needed to meet the requirements of the plant. That was a big gain, and a most important consideration in a dry district. The heavier dressing was also beneficial from the feed-production point of view, and that fact suggested the observation that some of them thought that because they were operating in uncertain country any sort of stock would do for them. They were wrong in that assumption. They should have on their farms the best stock within their means, and then take steps to ensure them being well supplied with enough good food.

LARGE HOLDINGS DESIRABLE.

Without discussing politics, he submitted that it would have been better for all concerned if those areas had been opened up in larger blocks. A holding of 4,000, 3,000, or even 2,000 acres would represent a good proposition. At the same time he did not think their position now was to be discounted in any way. When the good seasons came again they would gather big harvests and recover in a manner those battling in other country would never know. Large areas would enable them to husband their country and have something to fall back upon in bad times; but the men on the small holdings could not afford to build up reserves of natural feed and hay, because the opportunities were lacking. There was no question that the hay in those drier areas had a higher feeding value than that grown, say, at Mount Barker, and likewise the natural grass and the cocky chaff were superior. In New Zealand the straw was always stacked in the paddocks so that the stock might nibble at it whenever they liked. How much more should that practice obtain in northern areas of South Australia.

QUESTIONS.

In reply to questions the Director said there was no danger of the phosphoric acid leaching out of the soil. If they put it in one year, and took off no crop, it would be there available for the next crop. The humus and nitrates, however, would be lost. Barley would not malt in the ground so readily as wheat. There was a tendency, however, to attach too much blame to the super. for causing the malting of the grain. The weather was too cold in the winter in this district for rape to do well. Lupins might be tried with advantage. He did not think the use of the thresher practicable in this country.

Mr. C. E. Birks mentioned that he had purchased a thresher to handle from 80 tons to 100 bags per day some 16 years ago. He never worked it with less than ten men. His experience had taught him that it was not worth while touching a crop with this machine unless the average was over 22bush. per acre.

BUREAU WORK.

The Secretary of the Advisory Board (Mr. G. G. Nicholls), in a short address dealing with the work of the Branches, said that whilst districts represented at the Conference had suffered considerably of late, farmers in the Upper North had not lost sight of the value of the Agricultural Bureau. He urged the necessity for conducting the Branches on business lines, and mentioned that the repeated requests received for the sanction of new Branches had forced the Advisory Board to the position of considering whether it might not be necessary to close some of those already existing but displaying little activity, in order to make room for more promising Branches.

VOTE OF THANKS.

At the close of the gathering a comprehensive vote of thanks to the Minister, officers of the Department, members of the Advisory Board, and visiting delegates was accorded with acclamation.

CONFERENCE OF SOUTH-EASTERN BRANCHES.

The South-Eastern Branches of the Bureau held their Annual Conference at Millicent on Wednesday, March 18th. The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), the Director of Agriculture (Professor W. Lowrie, M.A., B.Sc.), the Superintendent of Agriculture in the South-East (Mr. W. J. Colebatch, B.Sc. Agric., M.R.C.V.S.), the Dairy Expert (Mr. P. H. Suter), Messrs. G. R. Laffer, M.P. (Chairman), C. E. Birks, and G. G. Nicholls (Secretary), of the Advisory Board attended, in addition to the following delegates from the Branches undermentioned :—Glencoe—T. F. Gratwick, J. Dow, H. A. Cameron, A. Dow ; Kalangadoo—S. Tucker ; Kybybolite—S. Shepherd ; Millicent—J. Bowering, H. A. Day, H. Hart, G. G. Serle, W. Downs, H. F. L. Holzgrefe ; Mount Gambier—J. H. Buck, W. A. Palamountain, R. P. Pritchard, G. H. Kilsby, A. A. Kilsby, R. Fowler, A. A. Sassanowsky, E. F. R. Schlegel, W. Barrow ; Naracoorte—J. M. Wray, W. E. Rogers ; Penola—D. A. Fullerton, W. Miller ; Tatiara—T. L. Trumann, and a large number of visitors.

CHAIRMAN'S WELCOME.

The President of the local Branch (Mr. J. J. Mullins) occupied the chair. He extended a hearty welcome to the Hon. Minister of Agriculture, who took a great interest in the farming community generally. He felt sure the Bureau was doing a useful work at the present time, and one could not help being struck with this fact when one read the *Journal of Agriculture* and noticed the excellent practical papers that were read at the meetings. He called on the Minister to open the Conference.

MINISTER'S OPENING ADDRESS.

The Hon. T. Pascoe, M.L.C., expressed his pleasure at being present. It spoke well for their earnestness in agricultural matters, he said, when the delegates found time to travel such long distances as they had that day. to attend the gathering. The evidences of prosperity in the district forced one to the view that the South-East must come into its own sooner or later. Hitherto it had not been the unqualified success that many legislators had predicted ; nevertheless, he was convinced that it would eventually become a very important part of the State. They had to put a greater amount of labor into the land than was necessary in districts with lighter soils, but when they had solved the problems with which they were faced their labor would be repaid a hundredfold. The very conditions which made for the success of the South-East this year had resulted in the failure in the North.

The dry seasons had told in favor of the South-East for wheat-growing; but they would find when the drainage system in this district was completed that they would not be so dependent on the seasons as they had been in the past.

More Meat.

If there were any particular branch of the producing industry that promised greater dividends than any other for the work put into it it was the meat industry. Prices had gone up, and would go up still furthur. There must be a tremendous shortage of meat in the old country, and America—which had been the great exporting country of the world—was fast overtaking the supply. Men in these lands were now turning their attention to Australia for supplies, not only for England, but for America itself. He was convinced that a large part of the success in the South-East would be in feeding their crops to stock for marketing as meat. When the railway to Portland was completed they would find this a wonderfully profitable system of working their holdings. He hoped they would have an informative Conference, and declared the meeting open.

THE RELATION OF LIME TO SOUTH-EASTERN SOILS.

The Superintendent of Agriculture in the South-East (Mr. W. J. Colebatch, B.Sc., Agric., M.R.C.V.S.) said—"I know of no subject, unless it be field drainage, that is more deserving of the attention of South-Eastern farmers generally and of this district Conference in particular, than that of soil amelioration through the agency of lime. The progress of our district has in the past been sadly hampered by the periodical inundation of much of our best land. The annual rainfall of the southern portion of the South-East is from 20in. to 30in., and since there are no natural drains of any importance, it follows that the surplus water must either find its way into subterranean passages, or else lie stagnating in and on the soil, to the detriment of both plant and animal life. In order to overcome these natural disadvantages some thousands of pounds are now being invested in the construction of main drainage channels, and the responsibility of turning the benefits thus conferred speedily into profit and of thereby making the venture a reproductive one falls on our shoulders; but, quite apart from these prospective benefits which are to result from the scheme now in hand, there are many who are already in a position to make further use of the information available on the treatment and handling of soils that need draining and sweetening. Land that is subject to more or less complete immersion and water-logging in the winter and spring, and newly reclaimed swamps, require special knowledge and particular methods of working. It would be a complete waste of time and opportunity for men brought up to our northern system to settle on our soils and attempt to work them on similar lines to those to which they have been accustomed; but perhaps it is not necessary to go so far afield to find a want of knowledge, or at any rate if the knowledge is not lacking in our own midst it frequently happens that it is kept too much in the background. Personally, I think it behoves us all to wake up to the fact that we have in the South-East some of the finest forage-growing land in the State, and having in mind the marketing facilities for stock shortly to be provided, and the strong probability that remunerative prices will rule, it is incumbent upon us to study the systems adopted under similar conditions elsewhere, and to embody the results of such experience in our own farm practice. It is because I have a firm conviction that one of the most important operations in the treatment of our soils, namely liming, is being sadly neglected at the present time that I chose this subject to-day.

HISTORICAL.

"The practice of liming land is an ancient one, dating back to the time of the Romans, and it is probable that it was in vogue in China earlier still. It became a regular practice in Great Britain during the 18th century, but about 60 years ago, owing to depressed prices and the introduction of artificial manures, it was to a large extent discarded. It is important to note here that even in those days it was clearly recognised that for lime to be effective the land must first be drained. Storer quotes an early author as saying, 'One most important thing is that lime must never be applied to wet land, or it will be thrown away. The beneficial effect is most strongly marked on newly drained, sour, rushy land with a strong subsoil, and on this and on mixed heaths and bents the fine grasses and white clover spring up plentifully after a good dose of lime.' Towards the close of last century the accumulated residues of crops and artificial fertilisers brought about unhealthy soil conditions, and the steady depletion of lime from the surface soil through leaching and chemical interactions with acid manures led to impaired fertility. The consequence was that the merits of lime were rediscovered, and the operation of liming was gradually reinstated in its proper position. The history of liming in the south-east of South Australia might be written in a very few brief sentences. No doubt odd patches have been tried, but I cannot find any record of systematic work carried out on drained soil with lime of known quality in conjunction with manures, nor can I discover any reports of observations as to the effects of lime on crops or pasture. Opinions based on haphazard trials are not valuable, and should not be regarded as important evidence in relation to the general question.

PHYSICAL EFFECTS OF LIME.

"We shall be in a better position to judge of necessity for applying lime to our soils if we first consider some of its properties. These we will divide into four groups, viz., physical, bio-chemical, physiological, and chemical. The physical effects of lime are most marked on stiff, tenacious clay soils, Lime has the property of inducing the finer clay particles to become aggregated into compound grains, which are in turn held together by the cementing character of the lime. This is termed the flocculating effect of lime, and clay soils are rendered much more friable and pervious when subjected to it. So powerful is lime in effecting these changes that one part will render 10,000 parts of turbid liquid quite clear. It follows, therefore, that a ton dressing will appreciably affect the texture of a soil to a depth of 6in.; the weight of an acre of soil 6in. deep being approximately 900 tons. Clay soils that have been well limed are improved in tilth and drainage, cultivation is easier and less expensive, æration is more perfect, injurious substances are oxidised, bacterial life is encouraged, and the soil is better able to supply moisture to plants as they require it. In addition, the rootage zone is deepened, and as a rule the crops ripen more quickly. In very dry years, however, the deeper rooting habits and the increased supply of water and plant food tend to prolong growth, and so counteract the blighting effects of an early summer. On light open soils lime cements the particles together and increases the water-holding capacity; but this action is less powerful than the flocculating effect on clays, and it is probably of less importance than the binding effect of organic matter on sandy land.

Bio-Chemical Effects.

" In addition to its physical properties lime possesses qualities that enable it to exert an important salutary influence on the germ life in the soil. By maintaining a neutral environment it encourages them to work more rapidly, and thus indirectly influences the soil conditions in relation to plant growth. There are four main groups of soil germs—(1) Those that cause the decay of organic matter. This is a most important group, for if they be retarded putrefactive changes occur and lower oxides and sulphides are formed. These are inimical to plant growth, and the action of lime in preventing their formation and accumulation is therefore an important one. (2) Those that are responsible for the production of nitrites and nitrates from organic nitrogen and ammonia. (3) Those capable of absorbing nitrogen from the air when living in symbiotic union with legumes. (4) Those capable of absorbing nitrogen from the air when living free in the soil. Lime assists all four classes of microbes when present in reasonable quantity, but if a soil be over-limed bacterial life is checked and retrogressive changes may ensue.

Physiological.

" All cultivated plants are not equally appreciative of lime. Some appear unable to tolerate it (*Calcifuges*), whilst others will not thrive in soils that are deficient in it (*Calciphiles*). A good deal of work has been done at Rhode

Island in connection with this subject, and as the result of several seasons' observations the plants have been arranged according to this table :—

Plants benefited—		Plants indifferent—	Plants injured—
Beans	Clover	Maize	Watermelon
Beets	Barley	Millet	Lupin
Celery	Wheat	Rye	Sorrel
Onions	Oats	Potatoes	Serradella
Cabbage	Fruit trees	Carrots	
Pease	Lucerne		

Chemical Effects.

" Lime is an essential plant food, but the amount required by crops is so small that nearly all arable soils contain sufficient to meet this demand for generations. It is believed that a sufficiency of lime in the soil favors the solution of the food materials in the grain and stimulates the young seedling. It is definitely known that indirectly lime is the means of liberating soluble plant food from the soil reserves. It is particularly active in setting free soluble potash, hence its value in encouraging clovers and other legumes. Whether it is appreciably effective in rendering phosphoric acid available is much less certain. Its presence in the soils, and especially in those rich in iron compounds, will undoubtedly check the reversion of water soluble phosphoric acid in added fertilisers to the insoluble phosphates of iron and alumina. Possibly also lime when added to the soil will react on the inert phosphates already formed and gradually bring them within reach of plant growth. Let it be clearly understood, however, that it is not a substitute for artificial manures. With the exception of almost negligible quantities of phosphorus and potash occurring as impurities, lime brings to the soil none of the important elements of plant food contained in artificial fertilisers.

Is Lime a Stimulant ?

" The action of lime in unlocking plant foods stored in the soil without assisting to replenish the supplies has led up to the opinion that it was nothing but a soil-exhausting material which enabled a farmer to profit at the expense of his landlord. The same charge was preferred against nitrate of soda, and in some districts at home tenants were prohibited from using them. The well-known saying that ' Lime enriches the father but beggars the son ' shows how widely that view was held. It is true that the indiscriminate use of lime may prove disastrous. For instance, an excess of caustic lime applied to light land may lead to the burning out of the soil humus and the wastage of nitrogen. Similar losses will occur if it be applied at the same time as dung or soluble nitogenous manures. These disadvantages, however, are attributable to the misuse of lime and not to the material itself. When judiciously employed its action on organic matter will be found highly beneficial and, speaking generally, it may be said that less stress should be laid on the depletion and more on the need for building up the supply of humus, since it is well known that a high condition of fertility can only be secured by the continual breaking down of the complex compounds contained in organic matter. At Rothamsted it was found that limed pasture gained much more nitrogen than unlimed, on account of the stimulus given to the nitrogen-absorbing germs. Again an overdose of lime may lead to the temporary checking of germ activity through excessive alkalinity of the soil moisture. When properly used, however, and when due regard is paid to the important principle that since production is stimutated through liming, a more liberal system of manuring must be adopted, lime will be found to raise the standard of fertility and to promote a healthier and more robust type of vegetation. Thus, whilst the old couplet, 'Lime and lime without manure will make both farm and farmer poor,' is true, it is equally correct to say that on many soils an intelligent combination of lime and manure will prove far more remunerative than the use of artificial fertilisers alone.

Lime Neutralises Soil Acidity.

"Looked at from our own point of view the most important chemical action of lime consists in its power to neutralise the accumulated organic and mineral acids—in other words, to 'sweeten' the land. Soil moisture should be neutral, or only slightly alkaline, in order to favor the growth of vigorous and nutritious herbage. If it be sour or distinctly alkaline bacterial life is checked and fertility reduced. Virgin soils are often fairly productive. even when 'sour,' owing to the abundance of soluble plant food present; but in the course of time this is used up and they tend to become unprofitable for cropping, even though well manured. A 'sour' condition deprives the soil of one of its most important sources of nitrogen by discouraging the growth of legumes. It also favors the spread of undesirable weeds, and in some obscure way diminishes the rate of production of available phosphoric acid. Land that has been long under crop, unless well supplied with carbonate of lime in its original state, will inevitably tend to become sour through the accumulation of crop and fertiliser residues and the gradual dwindling away of the lime compounds. Similarly on grass land the surface tends to become sour; in fact, with the exception of strongly calcareous soils and open sands, in which oxidation is very rapid. most soils under cultivation in humid areas will in time become so heavily charged with organic matter and so poor in lime that some form of alkaline lime will be needed to correct the acid reaction of the soil water.

What Soils Need Liming.

"The percentage of lime in soils varies within very wide limits. In some limestone soils it is present in the form of the carbonate to the extent of over 50 per cent., whilst in other soils it is nearly absent. An average fertile soil will contain from 2 per cent. to 5 per cent. According to Hall, soils containing 1 per cent. or less will all benefit by liming, and when the amount falls below 0·2 per cent. it is essential to lime in order that the manures may exert their full action. It is not possible, however, to decide as to the need for lime solely on the data furnished by a chemical analysis. Without actual field trials it is most difficult to say what effects lime will or will not produce. Wiley, an eminent American agricultural chemist, has stated that two soils apparently identical may be affected in very different degrees, and that actual experiments are the only reliable test. In interpreting analyses it should be noted that only lime in the form of carbonate will be effective in correcting sourness. Much of the lime appearing in the analytical results may have been present in combination with relatively strong acids, and in that state would be of very little value (if any) in neutralising acidity. For rough and ready field work what is known as the 'litmus' test may be resorted to. This consists in mixing a little soil with clean fresh rainwater in a saucer and then letting a piece of blue litmus paper lie in the mixture for 10 or 15 minutes. The paper is then removed, and the adhering soil washed off with rainwater. If the soil be acid the blue color will have changed to red, and the extent of the change is indicative in some measure of the need for lime. In carrying out this trial one must be careful to test the rainwater with litmus first to see that it is neutral; the saucer and spoon must be carefully washed in rainwater, and the fingers must not be allowed to contact with the test paper. If freshly prepared paper be used, and several tests be made, a positive reaction by this method may be regarded as decisive; but experience has shown that it is not safe to be guided by negative results. By far the most satisfactory test, however, is the farm trial plot, and I would urge every South-Eastern farmer who has reason to think that his land is acid to institute an inquiry of this kind this autumn. The trial blocks need not be large. Half or quarter acre plots are best; but the effects will come out quite as well on small plots measuring only a few yards each way. Plots of 40 or 50 square yards, selected on land previously under crop and properly drained, will do well enough. They will require from 20lbs. to 30lbs. of lime, and this must be carefully sown to avoid dust blowing on to adjoining plots. Have the plots three or four yards apart and sow the lime on a calm day. Then work it well in to incorporate it thoroughly with the soil before the seed and manure are sown. The trial should be continued for at least three seasons, as lime does not always demonstrate its effects straight away. In order to bring out the effects clearly it is advisable to sow one of the plots with mangolds or beet, since these crops respond much more quickly than cereals to lime dressings. Generally speaking, it may be said that lime is needed—(1) On heavy soils that drain badly and stick to the plough. (2) On light soils under good rainfall, when sufficient humus is present. (3) On newly-drained reclaimed areas. (4) On soils rich in iron and requiring phosphates. (5) On land that will not support leguminous herbage. (6) On land that has become sour from any cause whatever. Lime is contra-indicated—(1) On light soils deficient in humus. (2) On soils that waterlog and have not been drained. In carrying out preliminary trials different quantities should be used. Sandy soils, as a rule, need only sufficient lime to keep the soil water 'sweet,' and dressings of 10cwts., 20cwts., and 30cwts. per acre should be tried; 30cwts. for light land may appear too heavy, but in the first instance a relatively large amount may be demanded to neutralise the accumulated acids of past years. After the soil has once been sweetened much smaller amounts will be required, say from 5cwts. to 7cwts. every four or five years. On heavy land more lime can be used to advantage; because, in addition to correcting soil acidity, the texture has to be improved and maintained in good order. For this class of soil trials should be made with 1cwt., 1½cwt., and 2cwts. dressings. Subsequently doses of from 10cwts. to 15cwts. per acre every five or six years will be required. Generally it may be taken as true that the deeper the surface soil the more lime should be applied. Probably on some of our heaviest land dressings of 3 tons per acre will not be found too much, but recent experiments have proved that dressings of 4 tons and over are not profitable, even when the results are taken over a series of years.

DURABILITY.

"The tendency of lime to sink through to the subsoil and form a pan is well known, and an examination of the drainage waters reveals the fact that at Rothamsted it is being removed from the soil at the rate of nearly half a ton per acre per annum; or to put it in another way, from four-fifths to five-sixths of the total minerals in the drainage waters from manured soils is lime. Owing to this tendency the proportion of lime in the surface soil soon becomes reduced, and consequently a lime dressing does not exert its maximum influence for very long. However, in a gradually diminishing scale the benefit will be felt for a number of years. In earlier times, before the science of manuring was so well understood, 5 tons or 6 tons of lime were applied at a time, and the effects were discernible a quarter of a century later. The farmers of to-day, however, apply smaller and more frequent doses. In England, under the compensation clauses of the Agricultural Holdings Act, a period of seven years is taken as a basis for calculation.

KIND OF LIME TO USE.

"There are several different varieties of lime available for use on the farm, but they are not equally valuable weight for weight, nor are they equally serviceable under all circumstances. Prior to 1890 burnt or quick lime was chiefly used, but during the last decade of the 19th century the advantage of securing an even distribution of small quantities was realised, and ground quicklime promptly appeared on the market. The risk of adulteration and the corrosive action of the fine powder on the skin, eyes, and throat linings were serious drawbacks, and moreover, it was difficult to preserve in a caustic condition. Early in the present century air-slaked lime came into use as a cheaper and more trustworthy form. It was found to be quite as effective as the ground quicklime for most purposes, but the introduction of ground limestone rock has displaced it to a large extent. The results of a four-year's trial at the Jackson Experimental Station, Tennessee, showed that burnt lime and ground rock, when used in the proportion of 1 to 2, were equally effective, the figures being slightly in favor of the latter. An experiment in Lancashire in 1907 also pointed to the same conclusion.

"Lime is sometimes sold under the name of 'agricultural lime.' This is an indefinite term used to designate a mixture of water-slaked lime, and lime carbonate. Without a certified analysis, however, it quite impossible to calculate its worth. Unfortunately we have no protective legislation in regard to lime, as we have in the case of artificial manures. Standards of quality should be drawn up for all forms of lime sold for the farm, and we should then be in a position to buy intelligently and economically.

"Another material often referred to in this connection is gypsum, or land plaster. It is the sulphate of lime, and is useful under some conditions. Where the object in view is the liberation of potash gypsum will act as powerfully, or even more so, than lime; but as a means of sweetening acid soils gypsum can only be effective according to the percentage of carbonates present as impurities. In acid soils, therefore, it is usually far less efficient than lime carbonate, and, consequently, it cannot be recommended as a substitute for lime for this purpose, even when it can be procured at much less cost. It might be well, however, if a plot dressed with gypsum were included in the system of trial plots previously advocated.

"In judging of the qualities of lime it is noteworthy that limestones often vary considerably, even in the same quarry; the upper and more exposed layers being frequently poorer than those beneath. Again, some stones contain large amounts of magnesia, and are known as dolomitic limestones. It was formerly held that the addition of large amounts of magnesia would upset the natural ratio of lime to magnesia, and so interfere with plant growth. In actual practice, however, no damage has resulted. In Wisconsin the natural stone is all dolomitic, and it is largely employed on the farms. In Dr. Wheeler's Rhode Island experiments it was found that the magnesia was nearly if not quite as effective as air-slaked lime in neutralising acidity, even when applied by itself. For sour land, therefore, it is the percentage of total carbonates that is important, and in a good sample of lime this should not be less than 90 per cent.

"The particular kind of a lime a farmer should use will depend on many things, but the main consideration will always be the cost per unit of quicklime. In coming to a decision on the point the following facts require consideration :—(1) Where the physical action of lime is important, and where rapid action is looked for, the caustic limes are best. (2) On light sandy soils there is a risk of overliming when caustic limes are used. (3) For sour soils any kind of alkaline lime will suit provided sufficient carbonates are applied. (4) One ton of quicklime is equivalent to 2 tons ground rock, or 1½ tons air-slaked lime, or 11·3 tons water-slaked lime. (5) Where freight is heavy the cost of transporting the water and carbonic acid gas in the slaked lime and ground rock may exceed the expense of burning the stone. (6) Ground rock must be finely ground. All should pass through a 10-mesh sieve and 50 per cent. through a 50-mesh sieve.

THE POSITION OF THE SOUTH-EAST IN REGARD TO LIME.

"In the three southern counties of the South-East there are between 150,000 and 175,000 acres under cultivation, and I would venture the opinion that quite one-half of that area would benefit by liming. Yet I very much doubt if as much as 10 tons of lime per year is used to dress farm paddocks. During the last three seasons I have had experience in this matter in the Kybybolite district and on some of the lighter soils of the South-East. We do not require any special investigation to warn us of the deficiency of lime at the Government Farm. The rapidity with which sorrel spreads and flourishes, and the almost total absence of leguminous plants in the fields, affords proof enough and to spare. Further, there is the evidence afforded by the annual quantitative fertiliser trials which show that the soil will not respond to additional quantities of acid manures over 1cwt. There is also the case of one field which received a ton of lime to the acre four or five years ago, and which always produces a little Mount Schanck clover and tares in the stubbles. It is important to note these facts, as our experience will hold good for practically all the land between Frances and Naracoorte. We have also had evidence at Glenburnie, on Mr. Major's plots, that lime is required by the light lands of that district; and with more extended trials I have no doubt the field for liming would expand beyond anticipation.

"Between the Tatiara and the south coast we find such plants as sheep's sorrel and oxalis growing luxuriantly, and many of our grass paddocks are marked by mossy patches. In addition, the character of the native flora—honeysuckle, heath, black grass, 'billy button,' rushes, sedges, and water-grass—is suggestive of the lime requirements of the soil. In many of our lagoons also there is to be seen a reddish-brown deposit, due to the oxidation and precipitation of iron salts which have been dissolved out of the soil by the accumulated vegetable acids. Even on our rich volcanic soils the complaint is often heard that the white clover never comes now like it used to do years ago. Is it not feasible that in such a free draining soil the lime content has now been so reduced that the surface soil is no longer capable of supporting the white clover ? Possibly even here the soil is approaching a critical stage with regard to lime.

"It must, I think, be conceded that the evidence in support of lime deficiency is convincing, and we may congratulate ourselves that the district is well supplied with limestone. Furthermore, the stone is very well distributed, so that freight and haulage should never become a very serious consideration to us. Possibly those with a more prophetic eye can foresee the time when the authorities in our State will emulate the far-seeing attitude of the Dominion of New Zealand, where farmers' lime is carried free of charge in 6-ton truckloads over a distance of 100 miles. Wherever rock containing not more than 10 per cent. of impurities can be obtained it should be made use of, provided it is not too flinty and will yield from 85 per cent. to 90 per cent. total carbonates. With the introduction of pulverisers, such as are in regular use in the 'liming' States of America, it should be practicable to prepare ground rock at from 10s. to 12s. per ton. Crushing and pulverising plants requiring 30-h.p. to 40-h.p. to operate them will yield 5 tons to 7 tons per hour of ground limestone, so finely powdered that 50 per cent. to 70 per cent. of it will pass through a 60-mesh sieve. It is to be hoped that South-Eastern men will give this aspect of the liming question their very serious attention, as the present facilities for obtaining reasonably cheap lime for this district are lamentable, and constitute a serious drag on the wheels of prosperity in this part of the State."

OTHER OPINIONS.

Mr. A. A. Sassanowsky (Mount Gambier) said that although the South-East contained a great amount of limestone the percentage of lime in this was not known. From experiments made at Mr. Major's farm, in this district, it was evident that the addition of lime to the land was beneficial. He thought the Government should provide machinery and crush limestone for the farmers.

Mr. J. B. Mitchell (Millicent) asked the best time to apply lime to the land.

Mr. Colebatch replied that quicklime should be worked into the land before artificial fertilisers were applied, to avoid reversion. A fortnight or three weeks between the applications was sufficient. Ground rock could be put on at any time, provided it was not done too near seeding. Autumn was the best time.

Mr. G. H. Kilsby (Mount Gambier) asked whether lime from different parts of the district could be analysed.

The Director of Agriculture said the Government was subsidising two institutions for the purpose of doing analyses. Considerable numbers of analyses were made nearly every week, and it was simply a matter for them to send up one or two pounds of the material to be analysed, giving a description of the place from which it was taken and the purpose for which the analysis was wanted. They would then get the information free of charge.

With regard to Mr. Sassanowsky's suggestion that the Government should secure a milling plant and crush limestone, it was his opinion that farmers could do this work much more cheaply themselves. The few hundred pounds that would be necessary would be very easily secured. In New Zealand the practice was for the farmers to do work such as this co-operatively.

CARE OF WHEELS.

This subject was dealt with by Mr. T. L. Truman (Tatiara) in a paper which has already been printed on page 722 of the February, 1911, issue of the *Journal*. In reply to a question, the writer of the paper said the most satisfactory method of dealing with loose boxes of wheels was to put in wedges made from the timber of a kerosine case, or something similar. If there were insufficient space to allow of this, he would use pieces of bagging or hessian.

FRUIT-GROWING.

Mr. G. R. Laffer, M.P. (Chairman of the Advisory Board), in the course of a short address, mentioned that there was practically no limit to the production of fruit in this State. The difficulty with which they were confronted, however, was the small scope for marketing. The question of pruning was dealt with, the speaker mentioning that in the natural state of the trees an equilibrium existed between the growth of the tree and the root action. The aim of the orchardist should be to secure a sufficient immediate extension of the growth of the tree, and at the same time make provision for coming seasons. A tree left unpruned would bear a heavy crop one year and a light one the next, but this method of fruit-growing would not be found profitable. Regular crops, year in and year out, were desirable. This was best done by taking away sufficient of the branches to place the balance of power with the roots, and so enabling the tree not only to produce a crop but make growth. The export-trade, to which they had to look to a large extent for a market for their fruit, carried with it numerous difficulties. Transit was not only very expensive, but there was the risk of the fruit deteriorating on the voyage.

Mr. J. Bowering inquired whether there was a known remedy for bitter pit.

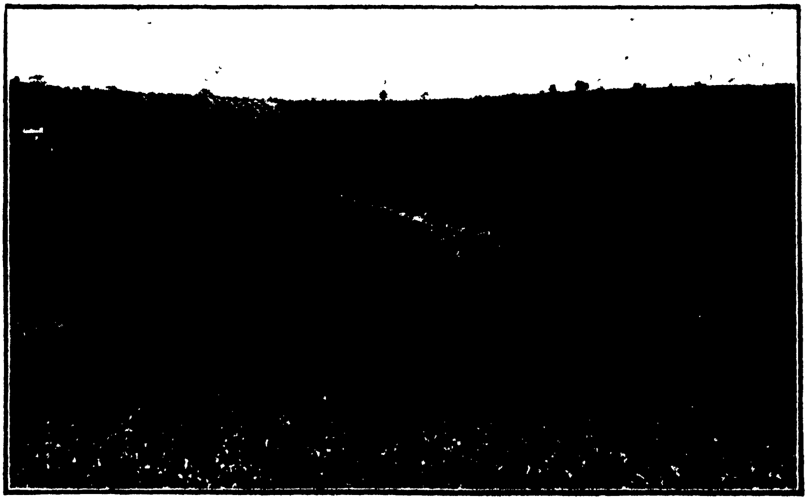
Mr. Laffer said that so far there had been no remedy found for this disease. Professor MacAlpine was investigating and doing a most valuable work in connection with this matter. The speaker's opinion was that the bitter pit was most troublesome where very hard pruning was practised.

Mr. J. M. Wray (Naracoorte) asked whether apricots of very vigorous growth should be pruned.

Mr. Laffer replied that excessive growth could be checked by judicious summer pruning, but the leaders should not be pruned. Apricots, peaches, and almonds had been very much affected during the past few years by a fungus which attacked the buds and caused them to become black. In a wet district it would be found necessary, in order to check this, to spray the trees twice during the winter with Bordeaux mixture.

Mr. R. Fowler explained methods of thinning and summer pruning that had been successfully adopted in the South-East.

(*To be continued.*)



Vineyards, Near Adelaide.

THE WHEAT MARKET.

Commenting on the wheat position, *Beerbohm's Evening Corn Trade List* of March 6th states—"Shipments last week were moderate, and compared unfavorably with the total in the corresponding week last year, but the total to date, so far as Europe is concerned, is still over 1,000,000 quarters larger than in the previous season, when the estimated requirements were several million quarters more than for the present season. Imports were quite small, and well below the requirements, but the returns of stocks held at the principal ports show that the quantity delivered during the month was about 150,000 quarters less than expected. According to a report from Odessa, it was estimated that there was still about 60 per cent. of the surplus from the last Russian crop available for export at the end of February. The exports having amounted to about 11,500,000 quarters, on this basis there would be about 17,000,000 quarters still to come forward, making a total of 28,500,000 quarters for the whole season. If this estimate be approximately correct, it would follow that the last crop was a little over 100,000,000 quarters, instead of 122,000,000 quarters, as per the official estimate. The quantity of wheat exported from the United States and Canada in the six months ended January 31st, according to the official reports, amounted to about 23,000,000 quarters, including 11,900,000 quarters from Canada, and 11,100,000 quarters from the United States. In the corresponding six months of the previous season, the official figures gave the exports from both countries at 18,500,000 quarters, whilst the actual shipments as cabled amounted to 18,400,000 quarters, or practically the same as the official export figures. The second Indian official reports for most of the important wheat-growing districts have been received this week, but being less complete than usual, it is impossible to form a definite opinion as to the actual deficiency in the yield compared with last year. It is quite clear, however, that there will be a serious shortage, especially in the United Provinces and the Central Provinces (the two districts which have suffered most), amounting to between 5,000,000 and 10,000,000 quarters. The world's visible supply decreased 425,000 quarters last month, against an increase last year of 945,000 quarters, and an increase in 1912 of 210,000 quarters. The European quantity shows an increase, but there has been a sharp decrease in the American visible."

The World's Visible Wheat Supply on March 1.

Steamer Freights.—(April 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 22s. per ton (7d. per bushel); to South Africa, 20s. per ton (6⅜d. per bushel). Parcels, Port Adelaide to London-Liverpool, or Continent, 20s. per ton (6⅜d. per bushel); Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel); to Sydney, 10s. 6d. per ton (3⅜d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 21s. 3d. per ton (6⅞d. per bushel); South Africa, 20s. per ton (6⅜d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on April 1st—

Butter.—The continued heat experienced throughout the month materially interfered with quantities of fresh butter coming forward, so that it was necessary to bring along importations to meet the demand. Values in top qualities show only slight fluctuations, but second and third grades are finding a better inquiry. Present values are:—Alfa, 1s. 4½d. per lb.; Primus, 1s. 3½d.; choice separators and dairies, 1s. to 1s. 1d.; store and collectors', 8½d. to 9½d. per lb.

Eggs show a seasonable improvement, with prices recording an advance of 2d. to 3d. per dozen during the month. Hen are selling at 1s. 3d. per dozen; duck, 1s. 4d.

Bacon is receiving better attention locally, and as the factories' stocks have been very much reduced rates have firmed to the extent of 1d. per lb. Quotations—Best factory cured sides, 9½d. to 10½d. per lb.; hams, 11d. to 1s. 1d.; lard in skins, 8½d.; bulk, 7d.

Honey.—Competition has been very brisk both for local and export, supplies not being nearly equal to oversea orders. Prime clear extracted brought 3d. to 3¼d. per lb.; beeswax, 1s. 2½d.

Almonds.—Although heavier parcels are coming to hand, and values rule higher, the brisk demand keeps stocks from accumulating. Brandis are selling at 6½d.; mixed softshells, 6d.; hardshells, 3d.; kernels, 1s. 4½d. per lb.

Live Poultry.—Supplies kept up remarkably well for the time of the year, the catalogues throughout the month being very extensive. This attracted a large attendance of buyers both for local and oversea trade, so that nice rates were secured. Good table roosters brought 3s. to 3s. 6d. each; plump cockerels, 1s. 9d. to 2s. 3d.; hens, 1s. 8d. to 2s. 4d.; ducks, 1s. 9d. to 2s. 6d.; geese, 3s. 6d. to 4s. 3d.; pigeons, 6½d.; turkeys—hens, 4s. to 6s. each; gobblers, 9s. to 12s. each.

Potatoes and Onions.—Potatoes have been decidedly scarce and values have appreciably firmed. Current opinion is that the havoc wrought by grubs, and the exceptionally warm summer, will effectively prevent the late crops from giving anything more than moderate results. Onions.—The demand for export has fallen off, but a good local inquiry has kept the market steady. Present quotations—Potatoes, £5 10s. per ton of 2,240lbs. on trucks Mile End or Port Adelaide: 6s. to 7s. per cwt. in the market. Onions—£7 per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 6s. 6d. to 7s. 6d. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of March, 1914, also the average precipitation to the end of March, and the average annual rainfall.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

April 8th and May 13th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

DAVENPORT (Average annual rainfall, 9in. to 10in.).

February 15th.—Present: seven members.

Agriculture, Past and Present.—Mr. Bothwell read a paper under this heading, in which he traced the evolution of agricultural practice from the time when primitive implements were employed and smaller areas were crudely cultivated to the present day, when immense steam implements were employed and motor power brought to grapple with the work of tilling the soil and harvesting and preparing its products. He claimed that the farmer of the present day was a man with a keen knowledge of his business, knowing the constituents of the soil and what it lacked. He was able to apply the required fertilisers, and thus secure the best returns. The writer of the paper also paid a tribute to technical agricultural education. The outlook of the farming community was better than in bygone years, and the better conditions had now given more leisure for social intercourse and amusement, rendering farm life more attractive and tending to counteract the migration from rural districts to the city.

MOUNT REMARKABLE (Average annual rainfall, 14·48in.).

February 12th.—Present: 12 members.

Veitch's Well Experimental Farm.—Mr. H. H. Davies, who had recently visited the Government Experimental Farm at Veitch's Well, gave his impressions. As harvesting had not been completed he was unable to quote results, but was much impressed by the nature of the work being done, particularly in the plots put down to test the relative value of different varieties of wheat. The farm consisted of a succession of sandhills, or sandridges, with intervening flats from five or six chains to a quarter of a mile wide. The sandridges ran, roughly, east and west. The flats showed a surface of drab, grey, or brown loam, with here and there limestone outcrops. The timber was chiefly mallee with a sprinkling of pine, needlebush, sandalwood, bootlebrush, and titree. Porcupine tussocks were plentiful, and, with the stumps left from clearing, helped to add a dash of sensation to the drive along the bush track. The mallee ranged in size from whipsticks of 7ft. or 8ft. in height to a size large enough to provide fence posts.

TARCOWIE (Average annual rainfall, about 15½in.)

March 10th.—Present: 16 members.

Farm Implements and Machinery.—Mr. Breuer contributed a paper on this subject. He favored a skim plough of up to 12 furrows. The body of this should be easily removable. Seven furrows were enough for fallowing, and when the ploughing was finished the body could be replaced and the implement used for working back the fallow. The skim plough was better than the cultivator for killing weeds, and it worked the soil better. At seeding time if the prong boards, which were only held by a stud and a bolt, were removed, the implement could be used as a cultivator. If the land on the farm was rough, a set of jump harrows was of more value than set harrows, although the latter destroyed weeds and broke clods better. On a paddock thick with weeds last year he had used this implement, and very few weeds had grown. It was much quicker to work this than the plough or cultivator, and the land was worked to a level condition. With the drill the seed and manure could be sown at the same time, and at an even depth. He preferred a four-horse drill, with hoes not more than 7in. apart. Many varieties of wheat did not stool out, but grew straight, and for this reason he was in favor of the closer hoe drill. The binder, in his opinion, was one of the most improved machines on the market. It saved the farmer a large amount of labor, and did not waste nearly as much hay as the old-style cutter. The one advantage with loose hay was that it was boxed about more, and the stock did not eat off the heads. The harvester had great advantages over the ordinary stripper. One man with a team of four horses could reap and clean the wheat, and where the crops were not too dirty, could produce as good a sample as the winnower. If the stripper were used, two extra men would be required to work the winnower, and this would prolong the harvest considerably. A greater area could be reaped each day with the harvester than with the stripper. Most harvesters were fitted with self-lubricators, and there was now no trouble in this direction. There was generally a large amount of carting to be done, and a wagon with a 2¾in. axle and 3½in. by 1in. tyres which would carry from 70 to 80 bags of wheat would be found most suitable. In the discussion which followed Mr. Burgess contended that the ordinary plough and cultivator was a better combination than the skim plough and cultivator harrows. Mr. Müller favored the skim plough, as the land remained level, was pulverised better, and provided a better seedbed. Mr. Bennett considered that the skim plough, followed by the scarifier harrows, would do good work if the land were in good condition.

WEPOWIE (Average annual rainfall, 13in. to 14in.).

March 17th.—Present: 10 members and five visitors.

Harvester v. Stripper.—Mr. Goss contributed a paper on this subject, in which he stated that in a fair crop the harvester had many advantages over the stripper. It saved labor, and the wheat could be removed at once from the paddock. There was also less danger from fire and storms. With the harvester reaping could be commenced quite two hours earlier in the mornings than with the stripper. The great drawback was the loss of the cocky chaff, but he had found that good clean bound straw was better than cocky chaff. The motor winnower made no better sample and wasted as much, if not more, wheat than the harvester. A crop could be harvested in about half the time and at much less expense with this machine. Bags should be sewn and carted direct to market, even if it were necessary to hire a team. No risks were then taken of damage by fire and floods. If a competent man were working the harvester there was little wear and tear on the machine, and very little waste of grain.

WILMINGTON, February 12th.—**Ensilage.**—Mr. P. Pickering read a paper which will be found printed on page 945 of the current issue.

WILMINGTON, March 11th.—**The Farm Employé.**—Mr. D. S. George read the paper on this subject written by Mr. V. R. Weston, of the Coorabie Branch, and printed on page 627 of the December, 1913, issue.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

BEETALOO VALLEY (Average annual rainfall, 18in. to 19in.).

March 9th.—Present: seven members and one visitor.

Poultry-Breeding.—Mr. C. Cox contributed a paper on this subject, in which he said that one of the first considerations for the intending poultry farmer was to study the breeds most suitable for his district. He favored a cross between the Brown or White Leghorn and the Black Orpington for this district. Good all-round fowls would be obtained from this cross. From crossbreds a better percentage of chicks, as well as healthy and hardy birds were obtained. He preferred the incubator for hatching, although it required plenty of care and attention. A brooder was also of value. Chickens should receive plenty of green feed, such as lucerne, rape, &c., preferably chaffed. Houses should be erected on sandy or gravelly land if the birds were to be enclosed. They should have a large run and plenty of scratching litter. Fowls kept in open fields picked up a considerable portion of their food in the form of insects and grass, and were more vigorous and free from disease. A good whitewashing with lime kept vermin away. The food should be good, clean, and wholesome, and inferior or damaged grain was not profitable for feeding to birds. Mr. Ryan thought the White Leghorn the best breed for both laying and table purposes. Mr. Murphy considered good housing essential.

PORT GERMEIN (Average annual rainfall, 12·84in.).

March 16th.—Present: five members and one visitor.

FALLOWING.—Mr. W. J. McDougall read a paper as follows:—" I do not believe in the so-called dry farming as opposed to our system of fallowing, in this district at all events. Our rainfall is at times too low to warrant the expense and work needed under the dry farming system. Fallowing, if done thoroughly, will give about the same results generally. However, we may improve our own system. We have only to look back a few years and find a very different style of fallowing to that in vogue at the present time. At one time the land was simply ploughed up roughly, and perhaps harrowed once, and that was thought sufficient for perhaps three or four years' cropping. At the present time most farmers fallow every second year, and some maintain that the land should only grow one crop in three years, and that always on fallow. From my own observation and experience I find in this district the most profitable way is fallowing every second year with one crop, on heavy land, with an occasional rest, say every five years, but on sandy soil I think it better to get two crops off the one fallowing. Thus the stubble is on the land the second year to check drift. Fallowing should begin early in the year, as soon after seeding as possible. More of the winter's moisture is conserved, and weeds have a better chance to germinate. I know some farmers contend that if they start fallowing early in the winter they plough up too much of their feed, but I have noticed that generally more feed will grow on the land if it is worked early in the winter than if it is left lying idle. Do not plough it too deep; in this district I do not think it wise to plough very deep, except in very wet seasons. In fact, I prefer to skim plough the land if it can be done in June or early in July, and plough it deeper later in the year if the season is wet; if it is not wet work it shallow right through the year. There is an old English saying that corn seed should have a ' hard bed and a soft blanket,' and I think that also applies to Australia. The seed bed should be firm underneath and loose on the surface, and to get that result we need to fallow early while the land is wet, and work the surface down fine afterwards. Do not work the fallow while it is dry if it can be avoided. It seems to be more subject to takeall if ploughed dry. It makes no difference what kind of plough is used to break the land up in the first instance, but the tine cultivator and harrow are the best implements to work the land down after it is once ploughed. Those implements tend to give the land a firmer seed bed by bringing the lumps and rubbish to the surface, and allowing the fine soil to go down to the bottom. This has several advantages; on stiff land, the rough stuff being on top helps to keep the land from running together on top; and on light land the cultivator leaves a rougher surface so that it is not so liable to drift. Of course on sand if there is much straw it is better to use disc implements and work the straw in. Some farmers contend that the straw ploughed into the land has a tendency to encourage takeall, but my experience has been that land that has been cleaned up preparatory to fallowing has suffered more from takeall than land on which I have disked in a heavy crop of straw and rubbish. In conclusion I might sum up the whole matter with these few words—Fallow early, work firm while the land is wet, keep it clean of weeds, but do not work the land dry if it can be avoided." Mr. Hacket (chairman) agreed with the ideas of the writer of the paper regarding clay land. Mr. Stone did not believe in using a skim plough for fallowing; a heavy disc or mouldboard implement was better. The light skim plough could then be used for working over.

PORT PIRIE (Average annual rainfall, 13·21in.).

March 7th.—Present: nine members and one visitor.

BEST WHEAT FOR DISTRICT.—Mr. D. L. McEwin read a paper as follows:—" The most profitable wheats for our lands have been those raised in our own district. We have had numbers of wheats from other parts, but their life in most cases has only been two or three years. As this is an early district it is almost necessary to grow early wheats. Late wheats are likely to suffer from hot winds unless we get suitable weather in September and October. Then the late varieties will yield more heavily, as most late wheats are heavier yielders than the early varieties. Over an average of years in this district early varieties will take the lead. This has been my experience in light soils, but as the soil varies it may not be general. For instance, the land near the hills is much heavier and should retain the moisture longer, therefore a later wheat may do better. I have tried quite 20 varieties, but keep only to two, namely, Gluyas Early and Carmichael's Eclipse. Those tried include Purple Straw, Red Straw, Bluey, Tuscan, Yandilla King, Federation, Nhill Lotts or Penny wheat, Steinweidel, Petatz Surprise, Marshall's No. 3, African Baart No. 1, Viking, King's Early, King's Red, Baroota Wonder, Ward's Prolific, and Budd's. The last three are raised locally. They have given good service, but are now out of date. King's Early and King's Red make nice hay, but I never had much success with them for grain. Some farmers object to Gluyas and Carmichael's for hay. I own they are not the best, but if they are not allowed to get too ripe before cutting stock will do well on them. I prefer Gluyas for hay for feeding as well as marketing, as it weighs well; but for grain I prefer Carmichael's, especially on fallow. Best results have been secured by sowing Carmichael's first and finishing with Gluyas, as Gluyas sown early is likely to become spindly, and is also more liable to black rust. Gluyas does better on stubble. It needs to be sown thicker, about 1bush. to the acre; while Carmichael's will give good results with about 45lbs., as it is a smaller grain and stools better. If the seed is pickled I would advise sowing thicker. I am inclined to think these two wheats are deteriorating. Some enterprising farmer should hand-select them. Careful grading may keep up a good variety, but it will not be so pure as hand-selected seed."

REDHILL (Average annual rainfall, 16·79in.)

March 10th.—Present: eight members and one visitor.

Construction of Farm Buildings.—Mr. C. H. Lines contributed a paper on this subject, in which he stated that on a new farm it was necessary to build the homestead and stables close to the water supply. The young farmer was usually a man of limited means and could not lay out too much capital in the one building. Plans should therefore be carefully prepared, so that when additions and improvements were being made it would not be necessary to pull down the old buildings. He advised the construction of a two-storied stable to accommodate eight horses. It should be four posts deep, the two centre rows being the same height. He would use the upper floor for a chaffhouse. He preferred 5in. x 5in. jarrah posts for the stable, and the width of the spans should be 10ft., which would allow of 5ft. stalls. The height of the centre posts should be 8ft. and the depth between the centre rows 10ft., which would provide space for the manger. It was necessary to leave a space of, say, 6ft. in front of the manger and 6ft. behind the horses, making the total width 22ft. and the length 40ft. All edges of timber against which the horses were likely to knock should be trimmed. The chaff should be fed to the mangers by chutes, two horses being fed through each. The length of the chaffhouse would be approximately 30ft., height in front 8ft., and at the rear 7ft. By placing the chaffhouse and stable under the one roof a saving in cost was effected. This building appeared to be more suitable for a man with capital, but it was really cheaper for the small farmer, and certainly more convenient. In the implement shed the place for the wagon should have enough height and width to allow the frame to be hung over it. This made it easier to put it on or to take it off. The implement shed and barn should be placed so that it would provide a breakwind for the stable. All buildings should be of wood and iron. Mr. Steele did not favor the erection of two-storied stables, and Mr. Button did not approve of building the barn on the end of the stable owing to the danger of fire. Mr. McAvaney approved of two-storied stables, but would not place the implement shed adjacent to it. In front of every stable there should be a small paddock of three or four acres, with a straw stack. Mr. Pengilly preferred a straw-thatched roof for both stables and implement sheds, as it was much cooler in summer.

The Kitchen Garden.—A paper on this subject, written by Mr. H. Curtis, of the Uraidla and Summertown Branch, was read by the Hon. Secretary. The writer considered that it was essential for gardeners to have their own nurseries, as they were much handicapped when unable to raise their own seed. The seeds should, if possible, be set with early rains in order to produce strong reliable plants. He recommended sowing cabbages, cauliflowers, and lettuces in rows 3in. apart and ½in. in the ground, but on small plots he would broadcast the seed. The surface should not be raked, but covered to a depth of ½in. with clean stable manure. The land should be watered before the seeds were planted, and every day until the plants were strong. Beds should be protected from the ravages of birds with wire netting fastened to frames. Plants raised from seed beds could be taken out of the beds as required. They should be watered well before transplanting, and this should be done on a cool day or in the evening, the roots being kept straight. The Redhill district was not suitable for root crops. He recommended growing turnips or swedes of the Red King variety, and the ground should be prepared to present a fine surface. The seed should be put in to a depth of ½in. with 6in. between the rows and thinned to keep the plants 5in. apart in the rows. Carrots should be planted similarly to turnips. He would not grow parsnips. Peas of the Yorkshire Hero variety were very reliable, and should be planted in rows 2ft. apart and 2in. or 3in. deep. In open country subject to frosts and winds the peas should be protected by two rows of broad beans planted round the beds. Beans should be planted in the same manner as peas; both should be put in in April, when the soil was in a moist condition. He recommended growing a few roots of rhubarb of Burdett's Perpetual variety. The soil should be 10in. deep and well worked, and the plants or crowns set 2ft. apart in and out of rows. They should be covered with 3in. of stable manure and planted in

June or July. Radishes of the Turnip and Chinese Red or White varieties did very well on land that had been well worked for a number of years. The varieties mentioned should be grown through the winter and spring months. Silver beetroot was also a useful vegetable. As each variety of vegetable ceased yielding it should be seen that the land was kept free from stumps of cabbages, &c., to prevent the garden becoming infested with blight, caterpillars, riddlers, &c. If the land were worked up and planted with summer vegetables it could be kept clean and would also bring in a profit. For this he recommended Round Red tomatoes, Turk's cap, or pumpkins. The soil should be worked and covered with stable manure. No summer plants should be sown on the surface, but in drills or round holes. They should not be watered in the heat of the day. Where summer vegetables were not grown a new plot should be selected for the kitchen garden every three years. He would not use manure except in winter months, when the rainfall was assured. Two ounces of sulphate of ammonia should be dissolved in a gallon of water and applied near the roots of the vegetables, care being taken not to touch the leaf, if the land were suffering from the effect of frost. This would add flavor and quality to the vegetables. A few roots of parsley were also of value. In the discussion which followed Mr. Potts considered the Snowball variety of tomato the best. He would run the water to the plants in drains in lieu of using sprinklers.

WHYTE-YARCOWIE (Average annual rainfall, 13·91in.).

March 20th.—Present: 15 members.

Sparrows, Starlings, and Grasshoppers.—Mr. G. A. Wittwer contributed a paper. Whilst the majority of Australian farmers regarded sparrows and starlings as nuisances in the wheatfields and gardens, he said, they overlooked the fact that these birds kept the grasshoppers in check, and so prevented greater damage. The number of other insectivorous birds, such as tomtits, larks, magpies, &c., was kept low owing to poisoning, but the sparrows were too wily to take the baits. He did not think it necessary to protect sparrows and starlings except north of the Burra, where the practice of paying for the eggs at district council offices should cease. Since the advent of the sparrow, he said, no grasshopper plagues had been experienced in the country south of the Burra. Mr. F. Mitchell agreed that birds were great insect destroyers, and supported the idea of district councils discontinuing the practice of paying for heads and eggs, at all events in the northern districts. Mr. G. W. Mudge had seen the sparrows and starlings at work, and agreed with the writer that they were responsible for the deaths of numbers of grasshoppers. He, however, gave greatest credit to a species of bluebird, which came in large flocks and destroyed myriads of grasshoppers during the early summer. The Hon. Secretary (Mr. E. J. Pearce) drew members' attention to an article in the *Adelaide Stock and Station Journal* of November 26th, 1913, pp. 23, on the economic value of our birds, which emphasised the value of birds as allies of the cultivator of the soil. Nature had a way of her own of dealing with her problems, and man with his partial knowledge often did more harm than good. In no case was this more apparent than when he set out on a campaign of promiscuous destruction of what he calls "pests." No observant person could fail to notice the diminution in the numbers of our native birds, and there could be little doubt that this was largely accounted for by the wholesale poisoning with phosphorus and other means for the destruction of rabbits. We were faced with the blowfly pest on sheep and the botfly on horses, pests that were unheard of a few years ago, and which were infinitely harder to cope with than the rabbit, which had some commercial value. It would probably be a practical proposition to sparrow net our small gardens, which would be far more effective than killing the birds in the most wholesale fashion. The Chairman (Mr. G. F. Jenkins) said he considered his vines this year would have, in the absence of birds, given him a return of 40 cases of fruit. He had been able to secure two cases only. He admitted the value of birds as insect destroyers, but it was necessary to keep all these potential pests in check.

WIRRABARA (Average annual rainfall, 18·91in.).

March 14th.—Present: 20 members.

Chaff-Cutting.—Mr. C. Hollitt contributed a paper on this subject. Hay for chaff should be taken from the stack the night before, and damped with water so that it would cut easily, he said. He damped the hay on a floor 6yds. by 5yds., laying it out in rows, so that it could be easily handed to the man feeding the chaffcutter. At this time of the year he would put 5galls. of water on each layer of hay. It could then be put in bags or run back into the shed. The rollers should be so arranged that the teeth did not run parallel, but dovetailed. The top and bottom rollers should run as close to each other as possible; they were then less likely to choke. He preferred needle points to chisel points on the rollers, because if the hay were dry and brittle they would not cut or splinter it. The knives should be kept sharp, and the mouthpiece in good order. Of the three lengths on a chaffcutter, he preferred the middle one. The elevator should have a dust screen or sieve underneath it to let out all dust that might be in the chaff. A screw bagger was of great advantage when any quantity of chaff was being cut. One member mentioned a safety attachment for chaffcutters which prevented men getting their fingers into the knives.

YONGALA VALE (Average annual rainfall, 13in. to 14in.)

March 5th.—Present: nine members and two visitors.

Bulk-Handling of Wheat.—Mr. I'Anson read a paper. If the system of bulk handling were adopted, he said, they could not expect the millers to pay as high a price for the grain and pay 8s. per dozen for bags for flour, pollard, and bran. Whilst the farmer sold the bag to the miller for 1½d., who sold it for 6d., which showed a net profit of 1½d. per bushel on the wheat; this fact was taken into consideration when the price was being fixed. The high price of jute, he thought, would result in increased production, which would be followed by a fall in the price of cornsacks.

PORT BROUGHTON, March 13th.—Mr. Whittaker outlined a scheme for co-operative experimental farms under Government supervision. The Hon. Secretary (Mr. J. H. Fletcher) read a paper on "Seeding." Both matters were referred to the Conference of Yorke's Peninsula Branches for consideration.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16·46in.).

March 14th.—Present: 15 members and three visitors.

Fodder Grasses.—The following paper was read by Mr. E. C. Deland:—"There is no doubt that in many countries the idea of only cropping the land periodically for wheat, without trying to grow grasses and other fodder plants in between times would be considered a rather wasteful procedure, but perhaps our greatest difficulty lies in the securing of suitable grasses that will stand the extremes of frost and heat at a time of the year when water is scarce, or where it is not available for irrigation purposes. Probably foremost of all fodders as far as nutriment is concerned is lucerne or alfalfa. Once established it stands any amount of knocking about, in fact the more the head of the plant is divided the better it grows. It should never be placed in the ground with the drill or deeply harrowed in. The best way of sowing it is to broadcast after mixing it with sand or even with ashes, and then drag light boughs over the surface. The ground requires to be worked down to a fine tilth first. Another method is to run the seed mixed with clean sand and manure through the drill without letting the points go into the ground, then covering the same as before. Once the roots are established they will last for a number of years, and it is astonishing the quantity of vegetation that will result. Lucerne does best in this part of South Australia if sown in the early part of the season; it then has a good chance to become well established before the heavy rains come on and before the frosts get severe. Lucerne grown in this way is not hurt by cultivation and will hold its own even when it is necessary to fallow and crop the land for wheat. It can be fed off several times in a season, and when in the hay field it vastly improves the hay. It does not stand continuous feeding off for any length of time. Grown in a plot of four or five acres or less, so that it can be mown at regular periods it forms a great help to the milk cows, and is extremely useful as a change from the dry feed for the other stock, and if it can be watered even by slightly brackish water several cuts can be taken off each season. There is no other fodder which responds so quickly to watering, and it will grow to a height of 2ft. or over in the clayey or loamy soil of these plains. It does not appear to do too well in the sandy soil, because the head of the plant becomes too deeply embedded by the accumulation of sand around and over the plant, but in damp seasons if sown on the surface in the stubble it will probably get a good hold in the ground. Other good grasses are now obtainable, and amongst the best are Giant Italian rye grass, Rhodes grass, and cocksfoot. These grasses mostly grow in tufts and give astonishing results in soil suitable for their requirements. Some of them stand the heat well and help to bind the soil if loose, but not many of them stand cultivation in the open field, as they are not deep rooted like lucerne. Grown in specially prepared plots, and sown on the surface and covered in with a bough brush they form a great standby in the summer months, but no grass has been found yet that will stand season after season the cultivation necessary to the land for wheat growing, with the exception of lucerne. Rape, vetches, and peas are all good fodder crops, and especially for sheep, but they only last the one season. On the other hand they are of great advantage in gathering nitrogen into the soil. They all do well in this district, but the seed must not be sown too deep. For binding the sandhills the ordinary couch grass or Kentucky Blue grass seem to be about the best. The roots and runners spread long distances under the surface, and although cultivation kills some of the grass it bears considerable quantities of seed, which comes up in the following season. The roots and runners, when buried in the sand, help very materially to bind it, and also to gradually enrich it in humus. I believe if these grasses were tried on the sandhills of this district in the damp seasons they would get a good hold and be of great advantage eventually. While they are not quite equal to the grasses previously mentioned as fodder, they are readily eaten by the stock in the dry part of the year. Like all these fine seeds, care is required in the sowing, as they must not be buried to any depth, but should be just under the surface. The seed is very light, hence the need of sowing when the weather is favorable and a good rain likely to fall almost immediately. In the foregoing I have not dealt with such fodders as holcus, sorghum, maize, soya beans, &c., because they all require special cultivation, and are more suitable for climates like we have in the hills, although a fine plot of maize has been grown this season close to the town without much artificial watering. This is a most opportune time to cultivate some of these grasses. The advantages to be gained are so many, particularly the introduction of more humus and nitrogen into the soil, and the provision of green feed for fattening lambs and sheep, and as a tonic for larger stock during the dry summer months."

JULIA (Average annual rainfall, 18in. to 19in.).

January 10th.—Present: 10 members and two visitors.

Stripper *v.* Harvester.—Mr. J. Jaffer read the following paper:—"Advocates of the harvester maintain that such machines gather more wheat per acre under similar conditions and crop, are less liable to choke in the comb, and are enabled to start earlier in the day to strip to satisfaction than the stripper. However, since from the points of the comb to the outlet of the thrasher harvesters and damp-thrasher strippers are identical, all arguments in this direction must be recognised as idle. It is also contended that more wheat is obtained through the heads constantly being circulated through the thrashers of the harvester. If the machine cannot sufficiently treat its passing products in the one rotation, sooner or later elevator passages or sieves must get blocked or choked. Giving the harvester as a mechanical production its dues as being sufficiently improved to treat its passing products in one operation, such choking up of elevators, with careful control, may seldom occur; but it must be admitted that mechanical ingenuity in this direction is not lacking in damp-weather strippers and power winnowers, whilst these, even under poor control, still give good results. A further argument which is brought forward and which, without forethought, appeals strongly to users of harvesters is the saving of labor, and getting through early with harvesting operations. Yet, since three men are able to manipulate any power winnower, it must thus be recognised that any farmer or producer employing three or more hands during the harvesting season would be well advised in using strippers and winnowers, since the same work under this system can be done by less experienced men with less horse power, and completed in less time, with more comfort and ease, thereby ensuring a better sample and gaining many other advantages. Farmers in a smaller way are using their petrol engines to drive hand winnowers, thus saving the labor of an extra man, and thereby also gaining every other advantage such mode of harvesting affords. Strippers are built as wide in the comb as harvesters. Whilst four horses are required in the harvester, three only are needed in the stripper. From the foregoing we can conceive no advantage the harvester may claim over the stripper; but numerous are the advantages in the reverse direction. We have heard that the initial cost of each mode of harvesting is similar, but strippers and winnowers have lasted in many instances over 30 years. What is the life of a harvester and the cost of upkeep in proportion to the other machines? Any intelligent boy can handle a stripper to perfection, whilst it takes an experienced man to manage a harvester. It is generally recognised that hilly, sandy, rough, and stumpy country is practically unsuitable for harvesters to give favorable results, and although the winnower portion on them is made to be regulated forward and backward, there is only one sideway adjustment, and when harvesting along the side of an incline it must naturally heap the crop to be cleaned on to one part of the sieves, whilst over the other parts it is scantily spread, the result being an uncleaned sample or waste of wheat. Similar results are experienced in turning corners, stopping, or starting, whilst winnowing sieves are in full speed. It is owing to these difficulties that at harvester trials the man in charge will keep his machine moving straight ahead until the sieves are cleared of all material under treatment, and only then turning to enter the crops on the opposite side, thus only stripping two sides of the plot at each round and never turning short to strip the ends. A further loss of grain attributed to the use of harvesters is whilst letting the wheat from the box into the bags. One must be again more than careful whilst taking off or dumping and sewing up bags. This also occurs in the ordinary way of winnowing wheat, but spilt grain is afterwards easily collected. However carefully the harvester is handled, it affords every opportunity of losing grain, whereas under the other mode of harvesting, even with careless management, every grain passing the thrasher outlet of the stripper into the box is saved and well stored. Placing bags of wheat all over the field has not only been recognised by many as an inconvenience in sewing and in loading afterwards, but it is also exposing the bagged wheat in case of fire or wet weather. The gathering of chaff with harvesters has proved itself a failure. This by-product has in times gone by been valued at 6d. per bag, and even within the last six months it has again proved its worth. Another by-product lost through the use of harvesters is the screenings. Some is collected in the box, but most of it is blown to waste with the chaff. With the stripper a crop can frequently be stripped long before a harvester can be put to work in the same field. The results of harvester-stripped green patches or irregular ripening grain are too well known to need further comment. With strippers the grain is left to ripen in the heaps amongst the chaff. Star thistles and other foreign matter is dried up there, and afterwards in winnowing it easily passes out with the chaff, whilst with the harvester thistle seeds, sheepweed seeds, backbones, &c., pass through into the wheat. Another undoubted advantage the stripper gains over the harvester is the collecting of obnoxious weed seeds. These the harvester scatters over the fields, and some who have had harvesters have a woeful tale to tell in respect to this trouble. There are many farmers of to-day who have given the harvester a fair trial who have since taken to strippers again, some putting their harvesters to use as stationary power winnowers."

JULIA (Average annual rainfall, 18in. to 19in.)

February 7th.—Present: 14 members and three visitors.

Storing Wheat.—Mr H. Pfitzner read a paper. He said—"One of the greatest mistakes that Australian farmers make is that of not storing wheat in their own barns until they wish to sell it. If they did so they should be able to obtain anything from 2d. to 6d. per bushel on an average more than they obtain under the present system. Stored wheat is practically always on the market and against a man when he wishes to sell. Wheat kept for about seven months will gain about 7lbs. or 8lbs. per bag in weight, and that means about another 2d. per bushel. If it is well stacked the mice will do very little harm. If wheat were carted later, say in the winter, the roads would not cut up so much, because such big loads would not be taken."

Cleaning and Marketing Wheat.—Mr. R. W. Rowett read a paper, in which he advised cleaning wheat for sale or for seed. The screenings were very useful on the farm for feeding poultry and pigs. The paper continued—"All farmers should have a grader, or otherwise have their wheat graded for seed, as I am strongly in favor of a good large and plump grain being sown. The wheat plant takes its first food from the grain, and therefore a much stronger and healthier plant must be produced than from a shrivelled grain. Farmers are well advised to dispose of as much of their grain at harvest time as will pay their way. There is little to be gained by holding wheat and having interest to pay; but the farmer who has wheat with which to trade should store it in his own barn."

MALLALA (Average annual rainfall, 16·88in.)

March 2nd.—Present: 12 members and three visitors.

Continuous Cropping.—Mr. Oliver gave the following particulars regarding six acres of land which he had cropped continuously for seven years. In 1907 it was drilled with King's Early, with 50lbs. super. per acre, and it yielded 1½ tons per acre. This crop was exceptionally early, being bound on September 20th. In 1908 oats were sown, with 60lbs. super., and returned 3 tons of hay per acre. In 1909 English malting barley, with 70lbs. super., was sown. It reaped 30bush. per acre. During 1910 King's Early was again sown, with 1cwt. super. It cut 2 tons hay per acre. In 1911 oats were sown, with 1cwt. super; 48bush. per acre were secured. Baroota Wonder was sown in 1912, with 1½cwt. super. It started very late but cut 15cwts. per acre. In 1913 four and three-quarter acres were sown with peas, which grew a very nice crop; one and a quarter acres were sown with barley, with 100lbs. super. On the 1st August this grew a very thick and strong plant; three horses were grazed on this piece for a month. He took them out on the 20th October. A good rain fell shortly afterwards and the crop yielded six bags from the one and a quarter acres.

Engines on the Farm.—Mr. W. H. Tomby read a paper. He said, "The engine can be utilised on the farm in many ways, such as for chaff-cutting, sawing firewood, winnowing, and crushing. The portable oil and petrol engines (6 h.p. or 8 h.p.) are the most suitable for farm purposes. With the stationary engine there is hardly any vibration compared with the portable type. I prefer the oil engine. The cost is much greater at first, but better value is secured. Benzine used by the petrol engine costs at the lowest 1s. 8½d. per gallon, whilst kerosene costs 7d. per gallon. To do the same work the petrol engine takes nearly as much fuel as the oil engine of the same power. The advantage with the oil engine is that there is no magneto or spark coils. To a man who does not understand electricity this ignition is very puzzling when anything goes wrong. Then again the speed needs some consideration. The average speed of a 6 h.p. oil engine would not be more than 300 revolutions, while a petrol engine of the same horsepower would make 400 to 500 revolutions per minute. Some favor the petrol engine because it can be started at a moment's notice; but, if the lamp is lit first whilst the cutter is being sharpened and oiled, the oil engine will have become hot enough for starting. Use high-grade oils or the engine will lose power and the rings around the cylinder will wear. The engine should be well looked after and have a good overhauling once a year. All of the bearings should be well cleaned with kerosene. The valves, especially the exhaust, should be taken out and cleaned occasionally."

NORTHFIELD (Average annual rainfall, 19in.).

March 3rd.—Present: seven members.

Farming in Scotland.—An interesting paper was read by Mr. A. Low. He referred more particularly to Aberdeenshire, and said it was difficult to get a farm in Scotland. There was no land board to whom one might apply, with the almost certain chance of at some time securing a farm; but instead a person had to wait until someone died, was evicted, or left to go to fairer climates. Then perhaps there might be 20 or more persons wanting the same piece of land. The owner usually, although not always, let it to the one that made him the best offer. The rent ranged round 20s. per acre, the first payment being made 18 months after taking possession. The system of farming practised was what was generally known as the five to seven shift system or rotation of crops. If the farm consisted of, say, 350 acres there would be 100 acres in pasture land of second or third year grasses, 150 acres in oats or barley or a small portion of green feed, 50 acres in hay or first year's grass, and say 50 acres of turnips. The manuring was a most expensive item. First for oats, say, 1½cwts. to 3cwts. superphosphates, bonedust, or potash; then after a few weeks, 30lbs. to 40lbs. of nitrate of soda, &c. Six bushels of seed were sown to the acre, and in the case of barley, 3½bush. Turnips, which was the most costly crop to produce was fed off with sheep or cattle.

RIVERTON (Average annual rainfall, 20.48in.).

February 24th.—Present: 17 members.

Wheat.—An interesting address on this subject was delivered by the Hon. W. Hannaford, M.L.C. He mentioned that so far as this State was concerned, the consumer called the tune as to price, and it was only as we were able to compete in production with other countries that our industry would exist. Since the use of superphosphate had become general, this State was able to produce grain in areas that were previously outside the margin of profitable cultivation; also, the best lands yielded more per acre, thus reducing the cost of production of the wheat. With the increase in the value of livestock he thought it might pay producers to co-operately purchase machinery and thresh some of their grain in order that they might retain more of the fodder value of the straw. There was a tendency for the farms to become somewhat dirty, and he strongly advised the grading of seed and feeding inferior grain to stock on the farm. Out-of-date machinery should not be countenanced. The question of bulk handling of wheat was awakening considerable interest in Australia. The fact that the price of jute had increased, and that the present sack held only 3bush. as compared with the 4bush. held by the old type of bags, was largely responsible for this. To introduce the bulk system meant a reversal of present methods from the farm to the port of anchorage. This system would in all probability be initiated in Victoria and New South Wales, where the railway system and shipping conditions were far more favorable to its inception. South Australian conditions were very different, and it was questionable whether the change would offer any advantages. Under present selling methods the farmer secured full value for the wheat which he sold, the merchant taking the risk of his agents' judgment. The farmer was paid immediately, or, if he desired to store in anticipation of a higher price, the merchant took all risk of damage by rain or vermin. In New South Wales the Government erected sheds in which the farmer could store his grain. He took all risk of damage through weevil or mice. It was problematical, however, whether his storage charges did not amount to more than he would have to pay a merchant for the redelivery of his wheat. The risk of the failure of the firm which held the grain was the only one, and the experience of the past did not point to this as being very great. In Victoria and New South Wales the trade was concentrated to one or two centres. Practically all the wheat of New South Wales was sent from Darling Harbor, and from Williamstown and Geelong in Victoria, so that the building of the necessary sheds would not dislocate the point of shipment; but if, in South Australia, we had to bring all the wheat to Port Adelaide and one additional port, we would find that the transit would be so heavy that the resulting advantage of bulk shipment would be more than mopped up by the increased cost. We had about 15 deep-sea ports for oversea shipments where even the convenience of jetties was not provided, the ketches simply lying on the beach and the farmers carting the wheat to them in their wagons. Possibly under conditions like those of Victoria and New South Wales the bulk system might be worked to advantage, but South Australia could afford to allow these States to take the initiative. If it were necessary to use bags for part of the journey from producer to consumer, these bags would be unfit for further use. It was more profitable to minimise leakages under direct control. Everything saved or conducted more economically would result in a greater profit than railing against high cost of cornsacks, unless we could see a more satisfactory method of dealing with the produce. The cost entailed every year in bags would eventually bring about some method to counteract the extra cost. Weighing by means of the bridge, and machinery for handling the bags of wheat from truck to ship's hold, the reduction of railway grades to enable the railways to take bigger trains, and the overlapping of agents, &c., left avenues still open for exploitation.

BALAKLAVA, March 18th.—Manures.—A discussion was initiated by the reading of an article dealing with the use of basic slag, and the heavier manuring of wheat lands. Several members expressed the opinion that it would soon be necessary to use something besides superphosphate on the land, although some had not had satisfactory experience with the use of basic slag some years ago.

CLARE, March 13th.—Explosives.—A short address on this subject was given by Mr. E. L. Elliott.

Pruning Match.—It was decided to hold a pruning match, and the following committee was appointed to superintend arrangements:—Messrs. W. Patullo, J. H. Knappstein, C. S. Jarman, R. Hunter, M. L. Nolan, F. W. H. Lee, J. Berridge, and P. H. Knappstein.

WATERVALE, March 9th.—Crops.—Members reported a fair crop of currants of good even sample; bucks were very prevalent. There was a very heavy crop of apples, but the quality was not up to the usual standard, owing to the dryness of the season. There was little summer feed in the district, for the same reason.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

MAITLAND (Average annual rainfall, 20·08in.)

March 7th.—Present: nine members.

Papers for the Branch.—In a paper dealing with this subject Mr. H. Bawden said that some members appeared to think that because they had not received a good education they should not write papers for the Bureau. This was a mistake. A fine literary effort was not required, but practical information, founded on experience, of matters of agricultural practice.

Harvest Results.—Mr. Wundersitz attributed the partial failure of the last season's crop to the prevalence of rust, hot weather in September, and frost. Other members expressed various opinions on the cause. Mr. Bently thought the best wheats for the district were Yandilla King, Federation, and Marshall No. 3; Mr. Jarrett favored Marshall's No. 3, Yandilla King, and King's Early; Mr. Wundersitz Marshall's Early Pearl, Marshall's No. 3, and Yandilla King; Mr. Heileman Federation, Silver King, and Bluey; Mr. Hill Silver King, Marshall's No. 3, and King's Early; Mr. Smith Marshall's No. 3, Silver King, and Federation; and the Hon. Secretary (Mr. C. Pitcher) Marshall's No. 3, Yandilla King, and King's Early.

PINE FOREST (Average annual rainfall, 14·15in.)

March 10th.—Present: seven members.

Grading Seed.—Mr. S. T. Barr read the following paper:—"In selecting seed wheat it is necessary to obtain the varieties best suited to local conditions. Two varieties of wheat grown side by side, put in under exactly the same conditions, will vary in yield as much as 6bush. to the acre. Having got the varieties which suit the district best, the preparation of those wheats for seed is something that should secure best attention. For this work I consider the seed-grader indispensable on the farm, for, by the careful use of this machine not only are all the weed seeds removed, but the cracked and smaller grains are taken out, thus leaving a nice even sample of wheat. Some say they can put 50 or 60 bags a day through the grader. If the wheat is a good sample, free from weed seeds, and only containing chaff and long straws, this may be possible; but when drake, sheepweed, nannyweed, wild oats, and other weeds have to be taken out, as is sometimes the case no matter how careful we are, it is necessary to put it through the machine steadily, and I consider 30 bags a day quite fast enough. The value of sowing well-graded seed has been demonstrated beyond dispute, as much as 2bush. and 3bush. to the acre being shown in favor of the graded seed. If we improve the yield of our crops to the extent of 1bush. to the acre, it is well worth our while; and if 2bush. or 3bush. to the acre are added the extra time spent on grading will be a paying proposition. The scheme as laid down by Mr. A. E. V. Richardson (once Acting Director of Agriculture in this State) would be a good one for us to adopt. That is, go through the wheats we intend to save for seed just before harvest time, pick out enough of the best of the heads to make 10lbs. of seed, sow this with the drill in one long strip of one-fifth of an acre. The following harvest go through this strip, again picking out the best of the heads, then reap the rest of it for a seed plot. By the third year enough should be obtained to sow 100 acres. To be successful this has to be kept up, the 10lbs. of picked seed representing the stud wheat plot each year. By this means the yield should be materially increased and the tendency to degeneration checked. This scheme would also be the means of getting rid of the barley from our wheats, which is becoming far too prevalent in some of the varieties; or failing this we could have, say, a five-acre plot, and when the barley comes out in ear pull the plants up by hand. With late wheats this is an easy matter, as the barley comes in ear first; but the early varieties of wheat are in ear before the barley, and with bearded wheats the barley is difficult to see. Our best plan then would be, after having graded the seed with the machine, to handpick a bushel of it. Sow this on an acre of ground. The following year we would have enough to sow 15 acres. To keep our wheat free from smut we must pickle the seed; a 1 per cent. to 1½ per cent. solution of bluestone is strong enough for this. Although the wheat can be sown a day or two after pickling, I believe it would be advisable for us to pickle some weeks beforehand; at all events the wheat would go through the drill better, and I think the smut would be more effectively destroyed." Members discussed different methods of pickling seed.

WESTERN DISTRICT.

COORABIE (Average annual rainfall, 11in. to 12in.)

March 7th.—Present: 12 members and two visitors.

Poultry on the Farm.—Mr. E. J. Stretton read a paper on this subject, from which the following is taken:—"There is a common impression that the production of eggs will soon be greater than the demand. This is a mistake, according to statistics. I would impress on everyone the necessity for making a start in poultry-keeping, not as an industry in itself, but as a side line on the farm. That there is money in the business I am convinced from my own experience, and from the point of view of profit I prefer a few good hens to a pig on the farm. I advise the purchase of a dozen or so White Leghorns, This breed is a layer purely and simply, and although on the small side it makes up for this by its hardiness in a dry climate like our own Other breeds are better meat producers and fair layers, but they cannot compare with the Leghorn for laying, and that is where the money comes in in a district where there is no market for the table birds. Erect an iron shed sufficiently large to accommodate the number of birds to be kept. Have the shed enclosed except at the front, and near to a large shady tree, in order to keep the birds as cool as possible in the hot weather. Place the perches not higher than 4ft. at the back. Keep the shed clean and give the whole building a good coat of whitewash frequently. This will keep the birds cool and free from vermin. Give them whole grain morning and evening at regular hours. Scatter it in clean loose soil or in a heap of straw to give the birds exercise. Cultivate a small plot of lucerne, rape, or kale, as a little greenstuff is a wonderful tonic and constitution builder. A little scrap meat minced up and mixed into bran mash occasionally in the winter mornings will keep up the egg production. During the hot months keep the water supply cool and clean. On very hot days throw a bucketful of water down in a clean patch of soft soil in a shady spot. The birds will bask in it as long as it is moist. Do not overfeed; give them just enough to keep them busy scratching for a few minutes. Sick hens should be immediately killed and burned. Delay in this matter is running the risk of further infection and heavy losses. Breed only from the best stock, and hatch out the chicks with a good barn-door hen. Choose the eggs from the best hens, and for the best results pick out the natural shaped egg. Eggs for the market should be infertile, as they keep best." Mr. Atkins mentioned that he had experienced no trouble in growing lucerne and rape without irrigation.

KOPPIO (Average annual rainfall, 22·40in.)

March 12th.—Present: nine members and one visitor.

Experiments on the Farm.—The Hon. Secretary (Mr. R. F. Richardson) read the following paper:—"It seems that we, as farmers, are apt to regard experimental work as something rather beyond us; something which must be left to the agricultural colleges, experimental farms, and a few enthusiasts. We read with interest of the work done and the results arrived at by these institutions and enthusiasts, and probably profit by them to a slight extent; but it is doubtful if any of us derive the full benefit from them, because we fail to follow them up. The fact that is lost sight of is that a few properly conducted experiments greatly lessen the risk of failure and enable the farmer to increase his yields. The plea 'want of time' is often put forward, with the result that experience is dearly bought. As a matter of fact experimental work should be classed with the current work on the farm. Conditions vary so much that what would apply in one part of the State would be practically useless in another, and in this particular district especially, which is situated so far from any experimental farms, systematic experimental work is almost essential. Further, in this district there is a wide field for such work, for besides cereal crops almost every farmer breeds sheep, and the abundant rainfall enables almost any fodder crop to be grown, and fruit trees of most varieties thrive remarkably well; but it would be a mistake to undertake more than could be carried out with thoroughness; for unless an experiment is accurately conducted the result loses much of its value. In my opinion experimental work should be one of the chief features of the Bureau." Members agreed that a systematic series of experiments would be of much value to farmers in the district. It was decided to conduct experimental plots. Messrs. G. B. Gardner, F. Richardson, and J. Newell were appointed a committee to supervise. Mr. J. Newell agreed to continue the manure tests which he had started last year, and Mr. Gardner undertook to conduct plots to test varieties of wheat on his farm.

MILTALIE (average annual rainfall, 14·55in.).

March 7th.—Present: nine members and three visitors.

Cultivating and Seeding.—Mr. M. H. Wilson read a paper. He said—"Fallowing, in my opinion, is essential in any class of soil to produce in average years a decent crop. Of course in the fat years on new land good crops are grown, but where there are weeds and the land is old, it would be more luck than good management to get a good crop by just ploughing the land in front of the drill. The land should be fallowed about 4in. deep, and cultivated to a depth of 2in. once before harvest at least, and again immediately after the early rains. When seeding time came a very light implement would be quite sufficient. The land should be harrowed crosswise after each working. The mallee shoots should be cut every year whether the land is in crop or not, especially on fallow, as they extract a lot of moisture. I do not believe in dry ploughing, as it encourages takeall, and does little good to compensate for the risk of that pest. Where cultivating is impracticable, sheep are a good substitute for keeping the weeds down. In a young district like this there are many difficulties which arise to make fallowing on a large up-to-date scale wellnigh impossible, such as shortage of feed and water. When the farmer has to cart the latter long distances, as many have, it takes all his time and strength. A good substitute for fallow is to plough the land immediately after the summer rains. By the time the stumps are disposed of it is time to commence seeding operations, and the land is ready to cultivate. Faulty implements also play a big part in the average yield. I do not believe in the long skim ploughs—12 furrows or more. To make them light the manufacturer has to make them weak, and the plough twists and strains until one furrow does the work of two. The result is that the land is improperly worked, and that means a decreased yield. A twin plough is a great deal better. The first time the land is ploughed a heavy standard mouldboard implement should be used, except where the land is very sandy. Then a medium plough does just as well. The second week in April is early enough to begin sowing wheat. Oats can, with advantage, be sown a little earlier. The seed should be sown about 2in. deep. It is always a good plan to harrow the land immediately after sowing. After the middle of May it is advisable to sow only early wheats, as then the crop is far enough forward to stand frosts and the strong north winds. If the plant is young the latter succeed before long in entirely blowing it away."

ROBERTS AND VERRAN.

March 10th.—Present: eight members.

Summer Fallowing.—Mr. G. Plew read a paper as follows:—"I would start fallowing as early as possible, say about the middle of February, and work to a depth of at least 3in. I would not put the harrows over the land, as if it is at all hard it will set down, making the working back much harder and less effective. Land fallowed early will grow quite as much, if not more, feed than that left until after seeding. The seeds germinate more readily if the land is broken early, thus retaining moisture that might otherwise run to waste. Summer fallow should be worked directly after seeding is finished, and any other fallowing can be done afterwards. The early fallow will then stand another working if it is at all dirty. Returns from this are better than those from ordinary fallow. The land is kept much cleaner and the crop will stand a dry spell much better if properly worked. If the ground is at all likely to wash or to cake it is advisable to turn in the straw. This helps to keep it loose, and it will be quite damp when other land is very dry." Mr. F. Masters thought summer fallowing impracticable in this district. Members generally agreed that the practice was one that could be profitably carried out in the district, but the time was hardly ripe for its adoption.

UTERA PLAINS (Average annual rainfall, 12·06in.).

March 7th.—Present: eight members.

The Fire Rake.—Mr. W. Gale contributed a paper on this subject, in which he said that the fire rake was very useful in this district, as the straw did not grow thick enough on the sand rises to secure a good burn. It removed the straw and at the same time killed many of the shoots. Some might grow again, but they would not trouble the reapers. It was advisable to burn the straw against the wind. One man had in three days cut all the shoots left on 240 acres, which he burnt in April. Many of the shoots had made no subsequent growth, but in another paddock, where the shoots were cut in July, it took two men four weeks to cut them. This year he fire raked the paddock, and most of the shoots were killed. He had found axle grease better than oil for the wheels of the rake. The rake he used was 15ft. wide, and it was not heavy for two horses. More shoots were killed when working the rake at a steady pace than at a fast rate. Members emphasised the necessity for having high wheels for the rake and the use of axle grease in the place of oil.

YADNARIE (Average annual rainfall, 14·09in.).

February 7th.—Present: 16 members and a large number of visitors.

Water Conservation.—Mr. H. Bauer read a paper on this subject. A water supply was the most important factor in the settlement of new country, he said. For domestic purposes the roof of the homestead would generally supply all the necessary water, except in very dry seasons. Many points were to be considered before deciding on the nature of the supply. The cost of the undertaking had to be taken into account, and whether the necessary time was available to commence a large scheme. It was sometimes advisable to put up with a temporary supply and increase it as opportunities offered. He favored boring, especially in this district, where it had been proved that good stock water existed. A dam did not retain water long in such dry seasons as the present. The water evaporated quickly in scorching hot northerly winds. A site with a good catchment should be selected, and a fairly large dam constructed, say about 30yds. long by 12yds. wide, and from 6ft. to 8ft. deep. It should be long and narrow, so that a roof could easily be erected over it. A light and inexpensive roof could be constructed of wire netting and porcupine bush. The covering checked evaporation, kept the water cool in hot weather, and kept the stock out of it, and thus prevented pollution. A small force pump was a cheap and effective method of raising the water from the dam. Where there was a good claybed, but the catchment area was light and sandy, it was a good plan to spread the clay scooped from the dam upon the steepest slopes, and after a good rain it could be puddled. The surface would soon harden and provide a good run. Often, when a good catchment area was available there was no ground suitable for the construction of a dam, the soil being porous or stony. A tank should be constructed by ploughing the surface and scooping out as much earth as possible. The sides could be cut down with a pick, and a 9in. wall of solid stone well built would be sufficient for 25,000galls. capacity. It should be roofed with wire netting and porcupine bush, which was cheaper than timber and iron, and was quite as effective. He believed that boring would be generally successful on Eyre's Peninsula. It had been stated that stock would live practically twice as long on poor food and a good water supply than they would on an excellent food supply and a scarcity of water. In the discussion which followed, members generally were of the opinion that dams were best where good clay was available, on account of cheapness. Tank walls should be built 2ft. thick. Mr. J. J. Deer favored boring, and thought the Government should test the country to locate water supplies.

COORABIE, January 10th.—The meeting was devoted to a discussion on "Home Remedies for Horse Ailments."

COORABIE, February 13th.—Sixteen members and about 80 visitors spent an enjoyable social evening. Mr. E. J. Stretton contributed a paper on "The Commercial Side of Poultry-keeping on the Farms."

ELBOW HILL, March 7th.—Members discussed the subject of bulk handling of wheat. It was generally agreed that the system would eventually have to be adopted on account of the high price of cornsacks.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

BERRI.

January 10th.—Present: 14 members.

Dairying.—Mr. R. Stachling contributed a paper on this subject. This district, he said, was capable of being made into a first-class dairying area. With this object in view they should start from the first with the idea of getting the land into condition for the production of lucerne, maize, sorghum, and millet for summer fodder, and wheat, barley, and rape for early winter feed. Swedes, mangolds, and pumpkins were good milk-producers. Feed could be conserved either as hay or as ensilage. The cattle should be carefully selected, especially in regard to suitability for the district. Cows and a bull from a known milking strain should be procured. A careful record of the yield of each animal should be kept. Testing could be done with a glass tube milk tester or the Babcock tester. The milk should be strained and separated whilst still warm. The cream should be cooled immediately. It should be churned at least twice a week. The general opinion of members was that to make dairying an industry on the river settlements railway transit to the larger centres of population was necessary.

COOMANDOOK (Average annual rainfall, 18·01in.)

March 14th.—Present: nine members.

Scrub Farming.—Mr. H. Gosden read a paper in which he advised the planning of a scrub farm with a definite eye to the future. The homestead should be placed in the centre of the block, and the site should be fenced, four or five acres being enclosed. A narrow break should be allowed to stand on the outside of the homestead fence, and trees should be planted inside; fruits should also be put in. Pigs and poultry should be kept, and efforts directed to the clearing of 100 acres of mallee to provide grazing for sheep and cows. Ten acres should be worked for hay and green feed. Neighbors could combine in the purchase of such machinery as engine, seed grader, binder, &c.

Agents.—Under this heading Mr. L. Crouch read a paper, in which he stated that farmers should purchase implements and machinery direct from the manufacturers, thus doing away with the necessity for agents, and saving commission. The firms could ing the merits of their goods under the notice of farmers by posting them a catalogue e prices annually. Members thought that in the event of agents being dispensed with th prices of machinery would be reduced. It was decided to order requirements direct.

GERANIUM.

March 17th.—Present: 13 members, one visitor, and the Secretary Advisory Board.

Experimental Work.—As this was the first meeting of the Branch since the harvest, several of the members who had conducted some rough tests presented the results to the meeting. *Manures.*—Mr. R. Jacob put in 45 acres of stubble with 1cwt. super. per acre, and from 40 acres of it reaped an average of two bags per acre. On the remaining five acres of this block, however, he applied a top dressing of nitrate of soda at the rate of ½cwt. to the acre, and from the portion so treated reaped three bags to the acre, or approximately a 3bush. increase on the super. only, at an additional cost of 7s. per acre for the nitrate of soda. The land was necessarily put in in a fairly rough state, and with better cultivation he believed the enhanced profit from the direct nitrogenous manure would have been greater. On another plot a mixture of nitrate of soda with basic slag gave no better result than the part manured with the 1cwt. of super. *Peas v. Fallow.*—Mr. Jacob also had a block of fallow adjoining land previously under peas. Lott's wheat was sown on the fallow, and for a few drill widths on the pea land. As the whole was cut for hay he could not give exact returns, but there was a marked difference in the appearance of the crop in favor of the pea ground, where the wheat stood quite 6in. higher than that on the fallow. The pea ground, however, would have had the advantage of any residue of the ½cwt. of super. per acre, which that land had received with the peas. *Potash Manures.*—Mr. W. Pannell had put in an acre of peas, half of it with super., and the balance with super. and about 10lbs. sulphate of potash per acre. The yield was much heavier where the potash had been applied. To test the matter further he had bought this year a ton of phosphatic manure containing in addition 15 per cent. of potash manure. This manure cost about £6 3s. 6d. per ton, but he believed that it would pay. *Takeall.*—In one of Mr. Pannell's paddocks a considerable area of the crop on fallow had been destroyed by takeall, and the stripper was not put into it at all. Part of this fallow, however, had been harrowed once, after a rain at haytime, and on that part a satisfactory yield was reaped. The harrowing of the fallow after rain made all the difference between success and failure in that instance. *Quantity of Super.*—The Chairman (Mr. W. Mitchell) had a big block of Nhill wheat grown from ungraded seed, sown at 60lbs. per acre. The bulk of this was manured with 60lbs. of super. per acre, but on half an acre, carefully measured, 112lbs. of super. per acre was applied. This half-acre and a similar area of the main crop was harvested separately, and the grain weighed. The result was 9bush. per acre from the 60lbs. super. and 11bush. 24lbs. from the 112lbs. super. The balance of the paddock where only 60lbs. super. had been applied, also yielded an average of 9bush. per acre. The extra super., therefore, returned an extra net profit of say, 5s. 10d. per acre. *Rotation of Crops.*—An address on this subject was delivered by Mr. R. Jacob, who at the outset referred to the antiquity of the practice of rotation of crops. Some of the reasons for the practice were that by the growth of a variety of crops greater economy of food supplies was secured, and fertility was better preserved. The land was more continuously producing, greater value being won from its resources. The work of the farm was also more evenly distributed over the year, and there were fewer periods of rush. Some crops were a good preparation for others, the ravages of insect and fungus pests were discouraged, stock were moved more systematically over the farm, and a greater variety of food supplies was raised by the rotation of crops. It was evident that some system of rotation must be evolved for this new country, and it must be kept in view that for a long time to come wheat would be the staple product here. It had been proved that wheat continuously would not pay, neither would wheat and bare fallow only prove to be the best system for these lands. As wheat was the staple product, and takeall the greatest enemy, the growing of oats must be considered in any rotation. A rotation practised successfully in the Nhill district of Victoria was wheat, oats, grass, and fallow. Some varied this to wheat, fallow, oats, grass, fallow, and then again wheat. No leguminous crop was included in that rotation, but probably when left out to grass there would be in that old district an abundance of natural clovers which had not yet appeared in any profusion here. For their value in the fixation of nitrogen, therefore, he would include some leguminous crops here. Although it would be difficult to dispose of the produce from large areas of peas, every farmer should have some in each year, if only 10 acres. Catch crops, such as rape, turnips, &c., must go together with livestock, and were, therefore, out of the question at present. He therefore recommended for the immediate future a rotation of wheat, oats, fallow, with the addition of as large an area as practicable of peas. In the discussion the Chairman said that in view of the absolute necessity for growing oats to check takeall a relatively small area should be sown to this crop every year, instead of continuing with wheat until the bulk of the farm became affected with the takeall fungus, and it became necessary to put such large areas under oats as to render the disposal of the produce a difficult problem.

The best of hay could be cut from the oat crop. Mr. Pannel was convinced that disaster would result from the continuous practice of bare fallow and wheat Mr. Troubridge, of Lameroo, had never averaged less than 12bush. per acre from his farm, and he had always left the land out to grass one year in three, and was now carrying 700 sheep. *General Matters.*—The Secretary of the Advisory Board addressed the meeting on Bureau work generally. He congratulated the members on the work accomplished by the branch, and urged that the experiments being conducted by members should be co-ordinated to prevent undue duplication, and to secure the greatest results from the work. Such tests as those detailed at this meeting reflected credit on the men conducting them, and suggested the lines upon which the Bureau could do its best work for the members and the district. The variety of grasses and fodders seen that day at Mr. Jacob's farm, including perennial rye grass, cocksfoot, Bokara clover, millet, paspalum, and others becoming established under such adverse conditions as those experienced during the past two years, was exceedingly suggestive of the future stock-carrying potentialities of the districts and of avenues of work for the Bureau, which should enable it to contribute materially to the advancement of the district and the State.

LAMEROO (Average annual rainfall, 16·55in.)

February 14th.—Present: 13 members.

Farm Planning.—In dealing with this subject in a paper Mr. A. J. A. Koch said—"Mistakes made at the beginning often cannot be remedied, and it is always worth while to carefully consider before permanent buildings or fences are erected. In many instances the homestead (especially in mallee country where a track has to be cut to gain admittance to a block) springs up around where the first camp is pitched, frequently right in one corner of a big square block, or perhaps in the same position on a triangular farm. When the time involved travelling back and forward is considered, how much is saved by having the centre of operations in the right place? It might be wise from time to time to place in the *Journal of Agriculture* a guide as to how a farm should be planned. A variety could soon be obtained by asking members of the various Branches to send in plans of their own holdings. The best of these could be selected and printed in the *Journal.* With many who are selecting land at the present time—usually young men—want of experience is the great drawback. Older men taking up new country are careful enough to remedy any mistakes they have made before. With a rectangular block one can put a house halfway between the sides and about one-third the distance from one end. Fencing is not hard to plan. A fenced race from the road to the house and from the stable to the top paddocks saves a good deal of time driving horses, &c., to feed and water. Plenty of room should be left on that side of the stables from which the horses usually approach. Have all arrangements as simple and convenient as possible, and the stable, cow yard sheep yard, stock yard, and house yard should all open on to the race. Paddocks in front of the house and those behind, as well as any small barley or greenfeed paddocks, should also open on to the race. There should be room enough in a little square reserve near the stable (at the end of which the race should start) for a straw stack and a trough of water. The house is usually built on a rise, and the bore and windmill should be on the same level, as then a tank on a 10ft. stand gives splendid pressure to the stable, garden, and house alike. Around the house space should be left for a fruit and vegetable garden, and in mallee land at least two chains of timber should be left on three sides as a shelter from wind. Fowlyards, pigsties, &c., can be arranged at a safe distance from the house and on the outside of the house yard."

LAMEROO (Average annual rainfall, 16·55in.)

March 21st.—Present: 14 members.

Harvest Reports.—Mr. A. J. A. Koch said—"The season1912-13 will be long remembered by farmers on account of its extreme dryness. Had it not been that during July, 1912, very heavy rain fell, and advantage was taken of this opportunity to fallow for moisture conservation, the fallow land might not have been much better than grass land ploughed early and drilled in. Very little rain fell until June, only 4·04in. at my place, 2·32in. of that amount having fallen during February and March. At the end of July another 54 points only had been registered, and wheat that was in the ground and not up was having an extremely bad time. Good and timely rains in August (1·47in.), September (2·26in.), and October (1·74in.) turned what was a most critical position into one of comparative safety, at least for a fair average return, and at the end of October everything looked bright and prosperous. When reaping and cleaning time came so did the disappointments. Crops that looked good enough for 15bush. or 16bush. were only reaping 11bush. and 12bush. Taking a general view of the whole year I have come to the conclusion that land well worked, either fallow or stubble, and given a liberal quantity of super. should always, in ordinary seasons, provide payable returns. In many instances the variety of wheat has a lot to do with the yield. I had 68 acres of Federation drilled in with 90lbs. of super. and 43lbs. of wheat per acre on stubble land skim-ploughed and drilled. It returned an average of 8⅔bush. per acre. Just alongside, stubble skim-ploughed early and cultivated again before drilling a month later than the Federation (which was up) with 60lbs. of super. and 44lbs. of wheat, yielded 9⅓bush., or, with 30lbs. of super. less one extra working, a return of 40lbs. of wheat per acre more. Golden Drop on new land, ploughed, harrowed, and drilled with 46lbs. of seed and 67lbs. of guano super. per acre, returned 6¾bush. Walker's Wonder, 38 acres, 20 of which was fallow, drilled with 90lbs. of mineral super. and 52lbs. of wheat, yielded 10¾bush. Yandilla King, 84½ acres, 11 of which was stubble and new land, balance fallow that was well ploughed, but only harrowed and cultivated in spring, and cultivated, harrowed, drilled and harrowed at seeding, sown from April 30th to May 5th with an average of 40lbs. of wheat and 95lbs. of mineral super. per acre, yielded 16bush. Land fallowed early and during the year harrowed and cultivated many times, cross-drilled with 65lbs. of super. and 35lbs. of King's Early each way, yielded a splendid cut of hay, especially in the heavy flats, where the sand had drifted across. Crossbred 28, sown on fallow with 56lbs. of wheat and 104lbs. of super., yielded 12bush. Cumberland, sown immediately afterwards in the same paddock with 61lbs. of wheat and 104lbs. of super., returned 11½bush. Marshall's, in the same paddock on sandy land and drifted flat, sown a month earlier than the last-mentioned varieties with 95lbs. of mineral super. and 56lbs. of wheat, yielded 16½bush. per acre. I also put in some peas on two acres of grass land, ploughed and well-harrowed on July 21st and drilled in on 23rd and again harrowed. Super. at the rate of 1½cwt. per acre was applied and 1½bush. of peas sown. I fed these off with sheep, and had an average of 34 sheep per day on for three weeks. I intend to sow about 20 acres of this crop this year." Mr. E. T. Wray had sown Bud's Early early in May on fallow. It averaged 8bush. per acre, rough weather having caused it to shake out badly. Thirty acres of last year's fallow ploughed early in the summer, sown to Yandilla King, was badly affected with takeall. Sixty acres of this year's fallow sown with the same variety proved the best crop on the farm for the year. A grass paddock ploughed early in the summer, harrowed after rain in April, was sown with Florence, Baroota Wonder, Golden Drop, Marshall's Hybrid, Federation, and smut-proof wheats. There was no noticeable difference in the yields, except that smut-proof looked best and Baroota Wonder provided the best stubble. Oats sown during the first week in June cut 1½ tons of hay to the acre; 130 acres ploughed early in June, harrowed and drilled and sown with Gluyas and Federation, averaged 6bush. per acre. The former appeared slightly better, but it went down badly. In every instance 70lbs. to 80lbs. of super. per acre was put under the crops.

McNAMARA BORE.

March 1st.—Present: eight members and one visitor.

Cropping.—The following paper was read by Mr. D. Bicknell:—"During the past season I had under crop 250 acres of various wheats under different methods of cultivation. In April I cuiltivated 100 acres with a disc cultivator, and crossdisced about 20 acres. On this I sowed 50 acres of Bunyip and 50 acres of Gluyas. I sowed the Bunyip in the beginning of May, but it came up very thin owing to malting. The Gluyas came up and looked well until the hot winds cut it down in September. Then it ran straight up to ear before it got any more rain, with the result that the heads were small. Where the ground was worked twice the straw grew stronger and the heads larger. I next ploughed 40 acres with a disc plough. On this I sowed 33 acres of King's Early, which yielded 28 bags, and seven acres of Marshall's No. 3, which yielded eight bags. I next cultivated 20 acres twice with the disc, on which I sowed Baroota Wonder and Yandilla, both yielding nine and three-quarter bags, and last I cultivated 45 acres and ploughed 25 acres, in all 70 acres, off which I stripped 69 bags, about half of this coming off the ploughed ground. A small piece of about five acres which I cultivated and then ploughed crossways had a better crop on it, both in straw and larger wheat. The ploughed ground grew stouter straw and larger heads than did the cultivated ground. I also noticed that where the ashes were blown and settled along the east side the crop did better than on the west, showing that where there was more ashes the crop grew better. I also noticed that the crop did better on the south side of the hills than it did on the north." In discussing the paper, Mr. G. H. Perriam said the ground needed potash in addition to super. The past season Federation with very short straw gave a larger yield of wheat than Baroota Wonder with long straw. He had Marshall's sown at the rate of ¾bush. to the acre, which gave a larger yield of wheat than the same wheat sown at the rate of 1bush. per acre, although the latter was showing more straw. Mr. T. E. Bennier said that while roots were in the land from 30lbs. to 40lbs. seed and 40lbs. of super. had given him best results. He did not think it mattered much what kind of wheat was sown so long as it was a good sample of seed.

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.)

March 7th.—Present: 11 members and two visitors.

Rabbit Destruction.—Dealing with this subject in a paper, Mr. H. Frahn said that for poisoning with phosphorised pollard, five pints of boiling water should be put into a kerosene tin, from which one side had been cut. About 5in. of phosphorous, 1lb. of brown sugar, and two dessert spoonfuls of cinnamon should be well stirred into the water, about 1gall. of pollard being added whilst the other ingredients were being stirred. Where the rabbits were numerous the poison cart was preferable, but where they were not very thick a small furrow could be scratched around the burrows by means of a garden hoe. Baits should be placed in this during the afternoon. All burrows should be closed a week after poisoning. Sheep should be removed from the paddocks when the poison was laid, and any remaining baits should be carefully picked up. Mr. Tillbrook advised placing a small quantity of poisoned pollard in the burrows when closing them.

PARRAKIE (Average annual rainfall, 16in. to 17in.).

March 14th.—Present: 11 members and four visitors.

Scrub Farming.—Mr. Jose read a paper on this subject, in which he said that scrub should be burnt on the second or third hot day in February or March, and with a north wind. The straw should be levelled with a log or bar. He contended that a good stubble burn was worth 5s. per acre. The strongest shoots should be burnt first. Stubble that was not intended for cropping or fallowing should be sown with ½bush. of oats per acre. The seed should be drilled or broadcasted and harrowed. This would provide good feed for stock. On days in February and March not suitable for burning the time could be employed in cleaning seed wheat, picking stumps, or cutting shoots on the stubble where the straw was thin. He did not see why cutting shoots at this time of the year was not so good as burning, except that the latter was the quickest and cheapest method of getting rid of the mallee. Mr. Beelitz advised burning stubble in preference to cutting shoots. More shoots were killed, and the land benefited and grew better feed. He would not burn scrub until March. Earlier burning gave the shoots an opportunity of growing to an inconvenient height at harvest time. Mr. Lewis would not grow oats as feed on stubble without cultivating. Mr. Beddome also advised levelling the straw, and would burn scrub on the first suitable day in February. He thought this a better plan than risking a fall of rain and perhaps a poor burn. In reply, the writer of the paper contended that a good burn in February was best. A certain number of sticks were always left, and an early burn allowed time to clear these off. If it were left until later this opportunity was often lost, and the farmer was compelled to commence cultivating before the land was cleared. He would just cover the seed of oats intended for feed.

PARILLA, March 12th.—Tree-Planting.—It was decided to take steps to procure a number of sugar gums for the purpose of providing stock shelters in the district.

SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.).

March 9th.—Present: 15 members.

Vegetable-Growing.—Dealing with this subject in a paper Mr. D. R. Williams said:—"Asparagus might be grown more extensively. It is easily kept going when once fairly established, requires little time and labor at the beginning, and after that there is practically nothing more to do except in the winter to mulch it with well-rotted stable manure and give it an occasional drenching in the summer and keep all weeds down. Growing from seed is a very long undertaking, as the seedlings grow very slowly and cannot be put out of the nursery beds under two years old. It is a saving of time and labor to buy rooted plants. The plant needs well-prepared beds, which should not be any wider than one can reach across for convenience sake. The beds should be subsoiled to a depth of 2ft. or more, and manure such as old bones or cow manure should be mixed with it. Wood ash is very good. It is useless to attempt to grow asparagus without manure. The plants should be put in rows 18in. to 20in. apart, and 12in. between the plants. French beans require no particular soil. They will grow to perfection in stiff red clay if they can get through the surface. Sow in rows 21in. to 27in. apart, accordng to the habit of the variety. For runner beans there should be 4ft. or 5ft. between the rows, and 6in. or 8in. between the plants. I find it is best in sowing beans to flood the land, then plough and work it down, planting straight away into the drills while the soil is moist enough to bring the seed up. Cover the seed to a depth of 2in. They do not require watering until they are a fair size or else they will not make much root. They need to be banked up to give additional hold to the earth. Before they are banked scatter manure along between the rows, Bonedust and sulphate of ammonia are the best. Keep them well watered when they commence to flower and after every picking, which should be done systematically. Beetroot will thrive in almost any soil, but the best results are obtained from a deep loose soil, not too wet, which has been well manured for a preceding crop. Beet will grow any time of the year with little attention and an occasional watering. Sow the seed down about 1in. in rows 9in. apart, and thin the plants out to 4in. or 5in. Cabbages are grown extensively in this district with more or less success, according to the time and trouble taken with them. They need deeply-worked soil with plenty of stable manure worked into it to keep the land open and to let air down to the roots. They are gross feeders and should be treated liberally. They should be hurried from start to finish; if they are checked they will be tough and strong. Quickly grown cabbages are tender and finer flavored than slow grown plants. Cabbages will grow any time of the year as long as there is plenty of water to keep them going. Sow the seed in nursery beds, and when large enough transplant into rows 2ft. apart each way. Cauliflower growing is a fine art, and requires a lot of study. They have not been grown in this district for market purposes. The land must be well worked to a good depth and liberally manured, care being taken never to check the plants after they have been planted out, as they will never come to anything but buttons and seconds. Never plant them after cabbages, but they may follow peas, beans, potatoes, or any root crop to advantage. Keep the ground loose between the plants, and water well to get fine flowers. Force the plants with a little sulphate of ammonia when they are commencing to show signs of flowering. Sow in nursery beds and treat the same as cabbages. Cucumbers to be early should be put under glass in hot beds, and planted out when large enough and when the frosts are over into specially prepared beds 6ft. or 8ft. apart and about 2ft. across. Each bed should be deeply dug and have a large amount of stable manure mixed in with it. For later planting place the seeds in the beds where they are to remain. Keep the hoe and watering can going continually. Lettuce may be grown all the year round. Sow in nursery beds and plant out into rows 9in. or 10in. apart, with 6in. between the plants. Keep them free from weeds and water well. Bonedust and ammonia should be scattered along the rows and hoed in. Parsnips, like carrots, require a deep soil, worked but not freshly manured. If the soil is manured just prior to planting the roots become misshapen and forked. Sow in drills 1ft. apart, and thin to 5in. or 6in. between the plants when large enough. Pumpkins need the same treatment as cucumbers and as much water as can be given them without souring the land. They root at every joint, so it is well to have the land heavily manured. When the main stems have run out 8ft. or 9ft. pinch the crown out of them to encourage lateral growth, on which most melons set. All the melon tribe are alike in this respect. Peas should be planted in rows running north and south in order to get the warmth of the sun on both sides of the plants. The rows should not be any closer than the height to which the peas grow; 18in. is quite close enough for the dwarf sorts. The taller sorts require more space. Staking will keep the pods fairly free from black spot, from which they suffer if allowed to lie on the wet ground. Tomatoes for early planting should be sown under glass in hot beds in July. When 2in. or 3in. high harden them off and plant them out when the frosts are over. If they are planted out early, and frosts are still about, protect each plant with a piece of bagging supported on a stick. They prefer a good deep heavy soil. They are deep rooters, and should not be planted in heavily manured soil. New land is best, but as this tends to make a luxuriant growth of haulm and leaf the fruit, if any, will be late in forming, the first crop being more or less black ended. It is best to establish the plants and manure after by sprinkling bone super. around them, then banking up with the hoe. Tomatoes need plenty of water in the growing season until the fruit commences to ripen. Then cut the supply off and only water occasionally just to keep them going. To trellis tomatoes they should be tied up strongly to stakes and pruned. Just pinch off the shoots that grow out from each leaf; this will keep the leaders growing strongly, When they reach the top of the stakes or top wire, or whatever the trellis is, pinch out the crown and allow it to grow from anywhere, but do not let it grow thick, or no fruit will ripen. Keep the plants open to allow plenty of light and air into the centre of the bushes. They should be 3ft. or 4ft. apart each way and may be grown on the ground without stakes, in which case do not let the leaders grow. Pinch out their crowns, thus obtaining a bushy plant. Turnips to be tender and sweet should be grown quickly in rich soil in an open place. Sow in rows and thin them out when large enough. The tops of the young turnips that are pulled up may be used as spinach."

INMAN VALLEY (Average annual rainfall, 26in. to 27in.)

January 14th.—Present: 10 members.

Beekeeping.—Mr. H. J. Dennis read a paper on this subject. He explained that each colony of bees consisted of a queen, workers, and drones. The mating of the queen took place in the spring or summer. She laid eggs which were fertilised and which produced worker bees, and eggs which were unfertilised and produced drones. Larvæ intended to develop into queens was fed on "royal jelly," and worker larvæ on "bee bread," a mixture of pollen and honey. Workers were undeveloped females. The young bees first appeared as larvæ, in about 10 days changed to pupæ, when the cells were capped, and at the expiration of about 10 days the fully developed bee emerged. The queen lived for from three to five years, and had been known to lay as many as 3,021 eggs in 24 hours—by actual count. In a heavy honey season the average life of the worker was about six weeks, but when honey was scarce it would live for a year or more. The honey was carried in the honey sac, forming part of the digestive system and corresponding to a crop or first stomach. Bees were very sensitive, and any jarring of the hive or crushing of bees would cause the colony to become irritated. The site for an apiary should be sheltered from rough winds and as close as possible to the source of the honey. Langstroth hives were recommended. Top stories should not be put on weak colonies. The worst enemy of the bees in this district was the wax moth, which laid eggs in any cracks in the hive. The grub attacked and destroyed the combs and brood.

LONGWOOD (Average annual rainfall, 37in. to 38in.).

March 14th.—Present: five members and three visitors.

Mylor Type Orchard.—The Hon. Secretary (Mr. R. J. Coles) reported that the Branch had paid a visit of inspection to the Mylor type orchard.

Afforestation.—A paper on this subject was read by Mr. W. H. Hughes. He said—"When the scrub sections in this district were originally taken up they provided straight poles for building sheds, &c., and trees to split posts for fences. There are now no poles left worth mentioning, and none of us could split enough posts on his section to replace all his fences. More than half of the occupiers are buying firewood! Is not it time we began to think seriously of a remedy? The disappearance of our forest trees may mean less rain. Mr. Gill (Conservator of Forests) says that this State can produce as many cubic feet of *Pinus insignis* per acre at Bundaleer and Mount Remarkable in 26 years as can be produced in Germany in 60 years, viz., 6,000 cubic feet. Germany is planting extensively, and if it pays her to do so, how much more will it pay us? The natural question is, 'Can we do it in these hills?' I think we can. I have nearly 3,000 *Pinus insignis*, young yet, but doing very well. Some petted specimens are now 17ft. high at three and a half years from Belair nursery. I also have about five acres of wattles fit to strip, and a large number younger. Mr. Furniss cut a *Pinus insignis* this season. It was of 21 years' growth, and yielded a log 60ft. long, 17in. in diameter at the butt and 4in. at the small end. Last year the same gentleman cut a similar tree, and secured several planks 15ft. long, 9in. wide, by about 1in. thick of splendid looking deal, and a number of smaller boards which would be most useful for mending fruit cases, lids, &c. The fact that all timber costs half as much again as it did 20 years ago shows that the forests of the world are giving out. Well, then, what will the price of timber be in 20 years' time? Farmers maintain that pine posts last longer than mallee in white ant country. These pines do not require manuring, pruning, spraying, or cultivating, and will grow on steep or rocky land that is not fit for fruit. Wattles can be planted between them. Thin the wattles out as the pines grow. Slack days can be spent wattle-barking, and the sticks burn splendidly, even three months after barking. I have wattles 16ft. high at six years from planting the seed. On this ridge on which Longwood is situated the frosts do not cut wattles as they do at Echunga, Mylor, or Scott's Creek."

MACGILLIVRAY (Average annual rainfall, 19in. to 20in.)

February 10th.—Present: eight members and three visitors.

Poultry on the Farm.—This subject was dealt with in a paper by Mr. H. J. Wiadrowski. Poultry on many farms, he said, received insufficient attention. It was not necessary, however, to yard the birds in pens and scratching sheds, such as were adopted on up-to-date poultry farms. Continuing, the paper read—"We should not take eggs indiscriminately for setting, as is generally done, but should have a few selected hens and a rooster penned up, and only use the eggs from these, as blood and breeding are of as much importance in poultry as in any stock. Good birds cost no more to keep than mongrels, and give larger returns. Some think that by running a well-bred cock bird with their hens they are doing all that is necessary; but this is not sufficient, for even amongst, say, only 50 hens there will always be found several that do not pay for their feed. Set several hens at the same time. Then, if for any cause, one should desert her nest her eggs can be distributed among the others. The same applies to the chickens when hatched; give 16 or 17 to each hen and lock up the other hens for a few days. It will then not be long before they are again laying; much earlier than if they are allowed to run with the chickens. One hen, although not able to properly cover 17 eggs, can easily cover and look after 17 chicks. On the day the chicks are due carefully take the hen off the nest twice and take away any chicks that are out. Sometimes after a hen has a few chicks out she will desert the other eggs, and even if this does not happen the chicks are sometimes injured, or some of the unhatched eggs become encased with the other shells, and the chick has a double shell to break. Before giving the chicks back to the hen toemark them in order that their age can be told. A hen more than three years old is kept at a loss. The most profitable breeds to keep is greatly a matter of opinion. For egg-production alone the pure-bred White Leghorn, of a good laying strain, is the best. I have had very good results from a Leghorn-Orpington cross, which produced a good large bird and also an excellent layer of a good large egg. However, for a general utility bird I favor the Black Orpingtons, provided they are a good laying strain. Give the birds as much variety as possible in their feed. Of course this is not as necessary as where birds are continually penned up, but they will do better if they are given a change, such as an occasional feed of oats or barley when they are always fed on wheat. Chopped greenstuff will also be greatly appreciated by the birds. The hens do far better if the cockerels are kept apart. Better housing will greatly increase the egg-production. Often the birds are left to roost in the trees. They not only require more feed but are affected in their laying as well. Old 400gall. tanks make very good shelter sheds. These, with perches made like a ladder with a good lean, will easily accommodate 30 to 40 birds. Ducks and geese are not as a rule as profitable as well-bred fowls, especially where they do not have an abundance of water. Turkeys are very profitable, but the iguanas and crows do a lot of mischief, both to the eggs and young poults; but if they are kept penned up for the first few weeks until they are fairly strong the losses will not be so big. Here again it pays in the first place to buy well-bred birds for starting the flock."

MENINGIE (Average annual rainfall, 18·87in.)

March 14th—Present: six members and one visitor.

Vegetable Cultivation.—A paper on this subject was contributed by Mr. J. G. Hastings. He said—"In a district like ours, which is much exposed to storms in winter and hot winds and drifting sand in summer, a windbreak is an absolute necessity. The garden plot should not be more than quarter of an acre in extent and wind-proof on all sides. This can be done cheaply with light brush woven between wires; an evergreen creeper should be grown, which in time will take possession of the brush, and when trimmed will improve the appearance of the fence. It takes less from the soil than a hedge of more vigorous growth, and is much more easily kept in order. For choice of soil I prefer rich sandy loam, for, unlike the heavy black land, it is better drained and does not remain wet and cold during the winter months. while in summer, with surface cultivation, it retains the moisture and ensures a better return in produce than the latter. During the summer months the land should receive a liberal dressing of stable manure, which should be well rotted if possible and then dug in. If it gets a good soaking rain so much the better. This will hasten the process of decay. From then on till the time of planting out the soil should be frequently stirred with the hoe to admit the sun and air, which will sweeten it as well as add to its fertility. At the time of transplanting it should again be dug over to incorporate the manure with the soil. when it will be more readily available as plant food. After the first crop of vegetables is taken off the soil will be in the right condition for growing root crops, which do not thrive on manure freshly dug in. The hoe should be kept at work from the time the plants are set out until they have finished growing. It is a mistake to wait till the weeds appear, for once they get a start there will be no end of work. The soil must be kept stirred from the beginning to check their chance of sprouting, as well as assist the growth of the young plants by admitting warmth and air. In the case of summer crops the surface cultivation helps to retain the moisture and dispenses with a considerable amount of watering. During the present dry summer I noticed that tomatoes grown in the shelter of the windbreaks required little or no water whilst they grew larger and more vigorously than those in exposed situations, which received much more water. They also yielded a heavier crop of fruit. The reason for this is that there was less evaporation and no wind to knock the bushes about and cause the blossoms to fall. I also tried spreading straw and other litter around melons and tomatoes which were exposed, with fairly satisfactory results; but they still took too much water. Too much watering in sandy soil, because of its loose nature, results in the plant food being carried out of reach of the roots. I strongly favor surface cultivation, with a light watering occasionally. There should be windbreaks running through the centre of the garden to check the wind as much as possible."

MOUNT PLEASANT (Average annual rainfall, 26·87in.)

March 13th.—Present: six members.

Tree Lucerne.—Mr. H. H. Giles read a short paper as follows:—"I see very little tagasaste around here, and conclude its value is unknown or overlooked as a vigorous, quick-growing shrub and good fodder when greenfeed is scarce. It must be protected from stock or it will be eaten out. Grown in enclosed land it makes an excellent breakwind, in five years or less attaining the height of at least 10ft. It may be often pruned or cut back to ensure a thick growth. Bees are fond of the blossoms. When cut in small sheaves and suspended by its stems poultry are fond of it. It is specially valuable for shade, and should be grown not only to shade poultry but for pigs, provided they cannot get at the stem. The exhibit now tabled has grown since December 5th, 1913, and is about 3ft. 9in. high. I am surprised at its quick growth considering the dry, and at times very hot, weather we have till now experienced; and although I daily prune some I can soon get a second cut, and would not be without it for poultry." Whilst some members thought this plant of no use for food for stock, Mr. Giles and Mr. Tapscott maintained that it provided good stock feed, and it was especially good for fowls when grown in fresh ground.

MYPONGA.

March 15th.—Present: 10 members and two visitors.

Destruction of Farm Pests.—Mr. Bartle contributed a paper on this subject. He dealt chiefly with the eradication of rabbits. He advised netting the paddocks and grubbing burrows. During last winter he had employed several men to dig out burrows, and, although it was costly, the results proved that the expense was fully warranted. He advised the destruction of as much cover, such as scrub, as possible. Though the death of many lambs was attributed to foxes, he considered many of the supposed victims died from natural causes. He had seen many dead lambs that had not been touched, and when passing a few days later, had noticed that the tongues had been eaten. Members generally agreed with the views expressed in the paper.

NARRUNG (average annual rainfall, 17in. to 18in.).

March 7th.—Present: seven members.

Manures.—This subject was dealt with in a paper by Mr. C. H. Metcalf, in which he said—"When considering the value of a fertiliser, it should be borne in mind that the agricultural value and the commercial value of fertilising materials are not always in harmony. A fertiliser is cheap, whatever it may cost, if its use increases the crop to such an extent as to result in a fair profit. Most soils contain an abundance of plant foods, but generally only a small portion is available for the plant itself. Some of the manures used at the present time do not always fulfil the requirements of the district in which they are used. It would be of great benefit and interest to the man on the land if he were to conduct a series of manurial tests. Heavy dressings of phosphatic manures, for example, would increase the crop-carrying capacity of South Australian farms. Some farmers are quite content with light dressings of from 30lbs. to 60lbs. per acre. This I have found to be a very serious mistake, because the crop takes off more phosphoric acid than is put in. Additional manure would help the natural herbage, and so increase the humus in the soil. A few simple experiments, then, could be conducted on the farm, for there is nothing to prevent every farmer being his own experimentalist. A time will come when we shall find that our soils must have this attention. The farmer experimentalist who thinks of carrying on a series of manurial tests over a large area, such as the field, will find that he would be better off at the end of the season if he were to adopt the plot system, thereby gaining more control over the tests and more time for observation and correction. Perhaps one of the most valued manures we have is farmyard manure. How many of us use it to its full value? Some farmers, while knowing the valuable properties of this, will not go to that little extra trouble of taking it just a little farther in the paddock, but are quite content to allow it to lie for years in the yard or heap, or, worse still, to remain near wells, rock-holes, soakages, &c. I feel sure the farmer, or man on the land, no matter what he may be growing, would be amply rewarded for the extra work if he were to evenly distribute it over his land. Much more thought should be given to this all-important 'waste' of the farm. Another 'waste' that has at times been of use in the orchard is hen manure. This contains four times the strength of stable manure, and is a splendid improvement in the orchard. Pig refuse is another noteworthy item, this being an important vegetable forcer; thus it will be of interest to the farmer who grows his own vegetables. Sea shells, on account of the lime they contain, constitute another fertiliser. Lime is an all-important dressing for some of our lands. The action would be much quicker if the shells were crushed before being applied to the soil. Years ago some farmers used to buy a highly soluble variety of super. and mix it with sand, thus getting it to the strength they required. Coming back to the value of lime, I wish to point out that with its application to strong soils the physical action is most manifest. Our own soils would be much improved by a dressing. There are two ways in which manures may work on soils—by supplying plant food direct, and by acting on the food already in the soil and making it more available to the plant. A good manure for potatoes is 23lbs. of potash and a like amount of mineral super. Wood ashes and bonedust are two good fertilisers for potatoes. If we require a quick-acting nitrogenous manure, we cannot do better than apply nitrate of soda. It can be used with advantage with other fertilisers. Nitrogen is the costliest ingredient in fertilisers, and it is to the interest of every farmer to restore all kinds of waste material of a nitrogenous character to the soil. Vegetable and animal refuse should be carefully looked after, and used when the time allows of so doing."

STRATHALBYN (Average annual rainfall, 19·28in.).

February 10th.—Present: 12 members.

Sheep Dips.—Mr. R. H. Haines contributed an instructive paper. He described a sheep dip capable of dealing with 1,000 sheep daily. Mr. Cumming, who had had 30 years experience with sheep, made eulogistic reference to the dip. Detailed particulars of construction were given as follows:—*Dimensions* (inside measurements).—Length from extreme aft end to the fore end, 21ft. 6in.; and from the aft end, 18ft.; length at bottom, 12ft.; width at top at shoulder line, 18in.; width at bottom at angle, 12in.; depth, 4ft. 3in., including a 3-in. set-off at top and V shaped bottom, 6½in. *Construction.*—The dip is built of concrete with boards. If made with Strathalbyn lime the proportion is four of clean sand and gravel to one of lime; it should be well mixed and dry enough to ram properly. If too wet it will crack. It must also be thoroughly well set and dry before the cement is applied. The cement for plastering should consist of two of fine washed sand to one of cement. If cracks appear and cause leakage they should be chiselled out and rinsed with water, then filled with good cement. *Capacity.*—The average number of gallons to the inch is 10½, but when refilling it is necessary to allow about 14galls. to the inch. At the 4ft. line it holds about 504galls., but 421galls. or 3ft. 6in. deep is enough for dipping. *Cost.*—Six bags of lime at 2s. 9d., 15s. 9d.; and 2cwts. of cement at 7s. 6d., 15s.; 30s. 9d. in all. It will take about 40 hours for two men to complete the job, including the yard, etc., if the material is on the spot. The material required for the yard, which is 10ft. by 8ft., with sloping sides (holding about 45 sheep), is 40 5ft. 3in. slabs; six posts each 6ft.; two 9ft. rails; two 7ft., and one 10ft. 6in., and a small gate. Two posts are needed at the extreme aft end, and two 7ft. from it. The boards used in the construction of the walls (which are 4in. thick to top of ground and 6in. above it) can be used to cover the end. The slide door is fastened on the yard where it crosses the dip. The yard may be placed on either side of the fore end, according to convenience, or straight out, which is better, if the ground is rising that way or level.

Fencing Act.—Mr. C. Pyne read an interesting paper dealing in detail with the provisions of this Act.

STRATHALBYN (Average annual rainfall, 19·28in.).

March 19th.—Present: 12 members.

The Rabbit Pest.—A paper on this subject was read by Mr. W. H. Cuming. The annual loss through rabbits at present was more than it had been 20 years ago, he said. He dealt with the damage which had been wrought on the station properties, and the legislative measures which had been introduced to encourage the destruction of the pest. He contended that if the legislation at present in force were put into operation rabbits would be effectively cleared out from most places. The poison cart was very effective on large holdings in hot, dry districts, where the feed grew quickly and dried quickly after rain, but in the south, where there was green feed until the end of the year, it should not be used. Immediately the first good rains fell in autumn burrows should be dug out and filled in, rock-holes filled, and rubbish and hollow logs burned. One half-day per week subsequently spent in destroying any rabbits remaining on the holding would effectively deal with the pest. If every landholder did his duty in this regard, thousands of pounds would be saved annually. If he did not undertake the work without compulsion, the law should be set in motion. The presence of rabbits was largely responsible for the great shortage of store sheep which existed in this State at present. He appealed to every landholder in the State to devote some time to the destruction of rabbits, wild dogs, and foxes. Members discussed the subject at some length. It was thought that the practice of the district councils appointing local inspectors tended to make it more difficult to deal with the pest. It was suggested that the inspectors should have power to issue summons without having previously placed a list of defaulting landholders before the council.

CHERRY GARDENS, March 10th.—EXHIBITS.—Messrs. S. W. Chapman, T. Jacobs, C. Lewis, H. J. Jacobs, and H. R. Stone tabled samples of fruit and vegetables. Various matters of interest relating to cultivation, pruning, and spraying were discussed.

HARTLEY, March 11th.—EXPERIMENTAL PLOTS.—A committee of four was appointed to supervise experimental plots to be conducted by Mr. B. Wundersitz. It was proposed to test different quantities of super., ranging from 50lbs. to 200lbs. per acre, on four plots each one acre in extent.

MOUNT BARKER, March 18th.—AGRICULTURAL SHOW.—The exhibits at the recent local agricultural show were discussed. Mr. H. Jones dealt with the grain section, Mr. G. Milne the fruit section, Mr. C. Miels the poultry section, and Mr. Monfries the stock. Several suggestions were made and forwarded to the Agricultural Society.

MYPONGA, February 24th.—The Horticultural Instructor (Mr. Geo. Quinn) delivered an address. The orchard of Mr. F. Pengilly was inspected, and generally the visitors were agreeably surprised at its condition. Jonathan, Strawberry Pippin, Rhode Island Green, Rome Beauty, Reinette de Canada, Northern Spy, King David, Lord Nelson, and Cleopatra apples were doing particularly well, although the last mentioned were slightly affected with the bitter pit. Not more than 3 per cent. of the fruit was affected with the codlin moth, which was attributed to systematic spraying and cultivation. About 20 porkers were being fattened on windfall fruit and peas; and members were also interested in a paddock of Paspalum and an African grass of the Panicum family, resembling Crus gallai.

PORT ELLIOT, March 21st.—PRUNING.—Mr. A. W. Gordon read a paper dealing with the subject of pruning. He quoted two letters, one from a local orchardist and one from an orchardist in New Zealand, both of whom advocated the practice of allowing the trees to follow their natural growth until such time as they reached the required dimensions. Members discussed the matter at length, but could not agree with the idea of planting the trees closely in a dry climate such as that experienced in this State.

SOUTH-EAST DISTRICT.

MOUNT GAMBIER (Average annual rainfall, 32in.)

February 21st.—Present: 13 members.

BARLEY-GROWING.—An address on this subject was delivered by Mr. J. W. Innes. He mentioned that owing to the unfavorable nature of the season a large percentage of the barley grown in the district last year was unsuitable for malting. The variety generally grown here was Duckbill. He tabled two samples of grain: one constituted part of the third crop of barley taken off one paddock in four years. In 1911 it yielded 38bush. and the grain was one of the best samples in the district. In 1910 the crop was also a good one, and the sample prime. He had never seen a poor sample off the paddock, and yet on the better land on the same farm barley crops were spoiled by the wind. Manure helped to give the good quality to the Millicent crops, but he did not think it was of any use here, because the heavy rains caused the manure to leach out of the soils. He was more inclined to think that the earlier sowing at Millicent was an advantage. If they sowed late the growth was rapid and the stem was softer, and so could not withstand the hot winds. Farmers here said that they could not sow too early because of the weeds and caterpillars. In his experience in the barley trade he had always noticed that the early samples were the best. This year all the late crops were hardly fit for malting. In regard to the caterpillars it was generally thought that they were hatched in the ground,

but farmers who had watched the pest told him the larvæ were deposited behind the flag. If that were the case they would need to use something in the way of spray, like they were using on potatoes. If the pest were destroyed early the damage would not be so great as was the case with their present method of sowing poison. Mr. Sassanowsky said if they sowed late the barley grew quickly, and the main thing was to get it through without any check in the growth. This year all the barley on light soils was affected with the wind. He had sown during the first week in August. The heavy patches were good. His idea was that in the early part of this year they had a wonderful growth, with any amount of flag, and when the heavy hot winds came there was not sufficient strength in the soil to keep the sap flowing. Mr. G. H. Kilsby said the wind was most likely to affect the crop when the grain was in the milky stage. At Moorak later sown barley yielded the better sample. The ranker the growth the more susceptible it was to hot winds and grubs. Mr. MacCormack thought the first week in July the best time to sow. Mr. Innes, in reply, suggested that in the event of the crops becoming too heavy at the beginning of the season, as had happened this year, they should be fed off.

NARACOORTE (Average annual rainfall, 22·60in.)
February 14th.—Present: 14 members.

THE PLOUGH.—A lengthy paper dealing with this subject was contributed by Mr. J. M. Wray. Anxiety to get a large area under crop, he said, was one reason why so much ploughing was done badly. Whilst occasionally a roughly worked field might return a good harvest, it would generally be a failure: whereas a well-worked area generally yielded well. Continuing, the paper read—"The first and second seasons at Hynam I used a three-furrow stump-jump plough, but when the rain set in properly I found that even on high ground the plough and the horses bogged. I then tried two small ploughs—both two-furrows—and my experience is that one can do far better work with this class of plough in wet seasons than with a stump-jump implement. There is less draught, and therefore less tendency to draw the plough deep into a soft place. In taking note of those who have persisted in using the stump-jump plough during the last two years, when farmers have been able to plough early and turn the soil over in a more suitable state all through the seeding, I find that equal crops have been grown from land treated with the stump-jump and set ploughs. A settler should take care to choose the plough most suitable for the class of soil he has to work. Where grass grows freely and there are only odd stumps to deal with a plough that cleans better than a stump-jump and one that will make an excellent job of turning the grass under is needed. In order that an efficient implement can be secured it is necessary to bring the soil in this district under the special notice of competing manufacturers. This can be done by field trials." He strongly urged members to make arrangements for a field trial. In discussing the subject Mr. Bray said a nice even ploughing would kill grass, but it was necessary to turn the ground over roughly and allow it to lie open to the sun to destroy sorrel. Mr. S. H. Schinckel found it almost impossible to plough his land when it was wet. The general opinion of members was that a plough which would deal with the land when it was dry, and so enable them to destroy sorrel, was necessary.

NARACOORTE (average annual rainfall, 22·60in.).
March 14th.—Present: eight members and one visitor.

THE SEASON'S CROPS.—Mr. Schinckel said that in his locality Federation and Yandilla King were the wheats most extensively sown. Federation gave the heaviest yield, but it was badly affected with rust. Yandilla King yielded the best average. The yield of Federation was about 18bush. per acre, and Yandilla King yielded 20bush. Duckbill and Cape were the principal sorts of barley grown, and Duckbill yielded from 20bush. to 50bush. per acre. He could not say what Cape yielded. Mr. Pallant found Yandilla King yielded the best this year. Federation was not so good, as it was affected with rust. In previous seasons he had found Federation the best. Mr. Kelly had only sown Federation, and it had yielded 21bush. last year and 27bush. this season. There was a good deal of rust in it, but it did not affect the yield. He also had some Algerian oats which yielded 25bush. per acre. Mr. Heffernan said his Yandilla King returned 24bush., and Marshall's No. 3 27bush. Mr. Schinckel said the high winds that prevailed just when the wheat was ripening, and the grubs, affected the yield in many places. Members thought, in reply to the Chairman, that they could take the estimates given as applicable generally to the whole district, but it was impossible to get accurate returns.

KYBYBOLITE, February 19th.—The Superintendent of Agriculture in the South-East (Mr. W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S.), gave an interesting and instructive address dealing with harvest returns of the Kybybolite Experimental Farm.

POINTS FOR PRODUCERS.

International Plant Diseases Convention.

As the result of the Phytopathological Conference at the International Institute of Agriculture, attended by delegates from 35 countries, certain States, not named in the report, pledge themselves to take whatever legislative and administrative measures are necessary to prevent the distribution of all diseases of plants in their own countries, but specially to organise an effective service of supervision over nurseries, gardens, glass houses, and other establishments which carry on a trade in living plants. The proposed Convention, however, excludes vines, grain, seeds, tubers, edible bulbs, rhizomes, and roots, as well as fruit, fresh vegetables, field roots, and general agricultural produce. The measures include (*a*) the erection of one or more institutes for scientific studies and research ; (*b*) the organisation of an effective service of supervision over nurseries, including the packing and dispatch of plants ; (*c*) the issue of phytopathological certificates. They would bind themselves only to admit plants accompanied by phytopathogical certificates issued by or from a competent official authority, except in the case of plants which are imported for scientific research at an institute authorised by the Government. The omissions, says the *Agricultural Gazette*, include some of the most important products subject to diseases which it is desirable to control.

Export of Fruit.

The general manager of the Government Produce Department received a cable on April 15th from the Trade Commissioner in London, stating that the prices realised for this season's first shipment of fruit, which left South Australia by the *Marmora* on February 26th, and consisted of 125 cases of apples, 38 cases of pears, and 68 half-cases of pears, were as follows :—

No. of Cases.	Class.	Variety.	s.	d.	Average Price.
50	Apples	Worcestershire	13	0	per case, c.i.f., London
60	"	Cleopatra	12	6	" "
15	"	Jonathans	11	3	" "
38	Pears	Beurre Bosc Backhouse Bergamot	15	0	" "
68 (half-cases)	"	Backhouse Bergamot Beurre Bosc Beurre Diel	6	6	" "

The results above given show that the London market has opened very satisfactorily for fruitgrowers, and good prices should now be maintained through the season, especially as advices state that the London market is practically clear of American and Canadian supplies.

Beef Cattle Industry in the United States.

The beef cattle industry in the United States is in a most precarious condition, according to a report sent to the International Institute of Agriculture. This seems to be apparent from the fact that between January, 1907, and January, 1913, the number of beef cattle in the United States decreased by 15,970,000 head of cattle, or about 32 per cent. During the same period the population increased by about 10,000,000 people. And conditions, instead of improving, are going to be worse in the next two or three years. A few weeks' study of any of the stock yards markets will convince the most optimistic person that there are altogether too many cows, heifers, and calves being rushed to market. It is, wrote a visitor to the markets, a most pitiful sight, in the face of the present great shortage of cattle, to see that from 15 to 40 per cent. of the animals offered for sale are good young she stuff, just the kind needed for breeding purposes on the farms. This condition of affairs can mean but one thing, namely, fewer and fewer cattle in the years to come.

Condensed Milk Manufacture in Canada.

The manufacture of condensed milk and milk powders is becoming an important branch of the dairy industry in Canada. There are, states the February bulletin of the International Institute of Agriculture, 12 large factories engaged in preparing these products, and the number is likely to be increased. A total of 69,264,090lbs. of fresh milk was used for this purpose in 1910, out of which there was manufactured 27,831,596lbs. of finished products. The quantities are much larger at present, but the exact figures are not available. The principal seat of the industry is in Western Ontario.

Compound Fertilisers in the United States.

At the date of the last industrial census there were 550 chemical manure factories in the United States, with a capital of about £24,000,000. The great bulk of their trade is in the preparation of compound manures containing two or more ingredients of plant food. Thus, in one important province, while the total deliveries of chemical manures were over 150,000 tons, not more than 25,000 tons were simple fertilisers containing only one ingredient of fertility. Most of the mixtures contain 2 per cent. of nitrogen combined with phosphate—chiefly soluble—and potash. Every bag of manure must by law have attached to it a tag showing the analysis, and the authorities have a number of inspectors whose duty it is to take samples and have them analysed.—*Mark Lane Express.*

Sow Good Seed.

Good seed is the foundation of good crops, and as many farmers are now getting supplies of seed, it is opportune to point out the wisdom of being careful in the matter. Some farmers, says the *Mark Lane Express*, take great trouble to get the soil in good condition and furnish it with manure, but are careless about the seed, and yet how hopeless it is to expect a satisfactory crop if the seed is faulty. Even when dealing with reliable seedsmen it is as well not to take everything for granted. The seed may be pure, but owing to having been gathered in a wet season may have suffered in its germinating power. If the germination is poor, it is necessary to use double the quantity of seed, or the crop will be poor. Avoid cheap seed ; it is seldom really cheap, and too often leads to disappointment.

Egg-laying Records.

New records in egg-laying by pens of six pullets were established in the Burnley and Bendigo (Victoria) 12 months' contests which concluded on April 15th. In the first-named competition Mr. J. H. Gill's White Leghorns laid a total of 1,668 eggs, thus beating the previous best score of 1,632, which was put up in New Zealand last year. In the Bendigo contest the winning pen of six White Leghorns, owned by Mr. H. Hanbury, laid 1,675 eggs, or seven more than the Burnley record.

The World's Crop Production, 1913-14.

The March number of the *Bulletin of Agricultural and Commercial Statistics*, issued by the International Institute of Agriculture, contains a table with the crop figures of 1913-14 in the Southern Hemisphere. The total production of wheat in Argentine, Australia, and New Zealand is calculated at 68,113,670 quintals, or 88 per cent. of that in 1912-13 ; the production of barley and of oats in Argentine and New Zealand is estimated at 2,021,480 quintals (158·1 per cent. of that in 1912-13) and 12,837,225 quintals (66·9 per cent. of that in 1912-13) respectively. The area expected to be harvested for maize in Argentine is valued at 4,152,000 hectares, or 108·4 per cent. of that in 1912-13. On adding these figures for cereal production in the Southern Hemisphere to those formerly published for the production in the Northern Hemisphere, the Bulletin follows up with a table giving the world's production. These productions are :—Wheat, 1,066,527,734 quintals, or 107·4 per cent. of last year's ; rye, 469,442,761, or 100·5 per cent. ; barley, 339,494,094, or 109·4 per cent. ; and oats, 681,251,693, or 101·7 per cent. For rice another table shows the production in the Northern Hemisphere only, which amounts to 374,572,888 quintals, or 99·6 per cent. of that of last year, for the following countries :—Spain, Italy, United States, India, Japan, and Egypt.

Statistical Position of Barley.

The statistical position of barley compared with the two previous years is given in *Beerbohm's Evening Corn Trade List* of March 20th, as follows :—United Kingdom imports from August 1st to March 14th—1913-14, 4,274,000 quarters ; 1912-13, 5,030,000 quarters ; 1911-12, 5,423,000 quarters ; afloat for United Kingdom and Continent, 1913-14, 1,080,000 quarters ; 1912-13, 960,000 quarters ; 1911-12, 675,000 quarters. English average price, 1913-14, 26s. quarter ; 1912-13, 27s. 11d. quarter ; 1911-12, 31s. 2d. quarter.

United Kingdom Imports of Wheat.

Replying recently to a question asked in the House of Commons, Mr. Runciman (President of the Board of Agriculture) stated that on the assumption that the whole of the wheat imported into the United Kingdom was for human consumption, and that about 15 per cent. of the home crop is used on the farms for seed, &c., the proportion of home to total wheat consumption was 22 per cent. in 1894, 12 per cent. in 1904, and 16 per cent. in 1913 ; 1904 was a year of exceptionally low production in the United Kingdom.

A Concrete Silo.

Last summer, writes a correspondent in the *American Agriculturist*, I built a solid concrete silo, and after one season of use I am very much pleased with it. It has a 6-in. wall, is 14ft. in diameter, and 33ft. high. The roof, chute and all are built solid of the same material. I consider all makes of silos good, but like the solid concrete silo best and believe it the cheapest in the long run. My silo cost 450 dollars, and I had to do the hauling of gravel and cement, which would have cost 50 dollars more if I had paid for this. A man cannot appreciate the true value of a silo until he owns one. We started the corn binder when the corn was ripe enough to put in shocks and hauled it directly to the cutter. It took five hayracks and four men in the field to put fodder on them. One man fed the cutter and one stayed in the silo to keep the silage evenly distributed and well packed. We filled our silo in one day, putting in about 110 tons. It takes from eight to 10 acres of corn for a silo this size, depending on the yield. This will feed 40 head of cattle through the winter for three and a half months with no other feed than straw. This is exactly what we did with it on our farm last winter, and the cattle gained from 100lbs. to 125lbs. apiece, depending on their size and age. You may figure this corn that we put into the silo as equal to 500bush. at 50 cents a bushel, making 250 dollars, which would be just about equal to the growth of the cattle, but in addition to this we hauled out manure enough to cover 20 acres of ground heavily, and I fully believe this will be worth 20 dollars an acre.

Feeding Young Pigs.

The rations for young pigs, when they have been arrived at, should be given methodically, say, three times a day, and if profitable results are to be obtained the sty in which they are fed should be clean, warm, and well ventilated, but should there be an excess of heat troubles are sure to come. The study of the proper scientific operations from the point of view of protein or albuminoids, non-protein substances, or fat and carbohydrates, would take up too much space, but it may be of interest to know what has been found of value in actual practice. The best-flavored pork and the heaviest weight of the same was obtained in the case of milk-fed swine, and next to milk came the cereals, corn, barley, oats, and peas. Potatoes produce a soft, light pork, which loses a good deal in boiling. The meat of swine fed on flour-mill by-products is yellow, without body, and of a poor flavor. Oils meals produce a loose, oily pork of an unpleasant flavor. Beans produce a hard, indigestible, and flavorless pork, and acorns one that is light, hard, and unhealthy. Milk is looked upon as being the principal mixture with cereal foods, and there is little doubt that this is correct. There are now ample supplies of separated milk in all dairying countries, and this must be looked upon as being an excellent food for swine.—*Agricultural Gazette.*

Of Interest to Sheepgrowers.

Mr. Henshaw Jackson writes :—

The best returns from feeding sheep are obtained by keeping each draft of fats as evenly good as possible.

The more sheep you can keep and keep in good condition the less per head will be the cost of keeping.

Those who keep mixed flocks of sheep cannot expect top prices for their wool clip.

A sheep that is in good condition for growing a healthy fleece has a double value to the farmer, who then caters for the butcher and the cloth merchant.

The best sheep for the farmer is the one that is most adapted to the particular surroundings and situation of its owner.

Sheep are good weed destroyers, but do not expect to raise good mutton without fair pastures. What the sheep can do for you as weed killers and automatic manure spreaders, make up to them by putting good grass into the holes the weeds came out of.

Sheep-pasturing is not altogether easy. Amateurs and novices think it is, and make failures. Sheep pastures should not be overstocked, but rather changed a couple of times a year if possible.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"F. T." requests (1) treatment for working horses suffering from sore shoulders, and (2) advice concerning mare which has a film over eye as large as a currant, from the corner of which matter oozes.

Reply—(1) As a general dressing this is found very useful, both as preventive and curative—White lead 2ozs., neatsfoot oil 1 pint, to be applied to sore and collar two or three times a day. Beat the collars well as soon as dry, and if branbags will not prevent sores try sheepskin, wool to horse, or strips of zinc on the collar. For the one with proud flesh, dress twice daily with a little of this—Resublimated iodine 1 dram, methylated spirit 6ozs. When the wound seems to be healthy apply twice daily a few drops of tincture calendula. Let all the horses have daily as regular thing a teaspoonful of flowers of sulphur in their chaff. (2) The symptoms point to one of the little cancerous growths on the third eyelid caused by the irritation of flies. It will eventually have to be cut off—not a very difficult proceeding if a veterinary surgeon is obtainable; in the meantime blow into the eye twice a week a few grains of boracic acid.

"B. B.," Wilkawatt, has a horse which has been unwell for a few weeks; he stands all the time, never lies down; his breathing is very heavy, and he only nibbles at food. He is tired and sleepy.

Reply—The symptoms point to inflammation of the lungs, and probably little can be done after so long; but he may be tried with 20 drops of Fowler's solution of arsenic three times a day put in the mouth with a little molasses or bran.

"E. J. S. A.," Coonawarra, inquires in regard to a pony which is usually fat and gay, but lately has become dull, heavy, losing flesh, and eats dirt.

Reply—Suffers from indigestion, and will probably benefit by receiving in food twice a day a flat tablespoonful of this powder—Baking soda ½lb., sulphur ½lb., nux vomica ¼lb., gentian ¼lb., brown sugar ½lb.

"J. E. P." asks how often and for how long does a sow come on heat.

Reply—When not in pig or suckling, a sow usually comes on heat every 21 days for three days.

The Meadows Agricultural Bureau asks information concerning a ewe, which after being killed was found to be full of water. There was a hole in the bladder large enough to insert a straw. The ewe was in good condition.

Reply—The condition is dropsy, the hole in bladder (situation not named) is probably entrance of ureter, pipe from kidney. The probable cause of the condition is the germ which produces the large abscesses often found in sheep, the early stages of the disease being of a dropsical nature.

The Lameroo Agricultural Bureau asks treatment for a colt which has an abscess on side of and between lower jaw.

Reply—Probably the result of injury or teething. Open out and seek for grass seed or similar irritant, then swab with iodine 1 dram, methylated spirit 1 pint. When healing dress with Stockholm tar.

The Strathalbyn Agricultural Bureau reports that a member had a horse which developed tetanus (lockjaw). The animal was treated with tetanus antitoxin, the serum being injected in the neck, with result that it recovered. They ask if the Government Veterinary Surgeon keeps a supply of the antitoxin.

Reply—The leading European authorities are agreed that this antitoxin is very useful as a preventive of the disease, but is of little avail as a curative. Nature, however, is very kind, and often allows recovery without and even in spite of treatment, so that one must beware of the logical fallacy, *Post hoc propter hoc*. The Agricultural Department does not stock sera or other remedies, but has never found any difficulty in procuring them from the druggists.

"A.," Bews, asks—Are cows in calf less liable to dry bible than those not in calf ?

Reply—Not necessarily, but barren cows as a rule do not get as good feed as the rest. Also maternal instinct compels an in-calf cow to do her best for her future offspring.

"A. A. L.," Keith, asks treatment for horse which has been treated for sand, but is out of condition and is always turning up his nose.

Reply—If his eyes are yellowish the turning up the nose points to disordered liver, which would seem to be the case from the general symptoms; a physic ball—6 drams—should work him if he is prepared by feeding bran mashes for two days, and it would be advisable to try this again after its effects have passed off; 20 drops of dilute hydrochloric acid in his drinking water once a day for a week or two should pick him up.

"W. T." writes—"I am still having trouble with the sheep blowing on the lucerne. I have tried putting them in three times a day for half an hour each time, but still I have losses. If I cart out lucerne hay they only half eat it and soon get hollow and tucked up, wanting to get back on the green feed. The lucerne is too short to run the cattle over it. I have tried cutting all that was any length, but what is left seems to blow them, and what is cut they do not care to eat."

Reply—Apparently the quick growth of the lucerne is the cause of the trouble, which should be lessened if the sheep can be steadied with a bellyful of dry stuff before going on to it, and they should never go on before the sun is well up or when it is damp from rain or dew, nor should they stay on more than a few minutes at a time to start with. A lick of equal parts common salt and sulphur may help, if the sheep will take it with dry feed at the rate of ½oz. salt and ½oz. sulphur per head. When blown they may be quickly relieved by passing an ordinary horse catheter, without its cane, down the throat and allowing the gas to escape. Half an ounce hyposulphite of soda put into the mouth dry is also useful; or about 20 drops of carbolic acid, lysol, or similar disinfectant given as a drench with two tablespoonsful of water; or half a teaspoonful of household ammonia in a similar amount of water; or a half a teaspoonful of powdered carbonate of ammonia put into the mouth with a little molasses.

"A. J. H.," Coonawarra, has a mare which, after drinking or having been driven, holds her head up and turns up her top lip. She does not thrive well.

Reply—As the mare is four years old she is about to cut her last four molar teeth, corresponding to the human wisdom teeth; this is always a trying time for horses, and the symptoms are caused by it; the turning up of the lip generally points to derangement of the liver, so it would be well to keep the bowels loose with a bran mash every night for a week, and get from a chemist half a dozen powders, each containing mercury and chalk 20 grains and sugar of milk 20 grains, put one of these either in the mash or on the tongue each evening and improvement will follow.

"F. G. F.," Brooker, asks treatment for horses which appear very tired and dejected, the result probably of having had to drink inferior water. Bloodworms are suspected. They also eat clay from sides of the dam.

Reply—The history and symptoms certainly point to infestation by parasites, and arsenic is indicated, as so often prescribed in the *Journal*; also arsenical preparations can be obtained very reasonably from the chemists at Port Lincoln and Tumby Bay, who would supply the directions with their preparations. It would be well to treat the water with chloride of iron, as recently described, or, in the alternative, 1lb. chlorinated lime per estimated 1,000galls. stirred into the water every week or two is advisable. For the very weak ones, 20-30 grains, roughly a teaspoonful, of sulphate of quinine once or twice a day in a little bran will be found useful.

"R. C.," Alford, has a 5-year-old gelding which has been suffering from abdominal pain on and off for the past 18 months. The horse improves a little with rest, but fails again when at work. He has been treated for sand and bots without good results; condition powders fail; and he looks like an old worn-out horse.

Reply—A veterinary surgeon, seeing the horse, would probably be able to diagnose the complaint, otherwise it is impossible; the symptoms are those of cancer on some abdominal organ which, however, is not common in young horses; or of tuberculosis—this is most likely the cause and is incurable. There are other possible causes.

"J. H. N." asks cure for 12-year-old mare which crib bites and sucks wind, even during feeding.

Reply—A mare 12 years old with such a well-established habit cannot be cured. If there are others in the stable they may also take up the habit in imitation. A padded strap, obtainable at any saddler's, put tightly round the neck will prevent the habit somewhat, and a dram of carbonate of ammonia in the feed once or twice daily will mitigate the severity of the symptoms somewhat.

"H. C. J.," Parilla, asks treatment for two sows, one of which has become stiff in legs like a foundered horse, and the other paralysed in hind quarters.

Reply—The stiff one has probably had an attack of pleurisy, or the stiffness is caused by worms in the muscles. The paralysis of the second is most probably due to worms. Give both of them 10 drops of tincture nux vomica in a little milk two or three times a day; also a teaspoonful of sulphur twice a day in their feed, which should be soft, sloppy, and green if possible. To relieve the constipation give them an enema of a tablespoonful of glycerine. Give charcoal or cinders regularly in the feed.

"A. B.," Kanmantoo, asks advice concerning sheep. When driven a short distance they drop and die, often without a kick. When opened no disease is found, and kidneys are completely covered with fat.

Reply—When lecturing at Kanmantoo, the Veterinary Lecturer referred to this sort of thing, and fancies that at *post mortem* water is found about the heart and inside the belly, though not mentioned. The disease somewhat resembles braxy, the germ which causes it being well known and common, but only active when the sheep are beginning to do well, as the *post mortem* shows. The remedy is to keep moving them every few days, so that the pastures do not become infected badly. If one is noticed to stagger, the eye vein should be cut and probably its life will be saved. If the sheep are used to a lick, or can be made so, sulphur at the rate of 1 dram per sheep per day added to it will be of use.

"C. M.," Ironbank, asks cure for corns on horses.

Reply—Yes; corns can be cured by paring out well and shoeing with tips or three-quarter shoe, missing over seat of corn. Keep constantly dressed with Stockholm tar. A cure takes from three to six months to effect.

"E. J. T.," Lameroo, asks treatment for mare suffering from stoppage of water.

Reply—(1) Rub flanks well; (2) backrake, remove dung from hinder bowel; (3) warm soapy enemas; (4) pass fingers into urinary passage; (5) drench with ½ pint gin, 25 drops essence peppermint, ½ pint water.

"J. K." had a colt, rising 2 years, which suffered from loss of appetite, moped about for a fortnight, and then died. The *post mortem* showed liver, etc., full of decay and matter, smelling badly.

Reply—The animal suffered and died from an abscess on the liver, probably brought about by what is usually termed "bastard strangles," the germs which cause the strangles swelling under the throat having escaped those glands but overcome those of the liver, which suffered in consequence. If this had been known during life, an ounce of hyposulphite of soda twice a day for a few days in a little bran would possibly have prolonged life, but it is doubtful if it would have saved the colt.

"R. C." asks how to remove warts on cows' teats.

Reply—Can generally be removed by dressing with castor oil one day and vinegar the next, till gone. If big enough, cut off and touch with red hot knitting needle or similar article. If not successful with above paint daily with tincture thuya.

HORTICULTURE.

(Replies supplied by Mr. G. QUINN, Horticultural Instructor).

"E. J. P.," Whyte-Yarcowie, forwards specimens of bush and fruit of tomato showing peculiar malformation of the plant and flower buds. The fruit was mottled and of an unsatisfactory flavor and appearance.

Reply—I can see no insect or fungus present on these tomato flowers or fruits to indicate that such an organism can be blamed for the malformation and injury. These specimens are not uncommon evidence of the presence of this defect in the tomato plant, in fact it is quite the reverse, and the explanation is as yet obscure as to why the floral organs should undergo such transformations as exhibited in those to hand. Why certain cells, which normally are grouped into the shapes characteristic of and possessing the functions of the reproductive organs should go awry and become merely thickened stems and foliage leaves is not, to my knowledge, freely understood, beyond that some stimulus, not as yet under human control, must operate upon them at a critical stage of their development. In horticultural circles such plants are termed "blind," and are rigidly discarded from use in further propagation of their kind.

"W. S.," Watervale, asks for information respecting the working over of old but healthy orange trees to new sorts by means of budding.

Reply—There are two common methods of working over mature orange trees, each of which has its advocates. The first consists of cutting the tree back to its main limbs and budding into selected young shoots which usually emerge from these arms. The tops of the old trees are generally cut away in early spring, about August or September, and the young shoots budded before the end of the year, say before Christmas. Sometimes the tops of these shoots may be removed and the buds forced into growth that same summer or autumn; but in a locality such as yours, I am afraid these late shoots from the inserted buds would not ripen sufficiently to withstand the frosts. In this case, the buds had better be left dormant by not removing the tops until the following spring. The second method consists of inserting the buds directly into the bark of the old limbs in spring time and binding them with waxed cotton bands. After the buds have "taken" the top of the limb is cut off a few inches above the buds in each, or it may be only cinctured by the complete removal of a band of bark ¼in. wide. This latter method permits a certain amount of sap circulation to the old top, which in turn, maintains the activities of the root system until the buds have grown and made enough foliage to take its place, when the top may then be cut off. This old top, in the interval, may also be justly valued as a shelter for the tender first growth from the buds. It is a very good plan to give the stems and stumps of limbs a thick coating of limewash to protect the bark from the sun, as the tree will not, as a rule, make enough foliage on the growth from the buds the first summer to adequately shade the old framework. The bark on these decapitated trees sunscalds much more readily than when they carry even a meagre amount of natural top. It may be mentioned incidentally, that when buds are inserted in young shoots they should be put in close down to the junction of the shoots with the parent limb, and as in the case of those inserted into old limbs, be put into the outer or under side. Further, all large wounds made in removing the tops of the limbs should be made in a sloping direction, preferably to the south, and smoothed over before receiving a coat of thick lead paint. If growth from the buds be slow, the white-washing and painting of wounds may be repeated the second season with advantage.

"E. M.," Port Pirie, asks:—(1) Why melons formed on plants and then wilted away; (2) whether stiff clay soil was suited to melons; (3) the best time to sow melons and beans; (4) how to keep fruit trees dwarf when grown in pots or tubs?

Reply—In respect to the non-setting of the fruits although flowers are freely produced, as you probably are aware, the flowers on melon plants consist each of a separate sex. That is, one flower contains the female organs (pistils) and the other the male (anthers), and it is necessary for the pollen from the male to come into contact with the pistil at the right stage in the development of the stigma or end portion before fertilisation of the ovules can take place. This right stage is outwardly revealed by the presence of a sticky surface on the ends of the pistil. If you examine the flowers on the melon plants you will usually find these two sexes grown on the one plant, and botanists call plants with this arrangement "monoecious"; but when all the flowers on a plant are of the one sex, such are called "dioecious" flowering. You can readily distinguish the male flowers from the female by the fact that usually the petals (the yellow envelope) are larger on the male, and below the whorl of yellow petals there is no thickening of the stem which, in the female flower, is really the embryo melon carrying the unfertilised ovules which, when fertilised by the pollen from the male flower, change into what we know as seeds. Now, without this takes place there will be no quickening of the plant cells which go to make up seeds and the pulp surrounding them, and in consequence of this the plant-forming sap is not concentrated about the young fruit, but is distributed into those channels which make for the growth of more stems and leaves. Hence, we see a plant which does not set fruit usually making greater growth. It may be in your case there were no male flowers, or not enough, or *vice versa*, the male flowers may have predominated. As you remark, however, in the case of your marrows, the fruits form, but wither away, the absence of male elements was probably blamable. There is another factor, and that is the arrival of the right condition of the pollen and stigma at the proper day and time to enable them to unite, and if insects be at hand to carry the pollen to the pistil. Generally, in nature, bees and other insects effect the necessary fertilisation, but it is possible for them to be scarce, more especially early in the season. In such a case where a small number of plants is being grown it is not only possible, but even simply done, and proves a more interesting experiment for the grower to cross fertilise the flowers artificially. This is done as follows :—When the pistils are sticky, and the male flowers are available, select a time about midday when the flowers are free of dew or rain, and taking a small glass bowl, smooth inside, hold it under the male flowers, and if the pollen is ripe the flower on being tapped with a stick will shed its pollen into the bowl if held close beneath. Then with a camel's hair brush, such as school children use in tinting, convey a little pollen on to each sticky pistil by gently brushing it on. The pollen will adhere to the brush more readily if the breath be exhaled quickly into the hair before placing it in contact with the grains. If you wish to secure pure seed after pollenating the female flowers, cover them with a hood of fine muslin gathered and tied around the stem, but not tightly enough to stop growth. This is worth doing to your first batch of flowers, as these produce the plumpest and best seeds if the melons get a fair chance to grow. It is a very good plan to stop the points of the shoots carrying the blossoms by pinching out the terminal buds when the fertilisation is performed. (2) In respect to your soil, it is not calculated, in the condition you describe, to produce melons. All these plants like plenty of organic matter in the soil, and the best way to supply this is to dig in all the stable manure you can get. If it is not well rotted, dig it in to decompose during the winter and grow a crop of cabbage or turnips on the spot. Then, when the spring arrives, dig the ground well again, and in the spots where you propose to sow the melons, break the soil 18in. deep for a space of about 3ft. square and work into each about half a wheelbarrowful of well rotted stable manure. It is possible to get a second crop of fruits or marrows and trombones, in fact, these are more abundant than the first if the autumn be prolonged. (3) It is not much use sowing the seeds of heat-loving plants such as melons, maize, runner or French beans outdoors here until the ground temperature begins to permanently rise. Generally, this is about September or October in South Australia. (4) In respect to how to dwarf fruit trees so as to grow them in pots or tubs, the method usually adopted is to lift them out of the soil each winter and prune back the stronger roots as well as the tops. Trees grown in this manner must be fed with good soil, given in winter when repotting, or liquid manure applied during the growing season, otherwise they become too stunted. It is surprising what can be done with hardy plants carefully handled in this manner; but, of course, it is not a commercial proposition in this country.

DESTROYING MALLEE SHOOTS.

"F. W. B.," Karoonda, asks—(1) What is the best time of the year to cut mallee shoots? (2) In cutting them is it better to cut right down or slash only about two-thirds off? (3) Does the continual slashing finally kill the shoots, and what is the average period taken to kill same?

The questions were referred to Mr. L. S. Davie, manager of the Experimental Farm, Veitch's Well, who replies:—(1) The greatest check to mallee shoots is given if they are cut between harvest and seeding. If this is done in January, or early in February, the shoots may be fire raked, but if carried out later they would have to be horse raked and burnt in the rows. It is necessary to burn the shoots if cut before seeding, or otherwise they will block the implements, and afterwards make it impossible to seed evenly. The above method is preferable to any other on fallow, but if stubble land is sown a good fire raking will save three-quarters of the root cutting, and in that case there is a great advantage in leaving until after seeding; the dead shoots are knocked off by the plough. It is necessary to have the fire raking finished before the end of February to obtain good results. (2) If shoots are cut with a slasher, best results are obtained by cutting off about two-thirds of each shoot; this results in weak growths from the bottom portions instead of fresh shoots growing from the stump. By using a mattock and knocking the butt of the shoot out of the root a much greater number are destroyed in cutting than by using a slasher. (3) Continual slashing alone would not kill all the shoots in ten years, and it would not kill many at all unless done at least three times a year. The scrub farmer must have a fire rake, and, for the first four or five years the most important work he has to do is to get a stubble burn in the hottest part of the summer. With a stubble burn each year of crop—two crops in succession and then fallowing—burning 90 per cent. of the shoots each time, the land will be practically clear of shoots after the third burning. The length of time it takes to clear land of shoots depends altogether on the stubble burns, according as they are good or bad.

THE SHEEP LOUSE.

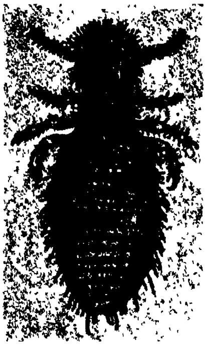
(*Trichodectes spherocephalus*)

(By T. H. Williams, Chief Inspector of Stock.)

Unfortunately the sheep louse has been discovered by the Stock Inspectors in almost every part of the State south from Melrose. They were introduced into South Australia on Lincoln sheep imported from England about 30 years ago, and were first discovered on rams at Mount Gambier by Mr. C. J. Valentine, the ex-Chief Inspector of Stock. As Linclon rams spread over the State, so the parasite spread. Many sheep authorities contended that Merino sheep would not become infested, but this has proved a fallacy, as they have been found on every breed of sheep, the Merino being the breed to suffer the greatest loss in wool and condition. The writer has seen infested Merino sheep, which had been neglected for a few months, become practically denuded of the wool on their sides as the result of biting and rubbing to relieve the constant irritation caused by the bites of the parasites.

The Parasite.

The parasite is not bred by poverty, as many fallaciously assert. There are males and females, and the life cycle is completed as the result of the latter depositing her fertile egg in the yolk about the roots of the wool, where they soon hatch out, and increase the sufferings of their unfortunate hosts by sucking blood, and in their turn becoming breeders. The louse, which is a greyish pink, is about the 30th of an inch in length, and lies close to the skin. The accompanying cut—by Professor Gilruth—will give the observer an idea of the appearance of the parasite when highly magnified.



Common Sheep Louse. (*Trichodectes spherocephalus*)—Gilruth.

HEAVY ANNUAL LOSS.

The annual loss to the national wealth which has resulted through the presence of this destructive parasite has been immense; far greater, in fact, than that caused by the sheep tick—an intimate associate which assists in worrying the host. Reference to a photograph of a lousy Shropshire ram should convince sheepowners of the importance of seeing that their sheep are kept free of such a pest. The ram was badly infested.

HOW THE PARASITES ARE SPREAD.

Lincoln, Shropshire, and Dorset Horn rams have been the means of spreading lice everywhere they have been taken. Ewes become infested at mating time, and are carrying a full supply when their lambs appear. The parasite evinces a particular liking for lambs, and will speedily multiply on them, reducing their condition and the owner's profits.

A LOUSY SHROPSHIRE RAM

RAMS.

Owners buying rams—more particularly of the long wool varieties—will do well to dip them before putting them with the ewes.

DIPPING.

The only known remedy for lice is to dip the infested sheep in some of the best known poisonous powder dips, and as the eggs are likely to escape destruction in the first dipping, a careful examination should be made in a few weeks, when a second dipping may be advisable. New Zealand authorities assert that sheep need to be dipped twice to thoroughly cleanse them.

THE LEGAL SIDE.

The legal side of the question is set out in the article on Sheep Tick which appeared in the April number of the *Journal.*

THE WOOL INDUSTRY.

COMBING AND CLOTHING.

By HENSHAW JACKSON, Wool Instructor, School of Mines and Industries.

A recent query from a woolgrower respecting the definition of clothing and combing wools opens up a very interesting question, and one that, so far as I am aware, has not been previously discussed or explained outside books of a technical nature. The inquiry referred to indicates that the questioner wished to be enlightened as to what constitutes a combing or clothing wool sheep, probably with a view of entering his animals in either class at a show. Whether it is correct to use the terms "combing" and "clothing" in this connection is open to argument, and might be to some extent misleading. It will, perhaps, prove to be the best way to confine ourselves to the terms strong, medium, and fine wool in regard to sheep, leaving other terms where they properly belong, viz., description of shorn wool for the guidance of those concerned in cataloguing wool for sale who understand certain words in a technical sense, and value them accordingly.

The full application of the words "combing" and "clothing" marks the division of the manufacturing section of the wool industry into its two component parts, termed "worsted" and "woollen" trades respectively; combing wools being employed in the former and clothing wools in the latter. The properties which render wool suitable for either branch of manufacture are in some respects similar; but each description possesses other characteristics peculiarly adapted for different processes of manipulation that make them distinctive with regard to their fabrication into worsted or woollen yarn.

It is entirely in the construction of the yarn or thread that the difference lies, and not in the cloth; for while it is possible to build up a fabric composed of worsted and woollen threads in warp and weft respectively, a single thread cannot be made from a sliver of combed or carded wool that combines the characteristics of each in its own body.

The requirements for a combing wool, properly so called, are uniformity of length and soundness of staple combined with the greatest possible fineness. Imbrications, or crimps on the surface of the fibre, are valuable, not from a milling or felting point of view, but because their presence allows the least possible number of fibres to adhere strongly together when twisted into a thread, and so enables the extreme length to be spun out of any given weight or quality of combed wool. A clothing wool, on the other hand, to fulfil all that is required of it should be shorter and softer than a combing, with equal or greater fineness and a clear white color, and display a marked crimpy formation in very short waves over the surface, indicative of the maximum number of serrations of the fibre. These latter are, in this case, of the utmost value in milling or felting, which is one of the chief processes in the finishing of a woollen fabric, the dull appearance of which, in comparison to worsted cloth is due to the innumerable small serrations breaking up the reflected light.

Strength, or more correctly, soundness, and elasticity are two properties that each description of the staple should possess in common, for upon them depends the wearing capacity of the cloth.

"TOPS."

The mechanical processes undergone by combing and clothing wools in their transformation from a mass of fleecy fibres into what are technically known as "tops" are quite at variance with each other, and a short description may prove interesting.

Combing is a term sufficiently explanatory of itself to enable us to mentally grasp what happens to the fibre in this operation, which is neither more nor less, practically speaking, than separating by means of teeth set comb fashion the short fibres from the long, leaving the latter lying parallel and straight their whole length, ready to be spun into a yarn of smooth hard surface that is extremely wear resisting. The short fibres or "noils" that are combed out—according to the translation of the term, which is dialect—being, from a worsted standpoint, a waste product, are afterwards used in woollen spinning where length is relatively unimportant.

The term "clothing," unlike "combing," does not convey much information regarding the after handling of this type of wool, the first mechanical manufacturing treatment of which, after teasing or willowing, is called carding. This process is infinitely simpler than combing, and may be termed a complete opening and breaking up of the natural or artificial arrangements of the fibres in order to present them in a perfectly loose and open condition, again to be crossed and blended together with mechanical nicety in their passage over the carding engine, so that they are thoroughly intermingled, long and short indiscriminately, in one common and uniform system. The short fibres being retained allow of the peculiar feathery appearance of woollen yarn in comparison with worsted, and contribute in no small degree to the felting process by gripping and interlocking with each other when being milled or fulled.

Generally speaking, it may be said that Australian Merino wool possesses very largely the qualities of softness and fineness requisite for the woollen trade, and were it not for the rapid strides made in perfecting combing machinery which enabled manufacturers to produce a superfine worsted, the larger proportion of our clip to-day would be utilised in the woollen industry.

From the foregoing it may be gathered that combing and clothing are purely technical terms used more nearly in connection with wool manufacture than wool growing; but sheepowners are concerned in them so far as seeing that in the " get-up " or classing of their wools for market they secure the services of someone who has an intelligent conception of the differences and can put a clip together accordingly.

Wheat Stacks Port Wakefield.

MENDEL'S LAWS EXPLAINED.

The application of Mendel's laws to stock-breeding are explained by Professor James Wilson in *Hoad's Dairyman.*

To get a first glance at Mendelism we shall take one of the simplest cases. The Shorthorn breed of cattle originated in the North-East of England by crossing the red and red-and-white cattle, which had come over from Holland three or four centuries ago, with a white race which had been in England, in all probability, since the time of the Romans.

The first cross produced roans. This color has been a favorite for more than a century, and breeders have all along hoped that by breeding with roans only, and especially with roans descended from roans for several generations, they would eventually produce roans that would breed true. But they have not been able to do so.

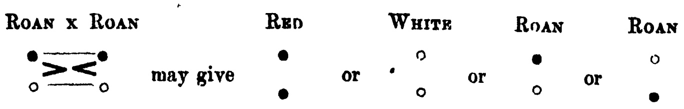
Roans bred with roans continue to throw whites and reds, as well as roans, and they will do so for ever. The numbers of whites and reds thrown are, on the average, one each to every two roans. At the same time, when roans are bred with whites half the calves are roan and the other half white, while when bred with reds half their calves are roan and the other half red.

THE MELTING POT.

Mendel's hypothesis explains these phenomena. Mendel himself really worked with plants, but we can transfer his reasoning to animals He argued that an animal must be indebted to both its parents, and that the thing which is going to determine its future in regard to any one of its points or "characters" must be duplex. He argued that when animals breed they cast replicas or duplicates of their own determinants into the melting pot of fertilisation, that the young takes a half from each parental replica and puts the two halves together to make a whole. This can be made clearer by a diagram.

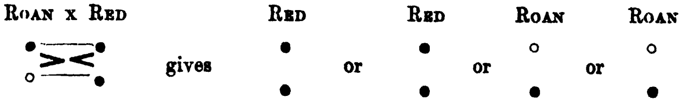
A red Shorthorn carries a determinant for redness, which we can represent by two small filled circles, thus : $\substack{\bullet \\ \bullet}$ A white Shorthorn carries another for whiteness, which we can represent in the same way by two small unfilled circles, thus : $\substack{\circ \\ \circ}$ When a red Shorthorn and a white breed they cast replicas of their determinants into the melting pot ; and the calf, taking a half from each, starts off with a mixed determinant, thus : $\substack{\bullet \\ \circ}$ and, as we have said already, this calf is neither white nor red, but roan, a color produced by a more or less uneven mixture of red hairs and white.

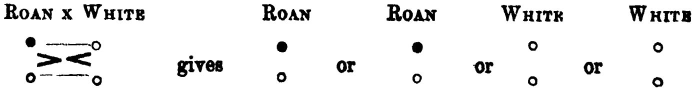
When a red Shorthorn and a white breed there is no possiblity of anything but a roan being produced, but when two roans breed together the calf may be any one of three colors. The red half determinant of one parent may meet the red of the other, then the calf will be red. The white of the one parent may meet the white of the other, and then the calf will be white ; or either half determinant in the one may meet the dissimilar one in the other, and then the calf will be roan. A diagram will show this :—



The chances are one in four for a red calf, one in four for a white, and two in four for a roan. This means that, given a sufficient number of cases, the calves of roan parents mated with roan must be red 25 per cent., white 25 per cent., and roan 50 per cent.

Similar diagrams will show what happens when roans are bred with reds and with whites. (In connection with this subject, it may be noted that red-and-whites are a variety of reds and breed similarly.)





Cases like the foregoing, in which the cross between two characters is somewhere intermediate between the parents, are the simplest, but they are by no means the most common.

A few of those already known might be mentioned, so that readers who are not familiar with Shorthorns might have a further chance of studying Mendelism through them.

White cattle and black have blue roan calves.

Cattle with a brown stripe along the back and a brown ring around the muzzle have brindle calves when bred with other colors.

Some large breeds of sheep have lambs of intermediate size when bred with smaller breeds ; as, for instance, Border Leicesters with Scotch Blackfaces or Cheviots.

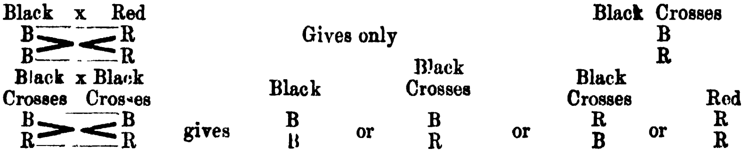
Some white-faced sheep have mottle-faced lambs when bred with black-faced sheep.

BLACK AND RED CROSSES.

Cases in which the cross is indistinguishable from one of the parents are more common. Unfortunately, they are slightly more complicated. The case we may use for illustration is the cross between the black cattle and the red. These crosses are all black, but a black indistinguishable from the black parent.

The Mendelian explanation is that these black crosses contain red, but that it is suppressed in the presence of black. They are crosses, just as are the roans, but with the difference that they cannot be told as such by the eye. That they contain red is clear from the fact that they throw reds when bred together. As a matter of fact, a quarter of such calves are red, another quarter are pure black like the black grandparent, while the remaining half are black crosses containing red.

A diagram will make this clear. We can use letters instead of circles :



Just as we did with the intermediate hybrids, we may mention a few other cases in which the crosses cannot be told from one of the parents.

HORNED AND POLLED.

Crosses between horned cattle and polled are polled. That is to say, the polled character is dominant to the horned.

The white face of the Hereford is dominant to the red or black face of other breeds.

The white fleece is dominant to the black fleece in sheep.

The round rump of Angus—and probably Hereford—cattle is dominant to the square rump of some other breeds.

The short legs of Dexter cattle are dominant to the long legs of the Kerries. Probably short legs in cattle as a whole are dominant to long legs.

Grey is dominant to all other colors in horses, and bay and brown are dominant to chestnut.

The five-toed foot of the Dorking is dominant to the four-toed foot of some other breeds of fowls.

DOMINANT AND RECESSIVE.

The two foregoing cases illustrate the ways in which characters are handed down from one generation to another. They may be summed up as follows :—

1. When the parents have differing characters their young are either obvious hybrids, intermediate between the parents so far as these characters are concerned, as in the case of white and red ; or,

2. Disguised hybrids, in which the character carried by one parent masks or obscures the character carried by the other, as in the case of black and red.

Mendel called the masking character the dominant, and the masked character recessive. These words should be remembered.

3. When both parents have the same characters pure—say white, or red, or black—that character is handed on pure to the young, who are white, or red, or black, as the case may be, just like their parents.

Having discussed the ways in which characters are inherited, how is this knowledge going to be useful to the farmer ?

Let us take first one of the cases we have already discussed. A stockbreeder has a herd of white cattle which he wishes to be turned into a red herd. Obviously his first step is to get a red bull to cross with his white cows. He finds all their progeny are intermediate hybrids—roans. His next step is to put a red bull again to the roan first-cross heifers. Half of the progeny of these will be red, while the other half will be roan. So if he continues the same process he will have a red herd so soon as he can afford to eliminate the last roan bred in the herd. If the same farmer could not find a second red bull he would have to mate a roan with his roan cows. Then a quarter of his calves would be red. The above is a case where the hybrid between the two characters is intermediate.

PROBLEMS EXPLAINED.

Let us now take the more difficult case where the hybrid is indistinguishable from one parent. A stockbreeder wishes his horned herd converted into a polled one. His first step is to get a polled bull to cross with his horned cows. Their progeny are all polled, but their power to have horns is merely suppressed. His next step is to use a polled bull again upon the hybrids. The progeny are all polled again, but, as we know, about half of them are hybrids again, and these cannot be distinguished by the eye. Now, there would be little difficulty in having polled calves in every generation if the stockbreeder could always get polled bulls that were pure for that character—that is, bulls in which both half-determinants are for hornlessness.

But if he wanted to use a polled bull bred in his own herd there might be a difficulty. The bull chosen might be either pure for hornlessness or he might be a hybrid, and there would be no way of telling until he had been bred from. If all his calves were hornless, then he is probably pure ; if some were horned, then he is undoubtedly impure. If the stockbreeder were absolutely dependent upon his own herd for a stock bull which would be sure to leave hornless calves, the only way of determining whether any of his bull calves are pure for hornlessness or not is to put them to horned heifers or cows and judge by the stock they produce. If all their calves from such cows are hornless, then the sire is pure for that character.

WHEAT REQUIREMENTS OF BRITISH MILLERS.

Mr. A. E. Humphries, Past President of the National Association of British and Irish Millers and Chairman of its Home-grown Wheat Committee, has written for the International Institute of Agriculture at Rome a valuable note on this subject. He remarks at the outset that the British flour-milling industry has, within the last thirty years, been subjected to revolutionary development in two principal directions, one economic and the other technological. At the beginning of that period, there were 10,000 mills in the United Kingdom producing flour; at the present time the number is less than 1,000, although the quantity of wheat ground per annum is now 80 per cent. greater than it was 30 years ago. Furthermore, one-third of the flour produced in the United Kingdom is made in about 30 large mills situated at seaports. The following facts are, according to Mr. Humphries, associated with these developments :—(*a*) The acreage under wheat in the United Kingdom has been greatly diminished, so that although the yield per acre has been increased substantially, the quantity of home-grown wheat, which 30 years ago was 36 per cent., is now nearly about 20 per cent. of the requirements; (*b*) the standards of excellence in flour have been raised, whereas the average quality of home-grown wheat has been lowered; (*c*) the milling system of gradual reduction by means of roller-mills has entirely superseded the use of millstones. The mills now existing are well equipped; (*d*) the development of new countries and the insufficiency of labor in most wheat-growing areas, have caused wheats to contain a substantial proportion of dirt, seeds, and other extraneous matter, so that elaborate and costly installations of wheat-cleaning machinery have been rendered necessary in British mills; (*e*) a system of "conditioning" has been elaborated whereby as a result of the skilful use of water, great improvements in the quality of flour, and great changes in the relative values of wheats have been made; and (*f*) under pressure of extreme competition, millers have to work on exceedingly small margins of profit per unit, and cannot afford to make mistakes in milling or tolerate irregularities in the quality of their manufactured goods.

Continuing, Mr. Humphries remarks :—"My next point is, that market value is not a true index of intrinsic worth. No person, or Government department, has set up in this country a standard whereby the intrinsic worth of a wheat or flour is to be judged, nor is any such action desirable, but certain characteristics in wheat are highly esteemed, and the trades concerned have come to regard the possession of certain qualities as a measure of intrinsic worth, principally because such wheats are generally in relatively small supply and usually realise maximum prices. A considerable amount of friction must be used in milling, but the millstone applied an unnecessary amount of friction in an unnecessarily severe way. The public demands a white or bright-colored bread, and in these days of good wheat-cleaning appliances the principal cause of dark bread is the presence in low-grade flours of an appreciable amount of bran powder. A wheat which is hard and possesses friable skin is more likely to be comminuted than a mellow one ; bran powder from a 'red' or brown wheat will darken the bread much more than the same percentage of bran powder from a 'white' or yellow wheat. So 40 years ago, in millstone days, a wheat which was mellow, white and strong, was considered excellent. Hence the high repute in which Dantzic, among foreign wheats, and Childham, among native varieties, were held in those days. But with the advent of roller-milling and imported flours made from wheats grown on the virgin lands of the United States and Canada, the older standards as to excellence of quality were changed, and we gradually came to recognise as specimens of high intrinsic worth the better grades of Canadian and United States spring wheats, hard friable 'red' skinned varieties, containing a high percentage of nitrogenous matter. Such wheats have for many years realised ordinarily the maximum prices of our markets, but not invariably. For we want other types of wheat as well, and supply and demand are far more influential elements in price-making than any current ideas as to intrinsic worth.

"The upshot of these considerations is, that British millers do not seek to impose any conditions as to the type or characteristics of the wheats offered them. All sorts and conditions of well-harvested wheat have a value on our markets, and can be sold therein. We do, however, attach great importance to various points of excellence, and believe that the plant breeder can in most, if not in all countries, provide varieties, in the highest degree suitable to the 'environments' existing there and to the commercial requirements of millers. British millers are to a greater extent than ever running their mills in a scientific way ; some have scientists on their staff. The idea that wheat is sacrosanct is passing away ; the newer conception is, that it is a fruit of the earth designed by Nature to be a seed and that in making it fit for use as human food the miller is right in obtaining not only the aid of the engineer, but of the chemist as well. With such aids he is the more disposed to make his own requirements subservient to the interests of growers. But he does ask that the arrangements made for marketing should in all countries be equitable. For instance if 'grading' be established in any country, the methods adopted should be uniform throughout the area concerned, and provision should be made for rectifyfng any substantial errors which are made in practice. He also asks that the glaring malpractices existing in connection with Russian grain shipments should cease. Such abuses in the long run will be highly unprofitable to the perpetrators, for buyers can take effective means of resenting them. Nevertheless as the recent history of the grain trade has shown, it would be better for all concerned that such evils should be rectified by the joint action of shippers, merchants, and receivers, with or without the co-operation of the Governments concerned."

In conclusion, Mr. Humphries recommends that the following points should be remembered by those wishing to sell wheats on British markets:—(1) Bulks should be uniform throughout, and the standard of quality, whatever it may be, should be maintained with a minimum deviation therefrom. (2) Wheats which contain the smallest percentage of dirt, rubbish, and other extraneous matter and which yield the highest percentage of good flour with the minimum of risk and trouble to the miller, are those which he prefers. Their virtues have a cash value. (3) Nothing should be done to hide or disguise any imperfections or faults of quality. A miller is more likely to buy wheat of poor quality at a reasonable price than run unknown risks by continuing to buy, except at a very low price, wheat whose real qualities he is unable to recognise or appraise. (4) Ordinarily the color of the bran is relatively unimportant, but preference should be given to white wheat. In this connection, it should be remembered that white wheats can possess great strength, and red wheats can be very weak, and that a dark-skinned wheat can yield a very white high-grade flour. Quality of endosperm is one Mendelian unit, color of skin is another. There is no inevitable correlation between them. (5) If on all other points they are of equal merit, wheats yielding a white flour are superior to those yielding a yellow or dark one. (6) A clear distinction should be drawn between wheats which appear to be hard, merely because the percentage of moisture they contain is low, and those which are really hard by nature, even when their moisture is raised to that of dry English wheat, say to 16 per cent. (7) Wheats, whether inherently hard or mellow, should always be of a "free milling" nature; in other words, it should be possible to obtain with the minimum of trouble and power the desired separation of husk from kernel. A mellow wheat which becomes "woolly" or a hard wheat which becomes "horny" when water is added before or during grinding, cannot be an ideal wheat. (8) The berry should be of average size, neither too short nor too long, neither too big nor too small. (9) Although bulks should contain no stones, dirt, seeds, or other extraneous matter, a low percentage of such impurities is not a great objection so long as their size and specific gravity differ substantially from those of wheat. Special care should be taken to exclude aromatic impurities, such as eucalyptus. (10) If the wheat come from a country where it is likely to suffer from the depredations of weevils, it should be of a kind which they do not readily attack, or it should be stored under conditions in which the risk of such damage can be minimised, or it should be exported soon after harvest. (11) If wheat come from a country where it is likely to suffer from an excess of rain or humidity at harvest time, those varieties should not be grown which are likely to sprout.

easily. (12) Durum wheats are not likely to realise maximum prices in British markets for flour purposes. The objections against them are much less now than they used to be, but in spite of all improvements in the methods of milling them, they are not so suitable for flour-making as wheats of the "ordinary" type. Some varieties of Durum are much superior to others, and if for agricultural reasons it is desirable to grow this type of wheat many varieties of it should be tested by growers, and those selected for extensive cultivation which suit the producer and are least objectionable to the miller. (13) Wheats which require different methods of cleaning and conditioning as part of the milling process, should neither be grown together nor mixed together before that stage of preparation has been passed. If that recommendation be not observed, the miller cannot develop or utilise to the utmost advantage the potentialities of the wheats so mixed, and cannot be expected to pay maximum prices for them. Therefore, an inherently hard wheat should not be mixed for sale with a naturally mellow one, if the best commercial returns are to be obtained by the producer. Furthermore, as white bran is not infrequently worth more than red, it is undesirable to grow together or mix before shipment white and red wheats. (14) Nondescript wheats are not of high value. If a wheat be really strong and poor in other respects, or if it yield flour of practically good color or flavor and on other points be of poor quality, its one great merit recommends it to buyers, whereas wheats of no outstanding merit on any point are merely "padding" and have no particular value. They can be sold, but at a low price.—*Indian Trade Journal.*

IMPORTS AND EXPORTS OF FRUIT, PLANTS, ETC.

During the month of February, 1914, 927bush. of fresh fruit, 10,384bush. of bananas, 106 bags of potatoes, 8 bags of garlic, and 59 packages of seeds, bulbs, and plants, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Of these, 1,132bush. of bananas and 9bush. of pines were destroyed (over-ripe). Under the Federal Commerce Act, 7,531bush. of fresh fruits, 1,736pkgs. of dried fruit, 60pkgs. of preserved fruit, 102pkgs. of honey, and 13 bags of onions were exported to oversea markets during the same period. These were distributed as follows:—For London, 709 cases of apples, 25 cases of pears, 102pkgs. of honey, 1,336 cases of dried fruit; for Germany, 6,317 cases of apples, 323 cases of pears, 25 cases of grapes; for New Zealand, 13 bags of onions, 325 cases dried fruit, 132 cases grapes; for India and East, 60pkgs. of preserved fruit; for South Africa, 75pkgs. of dried apricots. Under the Federal Quarantine Act, 849pkgs. of seeds, bulbs, plants, nuts, &c., were examined and admitted from oversea markets.

During March, 554bush. of fresh fruit, 6,738bush. of bananas, 3,093 bags of potatoes, 29 bags of onions, 31 bags of beans, and 68pkgs. of seeds, bulbs, and plants, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Of these, 116bush. of bananas were destroyed (over-ripe). Under the Federal Commerce Act, 58,597bush. of fresh fruit and 11pkgs. of seeds were exported to oversea markets during the same period. These were distributed as follows:—For London, 19,338 cases of apples, 364 cases of pears, and 187 cases of grapes; for Germany, 34,362 cases of apples, 2,861 cases of pears; for New Zealand, 232 cases grapes, 11pkgs. of seeds; for Tahiti, 5 cases of apples and 2 cases pears; for India and East, 1,196 cases of apples. Under the Federal Quarantine Act, 937pkgs. of seeds, bulbs, plants, &c., were examined and admitted from oversea markets.

During April, 816bush. of fresh fruits, 9,940bush. of bananas, 4,812 bags of potatoes, 226 bags of onions, and 81pkgs. of seeds, bulbs, plants, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Of these, 414bush. of bananas were destroyed (over-ripe) and 474 cases of bananas were fumigated. Under the Federal Commerce Act, 48,436 cases of fresh fruits, 3,546 cases of dried fruit, 56pkgs. of preserved fruit, 3 cases of jams, and 5pkgs. of seeds were exported to oversea markets during the same period. These were distributed as follows:—For London, 23,381 cases of apples, 1,261 cases of pears, 22 cases quinces, 60 cases of grapes, 1 case of peaches, 100pkgs. of Sultanas, and 1,275 cases of dried apricots; for Germany, 19,854 cases of apples, 717 cases of pears, 44 cases of grapes, and 2 cases of jam; for New Zealand, 72 cases of grapes, 35pkgs. of preserved fruit, 150 cases of dried fruit, and 5pkgs. of seeds; for South Africa, 920 cases of dried fruits; for India, 2,879 cases of apples, 145 cases of grapes, 21pkgs. of preserved fruit, and 1 case of jam; for British Columbia, 1,101 cases of dried fruit. Under the Federal Quarantine Act, 2,946pkgs. of seeds, plants, bulbs, nuts, &c., were examined and admitted from oversea markets.

POULTRY NOTES.

By D. F. Laurie, Poultry Expert and Lecturer.

OPERATIONS FOR APRIL.

Incubation.

A large number of breeders have hatched chickens which are doing well. These breeders will continue incubation throughout autumn, winter, and early spring. Others have not yet mated their stock and will not commence hatching operations for some time. Among poultry fanciers and those who, as a rule, hatch from 50 to 200 chickens, the practice is to defer incubation until August for heavy breeds and September for light breeds.

When to Hatch.

The question is often put to me—When is the time to hatch ? The answer is as follows :—*Turkeys,* as a rule, do not lay until July or August, but from that time until December the eggs may be set. *Geese* lay most of their eggs in August or September, and whenever they do so the geese may be encouraged to sit. *Ducks.*—With heavy laying strains one may have fertile eggs during a long period. The demand for out of season ducklings is not very good—still there is a chance of profitable work. Very early spring ducklings are in demand about the time of early green peas. To get these early ducklings May, June, and July hatching must be resorted to. For bulk hatching and for Christmas and January markets September, October, and November are the months. The best ducklings are Pekin or Pekin cross. Indian Runners are good layers ; and of these, on account of its plumage, the white variety is to be recommended. Muscovy ducks are bred largely in New South Wales, and several breeders are taking them up here again. The cross between Pekin ducks and Muscovy drakes results in an excellent table-bird. These crossbreds are true hybrids and are sterile. The period of incubation in ordinary ducks is 28 days, in the Muscovy duck it is 35 days. This duck is a native of South America, and Muscovy (relating to Russia) is a misnomer. *Chickens.*—For profit, either for eggs or for table poultry, hatch from March to September and a few hatches in October. For laying competitions the end of September and well on into October there must be successive hatches so that a proper selection can be made. For show, as soon after August 1st as possible, so as to obtain the greatest development.

How to Hatch.

Eggs may be hatched naturally (under broody hens, ducks, or turkeys) or artificially in incubators. Nests should be made on the ground, but selected so as to guard against flooding. Line with dry grass or short straw and keep free of vermin. Do not place under the hen more eggs than she can properly accommodate. The hen should not be fed on the nest, water should be within reach, but she should be encouraged to leave the nest each day. Feed on grain (wheat, oats, maize). Artificial Incubation.—There are numerous good machines on the market. The Poultry Expert cannot undertake to recommend any particular make of incubator. Follow the makers' directions, which are issued for the particular style of incubator. If in doubt have your thermometer carefully tested. Select only fresh eggs, the produce of healthy, properly-fed breeding stock. Avoid all over-large or any undersized eggs. Reject all misshapen eggs or those the shells of which are cracked.

For egg production the eggs should be laid by tested hens, or those of excellent pedigree as layers. Table-bird breeding should be from the all-round or general purpose breeds. Some people are very fond of crossing. The progeny, it is true, are very often fine table birds, but that is their value—so much a pound. If, on the other hand, you breed pure Orpingtons, Rocks, or Wyandottes you will always find a good sale for the best of your surplus birds at fair prices—much above the price of table birds. These cost no more to breed and fatten than do the crossbred.

Disinfect Incubators.

All incubators should be, before using, scrubbed out with hot water, soap, and soda. When dry they may be disinfected with a 5 per cent. solution of formalin, and then well aired for a couple of days before starting. This is important in view of the fact that white diarrhœa and other diseases due to germs are somewhat prevalent. Formalin is cheap—it should be kept stored in a dark cupboard. Light decomposes it. Repeat process after each hatch.

The Brooders.

The brooders need similar treatment to that recommended for incubators. Do not overheat these. For a start, run at about 90 degrees, then gradually cool off. It is more important to see that the chickens are not allowed to huddle in the runs and contract chills. They should be driven gently into the brooder. Much of the losses are due to chills contracted in this way. One need only watch a hen with a young brood. At frequent intervals, especially on a cold day, she "camps," and the chicks "snuggle" under her and remain warm.

Cut Greenfood.

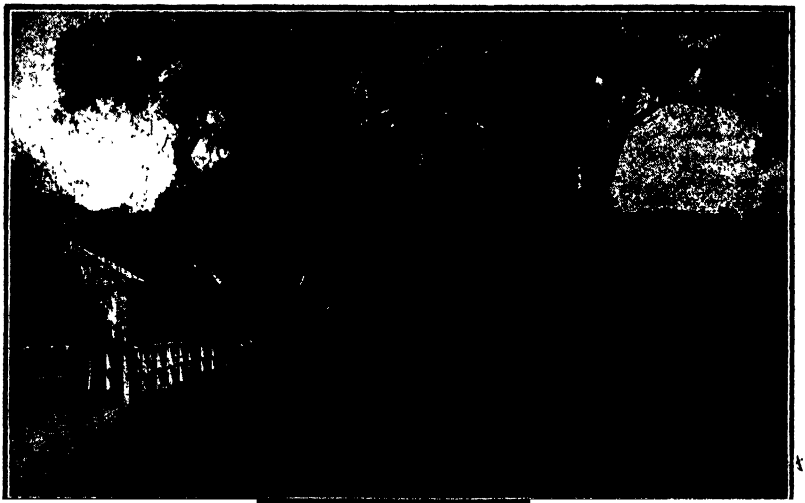
This is essential to all young feathered stock. It may consist of grass, lettuce, berseem, clover, kail, lucerne, &c. They will all consume large quantities. Chopped onion and garlic tops, or the tubers, may with great advantage be mixed with semi-dry mash, especially where turkeys are concerned.

Charcoal and other Grit.

This should be provided in hoppers. Chicken cracked grain mixtures are improved by the addition of a generous sprinkling of charcoal grit, sand, and gravel, and quartz grit. When dry mash is used there should always be an addition of charcoal.

Keep the Stock Growing.

If the stock is once checked the results are seldom satisfactory. "Little and often" is always a good maxim with young stock. Do not overfeed, but encourage them to scratch in litter and friable soil—they gain both exercise and food. Where earth worms abound thay should be dug up and fed to the chicks. They are greatly appreciated and cause fine growth. Change the ground as often as possible. Portable brooders are excellent. Move them to fresh ground as often as convenient.



A Suburban Road.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1914-15.

[Started April 1st, 1914, to terminate March 31st, 1915.]

Competitor.	Eggs Laid for Month ended April 30th.	Total Eggs Laid from April 1st, 1914, to April 30th, 1914.
SECTION I.—ANY BREED.—TEN PULLETS EACH PEN.		
White Leghorns.

PARAFIELD EGG-LAYING COMPETITION.

REPORT FOR APRIL.

The competition began, as usual, on April 1st. Four sections were arranged for, but owing to poor entries Section 2 (Producers' Class) was abandoned. Section 1.—There were 51 entries. Each entry was of 10 pullets, instead of six as in previous tests. Section 3, Single Testing, Light Breeds.—There were 34 entries. Section 4, Single Testing, General Purpose Breeds.—There were 25 entries. The single testing of pullets is an innovation, the principle of which was approved some years ago but was deferred until the removal to Parafield had been effected. Excellent results are expected, with benefit to the industry. The birds arrived on and prior to March 31st. Several entries were not forthcoming.

Health.—Three entries were affected with chicken-pox, but soon recovered. The owners of these birds, in sending stock infected with chicken-pox, committed a breach of the law.

Weather.—The weather has been generally fine and temperatures moderate. Rain fell on eight days; the total recorded was 1·96 points.

Egg Production.—Moulting is general among the occupants of the pens in Section 3, and also in Section 4 to a less extent. The severe heat during show week had a bad effect upon the pullets in Section 4, as these were exhibited at the show. These are reasons for the somewhat poor returns of eggs. In addition, many of the competitors were immature and will not lay for some time.

Greenfood is abundant, and a supply throughout the winter is assured.

Visitors.—During the month 64 persons inspected the Poultry Station.

D. F. Laurie, Poultry Expert.

FRUIT SHIPMENTS.

The General Manager of the Government Produce Department (Mr. G. A. W. Pope) received a cable at the end of April from the Trade Commissioner in London (Major A. E. M. Norton, D.S.O.) giving the prices brought by fruit forwarded through the department for sale on behalf of various clients.

The shipment which left South Australia in the s.s. *Otranto* for London on the 6th March, 1914, consisted of 314 cases of apples. The prices obtained were as follows :—

No. of Cases.	Class.	Variety.	Average Price.
114	Apples	Jonathan	12/3 per case c.i.f.
—	"	American Mother	12/3 " "
100	"	Cleopatra	12/6 " "
50	"	Jonathan	9/- " "
—	"	Munroe's Favorite	9/- " "
—	"	Cleopatra	9/- " "
50	"	Cleopatra	13/- " "

The shipment which left here in the s.s. *Telamon* for London on the 28th February, 1914, consisted of 571 cases of apples and 89 cases of pears. The prices obtained were as follows :—

No. of Cases.	Class.	Variety.	Average Price.
150	Apples	Biffons	10/- per case, c.i f.
—	"	Worcestershire	10/- " "
—	"	Bedfords	10/- " "
100	"	Jonathans	13/- " "
210	"	Reinette du Canada	10/- " "
—	"	Winter Majetin	10/- " "
—	"	Ribstone Pippin	10/- " "
—	"	Bedfords	10/- " "
—	"	Early Rome	10/- " "
—	"	Raspberry Pippin	10/- " "

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, April 8th, there being present Messrs. F. Coleman (Vice-Chairman) presiding, C. J. Valentine, A. M. Dawkins, J. Miller, W. G. Auld, T. Williams, C. E. Birks, Col. J. Rowell, C.B., and G. G. Nicholls (Secretary).

Marine Fibre.—A letter was received from the manager of the Australasian Marine Fibres Company, Limited, indicating that a cloth suitable for the manufacture of corn sacks could be made from the fibre, but the making of the bag by hand, under local conditions, would be an obstacle to the commercial undertaking of such an industry.

Veterinary Surgeon for District.—The Secretary reported that the Minister of Agriculture was unable to entertain the idea of placing a Government Veterinary Surgeon in the Lucindale District, and the Branch had been informed accordingly.

Gratwicks "Beatsall."—A request was received from the Wilkawatt Branch that the Government should test the value of a preparation known as above, as a fertiliser for wheat. After consideration it was decided to ask the Minister to secure a report from the Inspector of Fertilisers.

Rail Freights on Oats and Barley.—The same Branch asked that the Railways Commissioner should be approached requesting that oats and barley should be carried at the same rate as wheat. As a comparison of the rates revealed but slight difference in the charges, especially on the long distances, *e.g.*, 100 miles, and having regard to the extra bulk of these grains, it was considered that no action would be warranted.

Life Members.—Messrs. J. P. Pontifex, of the Paskeville Branch, and S. H. Schinckel and A. Caldwell, of the Naracoorte Branch, were approved as life members of the Bureau in recognition of their long and effective service as members of that institution.

New Members.—The following gentlemen were approved as members of the Branches shown :—Berri—J. Norman, E. R. Moss ; Maitland—J. Tiddy, H. A. Wundersitz ; Meningie—E. Lawson ; Mount Bryan—T. Beckwith, A. E. McWaters, C. Collins ; Redhill—L. Pengilley ; Pine Forest—W. F. Hewett ; Borrika—J. Drue ; Port Pirie—C. Davidson ; Kadina—P. D. Anderson, E. H. White ; Pinnaroo—R. McCabe ; Yadnarie—J. Darby ; Northfield—A. Sandercock ; Kybybolite—H. Lambert ; Naracoorte—G. E. Kelly ; Parrakie—J. Parkinson, A. McArdle ; Penong—J. C. Stiggants ; Meadows—Rev. E. M. Ingamells, B.A. ; Clare—E. Dack ; Mount Barker—G. F. Paltridge, J. E. Liebelt ; Mount Gambier—D. McGillivary ; Minlaton—E. Jahne ; Mount Remarkable—J. C. Collins, F. A. Turner ; Mantung—J. E. Pearce, E. Tonkin, W. J. Carnell ; Kalangadoo—G. Bennett, jun. ; Saddleworth—J. Graham.

THE AGRICULTURAL BUREAU.

CONFERENCE OF SOUTH-EASTERN BRANCHES.

(Continued from page 974.)

AFTERNOON SESSION.

FODDER CROPS.

The Director of Agriculture (Professor W. Lowrie, M.A., B.Sc.) said the growing of fodder crops had been discussed in this district for the past 25 years, and in spite of all that had been said the extent to which the practice obtained at the present time was very limited. Even those forage crops grown in a few isolated instances were a matter of plots. If the matter were thoroughly gone into it would be found that over considerable areas in the South-East the most profitable practice was to make the growing of these crops the corner stone of their activities. The export trade was providing a more ready sale, not only for South-Eastern stock, but for that of all other parts of the Commonwealth, than had formerly been the case in the history of the export of meat. There was good reason, therefore, for farmers living in districts where such crops were practicable for them to test them.

In the South-East they had considerable areas of poor land (to say nothing of the very good land) which, even after they had put some work on it, would not prove such that they could profitably crop it. It was worth an effort to bring it into condition by the growing of forage crops. In New Zealand they had a lot of very thin country between the good land and the hills. This was worth from £4 to £11 per acre in the market. It was land that if they took a crop of oats off the grass would perish ; but it would yield forage crops, which accounted for the prices. The practice was to cultivate, sow, manure, and feed down, and so on. There was the opportunity of doing something to make up the country here that was only carrying sheep ; but the man who undertook to do it would err if he expected to get back in his first crop all he put into it. The good land in this district was not as clear as it was 20 years ago ; forage crops would help to rectify this. Rape could be tried with advantage. If this were put in, and fed down with sheep, it would soon clean " fat hen " out of the land. Crops of this kind would also put humus into the soil. Whilst potatoes at £3 per ton would be found more profitable than the crops he was advocating, they could not continue to grow that crop with any degree of satisfaction. It was necessary for them to change with something more than a cereal and grass, and have something that would raise the stock-carrying capacity of the farms in the future. Unless they laid themselves out to make the quality of the land in this way their returns would never be of the highest.

DRAINAGE AND MANURES.

From the point of view of farming in this district, the first consideration was to get rid of the water. This would make the manuring problem easier. There would be less demand for nitrogen when the waterlogged condition of the soils was remedied. It was an elementary principle, however, that in growing forage crops it was necessary to use more manure than was the case for growing cereals. Farmers did not like drawing a big cheque for artificial manures; nevertheless they would find that the extra 4s. per acre put out in this way was more than recovered by the extra returns. On the poorer lands they would have to be more careful, and get the position brought about more gradually; but on the better lands he had not the slightest doubt that it would pay them to be liberal with their dressings of artificial manures.

THE CROPS TO TRY.

Of the crops which would be suitable rape was one of the most important. Kale, white mustard, Italian rye grass, vetches, oats, and Cape barley had already been tried in the district. Rape was easily handled, a rapid grower, and a good cleaning crop, and one of the very best of the succulent fattening foods that was within their reach. Careful tests of feeding values had been made in other countries, and it had been shown that an acre of rape was equal in feeding value to 50bush. of barley. It was not a crop that one would put in if the rains came late in the autumn. In early seasons, with the rains in March, it was very useful, but if the season held off until May other crops would be more profitable. In the spring there was difficulty with blight. This could to some extent be contended with by feeding the crop down immediately the aphis were noticed. The rate of sowing for this crop should be 5lbs. per acre, and it was a good practice to sow from 2lbs. to 2½lbs. of white mustard with it. White mustard by itself scoured the stock and they would pass it, but if they put it in with rape they would find that when the lambs were being weaned they would take to it first. Kale was fitted to a wider range of conditions than rape. It could be sown in the spring; a bulk of summer forage would be secured from it, and if it were not fed down too hard it would also provide light winter and early spring feeding. At Roseworthy he had secured 26 tons of forage per acre from this crop, and it would do much better in this district; whilst it did not fatten the lambs so readily very fat lambs could be turned off it. Of the cereals, Cape barley was the one on which most people put the greatest value, but it did not stand so much grazing as Dunn oats sown early. It was objected that these oats did not stool well, and took too long coming, but they could be grazed harder

Cereals for greenfeed should be sown much more thickly than if they were required for grain; 2bush. of barley per acre should be used and 2cwts. of manure should be put under it. It had been said that the extra hundredweight of manure would increase the acidity of the soil, but in discussing the matter with chemists he had learned that the small weight put on would be so distributed over the ground that neither the chemists nor the plants could discover a trace of it.

ITALIAN RYE GRASS.

A good deal of attention had been paid to rye, and on the very poorest land this would be found one of the best means of recovering it. Men who had done well with potatoes at Mount Gambier would do well to put 3lbs. of Italian rye grass on the land, and they would be astonished at the results. Cape barley would perhaps carry from 10 to 15 sheep to the acre for five months. From analogy and from experience he would say that Italian rye grass would carry the same number for twice the time. The Italian rye grass was a great winter grower, and excellent for finishing off the lambs. It was essential to get the best seed, however, even if they paid 8s. per bushel for it. Sutton's Giant or Westernwolth's sub-variety should be secured.

CAREFUL CULTIVATION.

His object was to urge on landholders the importance of putting these crops in better than they had, and trying different times of seeding, in order that they might find for themselves the best methods. On their ordinary cropping land they would find that phosphatic manures alone would not be sufficient. They would have to put a little nitrogen into the soil as well. One way of doing this was by sowing peas, either for grain or as a forage crop. There was also the French vetch..

QUESTIONS.

In reply to questions the Director said barley would come in for feed before Italian rye grass, but the advantage was only very slight. In Canterbury he made a practice of sowing it on wheat stubbles in March. About the first week in August it would be about 4in. or 5in. high.

Mr. A. A. Sassanowsky said Italian rye grass could not be put in after potatoes, because they were not in until June.

Mr. J. H. Kilsby asked whether as good a cut of hay could be secured from Dunn oats after feeding down as was obtained from Algerian.

The Director of Agriculture said that whilst they would not perhaps give the same weight of hay the quantity of oats would be there. Italian rye grass would make very good hay.

Mr. D. Tucker (Kalangadoo) asked whether, as this grass was very fattening, it would rob the soil and weaken it for the following crops, The Director of Agriculture said wheat after this grass would not do well. Oats did not feel the influence of it in the same way, however.

Mr. T. H. Williams (Chetwynd) asked whther it was generally recognised that a crop of Italian rye grass came on slowly after kale. He had had difficulty in getting rid of kale stalks, and was troubled with thistles.

The Director would not expect the grass to do so well, but he had destroyed the stalks of the kale with the disc plough.

The difficulty with vetches was the harvesting of the crop and the cost of the seed. At the moment they were scarcely within the range of practicability on these accounts. There was no reason why they should not grow as well here as in other countries. The hairy vetch was perhaps better than the French vetch, and this would come in for use on the poor lands. White turnips were the best. In this country there was a tendency to feed the grass paddocks constantly. By sowing turnips one paddock could be allowed to rest whilst they were feeding them. In the case of peas, if they had a sufficiency of feed to keep the stock going, it was as well to allow the peas to remain until they were ripe.

PIGS.

The Dairy Expert (Mr. P. H. Suter) addressed the meeting on this subject The serious attention given to pig-raising in older countries had not been accorded this branch of industry in Australia, he said. Here there was no animal contributing so much directly to our food supply, nor was there any so badly housed. Indeed, in many places the pig had been looked upon as a scavenger, and only too often treated as the housewife's best sink. We had in this State some excellent animals, the fruits of money spent by breeders, who imported pigs at considerable cost; but there was room for improvement generally, not alone in the type of pig, but in the general management thereof, particularly in housing and feeding. To many, he said, a pig was just a pig, although it cost no more to keep a good one than a bad one. The remarkable fact about improved pigs was the readiness with which they fattened, and the shorter time they took to reach that stage demanded by the butcher. An illustration was given to show the difference in profits that might be expected from a good sow mated with a well-bred boar, and a bad sow mated with an ill-favored boar, assuming that each produced two litters in one year, thus—A good sow produced 20 bacon pigs, valued at £3 10s. per head, or £70 ; and feeding expenses, including £5 for keep of sow, and £35, for the feeding of progeny, left a profit of £30. The inferior sow produced 12 young pigs, worth £3 7s. 6d. per head, or £40 10s. ; and with £5 for maintenance of the dam, and £21 for the feeding of the young ones, the net profit was £14 10s.

The instability of markets was frequently blamed for the erratic interest taken in the subject. This might result from over-production, but more often was due in this State to the fact that heavy supplies were obtainable in the eastern States. It was also quite possible that prices obtainable were not so profitable when the price of foods, such as barley, peas, &c., were at high levels, or that pigs were marketed when either too light or too old and weighty for trade requirements.

The industry would continue to have its ups and downs just so long as we had no outside market. The only way to secure a sure and permanent market for pigs was through the systematic development of a few bacon and ham factories, not in the city, but in suitable country districts, where conditions were favorable for economical and proper feeding. Manufacturers could then guarantee uniformity of supplies, qualities, and flavor. This could be arranged when low values were likely. It had been done in America, and there was no reason why the example could not be followed here. A few years previously the Advisory Board of Agriculture expressed the opinion that action was desirable, and when asked for a report, the manager of the Produce Export Department said, and rightly so at that time, that it was practically impossible to secure a supply of pigs suitable for the export trade. Inquiries were made for 100 suitable pigs, likely to create a favorable impression in London; but they could not be obtained. Spasmodic trial shipments were subsequently made with varying results, and in one case, after all expenses were paid, the returns were just equal to those ruling locally; but at that time bacon and pork were at low values in London. Only recently the Yahl factory (Mount Gambier) had sent to the London Dairy and Bacon show a few sides of bacon that had to compete with the best English products, and whilst not successful in gaining prizes, it was creditable to find that they beat the New South Wales exhibit by five points. Yet when sold the price netted was approximately 6d. a pound, which was not nearly equal to present local values. Australian bacon suffered by contrast with the English on account of not being specially dressed to English custom, and the flavor did not compare with the English specially fed hogs. England's bill for imported pig products during the past year was approximately 25 to 26 million pounds, and with American consumption overtaking supplies there was a brighter outlook for Australia. Yet the number of pigs had not shown any appreciable increase for 14 years. In South Australia alone 14,000 fewer pigs passed through the Adelaide market in 1913 than was the case in 1912. Present values warranted the feeding of pigs at high pressure, especially now farmers were experiencing difficulty in obtaining remunerative values for produce such as barley, oats, potatoes, &c. The reverse practice should obtain when foodstuffs were at higher values, and pigs were cheap. Then it was justifiable to treat the pig as the consumer of coarse farm produce, steadily growing into a good frame as a store, to be subsequently fattened up upon concentrated foods.

FEEDING YOUNG PIGS.

Successful feeding of pigs provided one of the most difficult tasks of the farmer. If he pulled the litter through the first 24 hours after birth he had gone a long way towards successful rearing. Half of the losses among young pigs occurred soon after birth, for many were laid upon unless vigilance was exercised. A lot depended on the health of the sow prior to farrowing. Sows should not be too fat, but should not be allowed to get too low in condition, or they would not provide sufficient milk for their young, nor would the young be so vigorous. Consequently growth would be checked at a period when the piglets should acquire a habit of rapid growth. The sow should come in two weeks before farrowing. A good practice was to give her half a pint of castor oil in the food within a couple of days before farrowing. For a week before it was recommended giving her two bran mashes, and a couple of handfuls of bran in the food daily. Prior to this she should have been in a small grass, lucerne, or clover paddock, where she could have sufficient exercise to keep her in good health.

These simple precautions often obviated a vast amount of trouble, and reduced loss by assisting the sow to more readily deliver her young in a much better condition. Often when a sow experienced trouble one or two suckers were born much earlier than the remainder, and in the cold weather these contracted a chill and died, or the sow, being restless, rolled upon them. Further, a sow judiciously fed before farrowing had not the same inclination to devour her young. This habit was due to a depraved appetite. After farrowing was completed, the sow should be moderately fed during the first four days, especially if her udder were well flushed with milk, as the young ones might not take it away fast enough. As a rule she should be given a nice warm feed of milk and bran with a little pollard, but no grain, because it might cause constipation and affect her milk, and consequently the young. At all times a supply of charcoal with say a mixture of 25lbs. of lime and 1lb. of salt, or ½lb. of saltpetre, should be placed where sows could readily get it in their sties. The sties should admit sunlight, possess good drainage, be free from draughts, and have well-laid floors. If possible a small railing should be placed around the three sides, say 5in. or 6in. high, and 8in. from the walls. The young pigs could then get away safely from their mother when she laid down. The bedding, or straw, for farrowing sows should not be long, for invariably it was the cause of a death or two among the young suckers, owing to the ease with which they become embedded and consequently laid upon.

Wheaten straw was the best to use for bedding. The little pigs until about three weeks old did little else but sleep and drink. They should not be allowed to roam at large with the mother. When it was noticed that they had a disposition to do so it was time to give them a little drink on their own, for much depended upon getting them to learn to drink early. Milk which had had the chill taken off should be supplied in a shallow, clean tin trough, where the sow could not gain access to it. Care should be exercised to see that the suckers did not gorge themselves, or bowel trouble would occur, If anything were mixed with the milk, say at four weeks, a little barley meal, but not bran, was recommended. As they grew the pigs might have a little scalded pollard added. This prepared them for the critical period of weaning, which should take place at about eight weeks old. Young pigs rarely went wrong, and if they did, it was generally due to ill-judged feeding just before or after weaning. All male pigs should be emasculated at about three or four weeks old. If castrated say at six weeks to two months they invariably possessed a much thicker rind when made into bacon. With liberal feeding in the form of milk or whey with pollard, soaked, crushed barley, wheat, and greenfeed, the young pigs should have made good growth at eight weeks old, and were then well able to look after themselves. Should they scour at any time when sucking the sow the food of the latter should be changed. When weaned they should be fed at frequent intervals to minimise the loss of their mother's milk as much as possible.

FEEDING.

" The opportunity to make money out of pigs is," he continued, " to a large extent governed by methods of feeding—the general aim should be to supply at the least cost a ration producing the highest quality of pork or bacon. In years gone by the main object was to produce a pig of extra heavy weight, but what is now required is a younger and lighter pig for Australian use ; for pork, say, 80lbs. to 90lbs., and bacon 120lbs., dressed weight. The English market demands heavier pigs, say, from 160lbs. to 180lbs. The pig killing 120lbs. weight for bacon is the most economically fed. A young pig, if properly fed, will produce 1lb. of green pork out of 4lbs. of food, equal in food value to pollard, whilst a fully-matured pig may take from 6lbs. to 8lbs. to make the same gain of 1lb. in weight. Taking pollard at 1s. per bushel, or 0·6 of a penny a pound, when fed to a young pig the pork will cost less than 2½d. per pound, whereas the cost of adding weight to a pollard-fed mature pig is over 3½d. each pound.

Pigs may fairly be said to be the most economical meat producers of all farm stock, judged by the quantity of meat for the food consumed. The average weight of a sucker when born is 2½lbs., and from reliable records we find that under proper management they will make an increase in weight during the first week of almost 2lbs., equal to an increase of, say, 76 per cent. The percentage gain in weight for food consumed becomes less every week, until in the sixteenth or seventeenth week, the increase is not more than 6 per cent. There is a difference of opinion in the mind of feeders whether it is better to cook grain or simply to soak it. Soaking has proved to be the preferable method, being cheaper and handier. Exhaustive experiments have proved that on an average 505lbs. of cooked grain will produce 100lbs. of pork, whereas 476lbs., soaked, will give the same results. Another point of interest was proved, viz., that by feeding mixed grains a saving of at least 15 per cent. in the amount required to produce a pound of pork was effected.

The maintenance requirements of a pig have been set down at 2lbs. of food possessing the equivalent food value of 2lbs. pollard for every 100lbs. live weight, and it is only when they receive food in excess of this amount that they make increased weight and lay on flesh. Providing they are properly fed, then the more they can be encouraged to consume in 24 hours the quicker will they be fit for market. The feeder should never allow any excess over requirements to be left in the trough, feeding only just what they will clean up. It is not advisable when feeding to give it in too sloppy a condition, but more of the consistency of porridge—say three of milk, whey, or water to one of solids—pollard, barley, wheat, &c. A plentiful supply of good water should at all times be available for the pigs. When young growing pigs are out running on pastures do not cut off their supply of milk and grain, but give a little always, and finish them off in the sty with grain. If during the period between the sixth to the twelfth week of the life of the pig it is injudiciously fed and stunted it will become a poor doer, and no matter what subsequent treatment it may receive will not be so profitable.

Solid foodstuffs recommended are—Peas, beans, barley, oats, bran, pollard, rye, wheat; greenstuffs include lucerne, clover, peas, barley; roots comprise potatoes, mangels, swedes, artichokes, &c.; and liquids, skim milk, water, and whey. Peas provide a large percentage of protein or nitrogenous matter, and are consequently good for young growing pigs, and the production of lean bacon. If fed whole they are very palatable, but prove too wasteful, a large percentage passing through the system undigested. When crushed they are better. Pea meal, whilst a valuable food, must not be fed alone. It is difficult to digest, and is likely to sicken pigs. A good plan is to add a little ground oats with the peas. Beans, where they can be grown successfully, prove excellent food. They are rich in protein, and are thus valuable for enriching the ration. However, if fed in any considerable quantity they will result in producing what is known as a soft bacon; so for best results it is advisable to feed them with other grain.

Barley may with truth be described as the best of all grains for pigs, especially for the production of good bacon. This applies both for quantity and quality. Barley should always be crushed and soaked, and for young pigs should be mixed with pollard. Damaged wheat is also a valuable food for the production of good bacon, and gives better results when converted into pork than when sold as grain. It takes on an average 5lbs. of wheat to produce 1lb. of pork. Split or damaged wheat can at most times be turned over to a greater profit in this way. Rye has a lower feeding value than either wheat or barley. It will, however, produce an equal increase in weight of the pig, but the quality of the flesh is inferior, and therefore it is advisable to mix it with other grain. Where oats are largely used the husks should be removed by soaking in water. They are excellent food for feeding grown pigs, making good meat, but they have a slight disadvantage, being of rather too fibrous a nature for young pigs. A little crushed oats are best mixed with other foods. The famous York hams are supposed to owe much of their excellent flavor to the fact that the pigs are very largely fed upon oatmeal.

MILL AND DAIRY BY-PRODUCTS.

Pollard has at all times proved an excellent food when fed to pigs of all ages and for all purposes, but having the reputation of producing pork of rather a soft nature, for this reason it may be better fed with a little barley or damaged wheat. Pollard when fed with milk gives very satisfactory all-round results. Bran, although rich in protein content, must not be accepted as a pig fattener. It is an excellent milk producer, and for this reason is valuable food for a sow just before or after farrowing. It also has the effect of keeping the bowels in good order. Because of the high food value of separator milk, dairying and pig-raising must go hand in hand for best returns. By no means can pigs be so profitably turned into good baconers as where a liberal supply of skim milk is available. To obtain fullest value it must be fed in conjunction with any of the grains grown upon the farm. Whilst of considerable value as a food, whey is not equal to skim milk or butter milk, especially when fed to younger pigs. Again, it will not produce as good a quality of bacon unless it has other foods rich in protein content added to it. The bulk of this valuable food constituent is taken from the whole milk to form cheese. The feeding value of whey is really only half that of separator milk. In Denmark the results obtained from most exhaustive experiments proved that for feeding purposes 6lbs. of skim milk were equal to 12lbs. of whey or 1lb. of crushed barley. When feeding whey it is advisable to use, say, 3lbs. to 4lbs. with 1lb. of crushed barley meal or pollard. Pure butter milk to which no water has been added is of equal food value to skim milk. Farmers must not forget that this when obtained at factories almost always has a large quantity of water, possibly 30 per cent. to 50 per cent., added to it. Many instances could be given of considerable loss being occasioned where pigs were fed on watered buttermilk alone, a form of starvation, there being insufficient nutriment or solids present to satisfy the ordinary maintenance or body demands. Buttermilk, as taken from the factories when fed with grain or pollard, &c., to make up for any deficiency in nutriment will give good results.

GAIN IN LIVE WEIGHTS.

Taking it that the young pig when ready to wean weighs 26lbs. to 32lbs. live weight, at 10 weeks he should weigh 40lbs., and at six to seven months he should turn the scale at 150lbs. to 180lbs. live weight. The following will produce 1lb. extra weight of flesh, viz., 4½lbs. of soaked barley; or preferably 3·64lbs. of soaked barley with 5lbs. of separated milk, putting on the extra weight from 40lbs. to 180lbs. at the following cost, milk being free :—Ten and a half bushels of barley at 2s., £1 1s. Seventy gallons of separated milk would also be required. Assuming the young pigs cost the breeder at 10 weeks 19s., the total cost till ready for the knife would be £2. At present values the pig weighing 160lbs. live weight would realise £3 10s., leaving a profit of 30s. per pig. This gives a return of 4s. per bushel for barley and 9s. for any little labor connected with the feeding and skim milk. The mating of very young sows with the boar at six to seven months is not always advisable. A difference of opinion exists whether to mate at six, 10, or 15 months, but generally the 10 months is accepted as the better age. The young sow may be very restless or excited when farrowing owing to inexperience, and at times a shortness of milk supply will result. In this case remove the young, and when the sow finishes farrowing quietly place one or two little ones to her teats ; she will then generally respond and let down her milk, when all suckers may be put with her. Young and very aged sows should be fed three times daily when suckling a good litter, the food being of soft character, warm, and easily digested.

RETURN FOR VARIOUS RATIONS.

Pigs of from 60lbs. to 100lbs. live weight consume on an average 3·35lbs. of foods, say pollard, per day, and when at 100lbs. to 150lbs. of live weight, 4¾lbs. If pure buttermilk only is fed, the pig would require to consume 6galls. to obtain sufficient nutriment, whilst 9galls. of ordinary diluted buttermilk would be necessary if used as a substitute. Potatoes offer many advantages to pigkeepers when the price is low, like barley and oats, so that nothing better can be done than to feed them. They require to be fed in conjunction with grain, more specially with milk or whey. The best results are obtained by feeding 4lbs. of soaked grain, four of skimmed milk, and three of potatoes. In food value 4lbs. of potatoes are equivalent to 1lb. of barley or wheat as a food. Potatoes, although good when fed raw, are improved very much by pulping and cooking. They should always be cooked, and the water from the potatoes should not be used, as the tannin contained in it will coat the stomach, and prevent a free and natural secretion of the digestive fluids. When fed to young pigs the following rations will be required :—No 1—Cooked potatoes, 3lbs. ; skimmed milk, 10lbs. ; or No. 2—Cooked potatoes, 4lbs. ; buttermilk, 6lbs. ; barley, 1lb. Sugar beets are preferred by pigs to any other roots. It is not advisable to give them too freely, but they may form a fourth of the ration. Lucerne, tares, and clover are all valuable for grazing, or feeding a little in the sties, but grain must also be given. Molasses is sometimes given to pigs in small quantities, say 1lb. per day; its chief value is as an appetiser. Any kind of fruit may be fed, but it must be distinctly understood that grain must also be added. All pigs are the better for a run in a nice, handy, well-grassed paddock of lucerne.

EARLY MATURITY.

The secret of producing early pork is to give a liberal allowance of green feed. When fattening for bacon it is advisable to put pigs in the pen at, say, five months old. At this age, if judiciously fed, they will develop into nice-conditioned baconers at six to seven months, and weigh from 120lbs. to 130lbs. dressed. Porkers should weigh 70lbs, to 90lbs., and this weight can be produced at four or five months, according to breed and feeding. Danish breeders mix their grain as follows :—For pigs up to four months old.—Mixture—Eight parts of wheat, eight parts of barley, one part of oats. For pigs over four months.—Mixture—Fourteen parts barley, four parts wheat, one part oats. All the food is soaked, crushed, and green food is supplied at midday. For a sow producing two litters, each of eight suckers, a year, a farmer would require to provide the following amount of food to rear them :—Daily rations for sow carrying litter—Seven pounds to 8lbs. of grain, 1½galls. separated milk, 5lbs. of good green lucerne. It will take approximately 18bush. to 20bush. grain and 75galls. skimmed milk to rear each pig, inclusive of feeding to sow; to rear 16, 36bush. grain, 1,250galls. skimmed milk, and green feed.

FOOD RATIONS AND COST.

Daily rations for pigs, supplying all that is necessary for body development and fattening, with skimmed milk not charged up in the costs, includes :—No. 1—Daily rations from two to three months old—Six pounds skimmed milk, 1½lbs. of pollard, 1lb. barley. The month's total food amounts to 45lbs. of pollard, 30lbs. of barley, and 18galls. skimmed milk. Total cost, 3s. 5d. No. 2.—Daily ration from three to five months old—Two pounds wheat, 2lbs. barley, 6galls. skimmed milk. Total requirements for the two months (60 days), 120lbs. wheat at 3s. per bushel, 150lbs. barley at 1s. 10d., 36galls. skimmed milk. Total cost, 11s. 6d. From five to six months old a daily ration is recommended as follows :—Three pounds of skimmed milk, 2lbs. of wheat, 3½lbs. of barley. This would cost for the month—Wheat 3s., barley, 3s. 10d.; with total cost for the month's feeding, 6s. 10d. In the final month (sixth to seventh month) peas may be fed with the ration to top off. Where no peas are grown feed daily 1½lbs. of wheat, 5½lbs. barley. With wheat costing 2s. 3d., and barley 6s., the total cost for the month would be 8s. 3d. The total cost of food from weaning to marketing condition would be £1 10s., made up as follows :—Barley, 9bush. at 1s. 10d. on farm, 16s. 6d.; wheat, 3bush. 45lbs. at 3s. on farm, 11s. 3d.; pollard, 2¼bush. at 1s. on farm, 2s. 3d. Where potatoes are low in value or unsuitable for market, they may be fed with much success. A good ration for fattening a pig is 1gall. skimmed or butter milk, 4lbs. soaked barley, and 3lbs. cooked potatoes. A little green lucerne during the summer, or lucerne hay during winter, is an excellent food in conjunction with the rations mentioned, varying the quantity from 1lb, to 3lbs. daily, according to age.

STUDY MEAT AND FODDER MARKETS.

It has been shown that one can raise a properly cared for young pig from two months of age until ready for market, when 160lbs. live weight, at a cost of 30s. Such a pig would realise from 75s. to 85s., leaving a substantial profit. To dairymen, who can best raise pigs profitably on account of their having skimmed milk, it requires approximately 80galls. to feed the sow and raise each young pig. Therefore, one sow to every 8 cows kept should be a safe margin, or perhaps it would be better to say one cow to every sucker. A sow producing two litters of eight in each litter requires the following food daily when carrying her litter for, say, eight weeks :—6lbs. to 8lbs. of grain, 1½galls. skimmed milk, 5lbs. greenstuff, lucerne, &c. With foodstuffs at present low values, and pigs realising excellent prices, there are great possibilities in pig-raising, especially in districts where cows are kept as the main source of income. Such a fine source of revenue should not be neglected. In conclusion, it may be said that a liberal feeder may easily let the profits slip through his fingers by keeping his pigs in dirty, draughty, and cold sties; feeding a badly-bred, non-thrifty, long-legged, and unshapely animal; or by irregularity in feeding and careless marketing. When forwarded to market the pigs should be well protected from the sun and given, if possible, a good hosing with water; this will add to their comfort, and improve their appearance. They should not be travelled upon a full stomach. This caution is especially applicable in hot weather, as it often means the death of one or more. At present values it would be ridiculous to think of exporting. This can only be entertained when values are at a much lower level. The pig business to-day, and so far as one can foresee into the future, is a most profitable proposition by reason of easy breeding, cheap feeding, and highly remunerative values obtainable at an early age."

THE NEED FOR A MODEL FARM ON THE DRAINED LAND IN THE LOWER SOUTH-EAST.

Mr. Holzgrefe delivered an address as follows :—"It is generally understood that the Agricultural Department of the State exists for the purpose of teaching and helping the people to use their land to the best advantage. But there is a great difference between telling us that, if we do so-and-so we will get along all right, and in showing us that the advice is good by means of practical illustration. The various experimental blocks we now have and have had in the Millicent district and in other parts of the South-East have been of little use to agriculturists, graziers, and others, excepting the fact that they have taught us to be careful about spending money in working the poorer classes of land. The block that was worked at Millicent some years ago under the superintendence of Professor Lowrie, and owned by Mr. C. A. Malone, was one of the best. Most of the others have been failures. What we should teach young men who desire to go on the land is how to manage a farm and how to make it pay.

"We do not want any experimenting on our average soils. We have a good, assured rainfall, and land that will grow almost anything—grain of all kinds, potatoes, root and fodder crops, and nearly all kinds of English grasses and fruit. The question for the young farmer is not what to grow, but how to grow it. We have our Agricultural Bureau, which is doing and has done good work in increasing our knowledge of scientific methods of dealing with different soils, handling stock, &c.; but very few young men earning a living on the land take any interest in the Bureau and its meetings. A good many of them have joined our Branch here at different times, and after attending one or two meetings, have drifted away again and withdrawn from the Branch. This sort of thing is too slow for them. They are not usually inclined to accept advice given in the form of lectures and discussions. If the points are demonstrated, however, they will not be slow to follow on the same lines. The result, I am sure, would be a distinct improvement in our methods of farming and in the management of stock.

"The main point in this paper is to discuss the question of establishing a model farm. By this I mean a farm conducted on ordinary commercial lines by a manager who thoroughly understands his business and is up-to-date in his methods. Let the Government select or purchase 500 acres, or not more than 1,000 acres, of land of the average quality of the soil that is now being drained, or is already drained, to the north of Millicent, or on some part of the flats. The most important thing to consider is the choice of a manager to work and superintend the farm. I would prefer a young man, the son of a farmer, and who has had a good agricultural college training. There are plenty of smart young fellows at Roseworthy who could fill the position. The man selected should be able to handle all classes of farming machinery and implements, and should have some knowledge of livestock kept on an up-to-date farm, where grazing and cultivation are carried on conjointly.

"Another important matter is that the farm should be well appointed. It should have substantial buildings, and paddocks fenced and arranged to the best advantage, as a good deal of time is lost on a badly-arranged farm. If a farm of this kind were established in a district where grain, fodder, and root crops are grown, and stock-raising was also included in the work, I am sure it would pay working expenses and interest on the capital expended in purchasing land, buildings, implements, stock, &c. It would undoubtedly be of benefit to surrounding settlers. There should be days set apart at frequent intervals throughout the year when all farmers could inspect the farm, and obtain information regarding the system followed in manuring, harvesting, cropping, etc., and with regard to the rotation of crops, "Balance-sheets covering each year's operations should also be published in *The Journal of Agriculture*, together with full reports from the manager. There is a Government farm at Kybybolite, but it is chiefly an experimental station. I have nothing but good to say of its management, but it is not of much value to those working on different classes of soil. It is 108 miles from Millicent by train, and it takes the best part of three days to get there and back again.

"Moreover, the rainfall at Kybybolite is about 10in. less per annum than that at Millicent. It is a great mistake to say that 'anyone can work good land.' A model farm on average soil would help us to make far better use of our resources than we are making of them at the present time."

THE DISCUSSION.

Mr. J. B. Mitchell said the State was not warranted in going to the expense that would be entailed in establishing and maintaining a model farm as suggested by Mr. Holzgrefe. If the young farmers had sufficient interest in their work they could get the information necessary from the sources already provided; they could also go around to various private farms that were well conducted, and learn lessons from these.

Mr. Wray thought that if the young farmers had not sufficient interest in their work to attend lectures, &c., they should give up their occupation. Men desirous of learning could take employment with competent farmers and gain experience in this way.

The Hon. T. Pascoe said he had listened to the paper with a good deal of interest. The writer had suggested the establishment of a model farm, and the appointment of a young man from the Roseworthy Agricultural College as manager. Attendance at a college would not teach a young man the business part of farming. The young man who went there was not of sufficient age to thoroughly grasp the business part of a going concern. He gained a certain amount of experience and technical knowledge that would be useful to him in the future, but he would not be the man to go on to a farm and manage it, and teach farmers how farms should be managed. If a model farm were started here they would have to farm on those particular lines which were most payable, and little in the nature of experimenting could be done. If experiments had not been conducted by the Government on the experimental farms, or by individual farmers, on which they had made a loss, farming in South Australia would not be up to the standard which it had reached at the present time. They could make the College farm at Roseworthy pay well by growing hay; but it would lose its value as an educational institution. The reason he was content to see the experimental farms presenting a balance-sheet showing no profit was that they were carrying on experiments that would prove of benefit to South Australia in years to come. They should not measure the value of these farms by the balance-sheets, but by the increased prosperity of the farming industry in this State,

VISITORS ENTERTAINED.

The officers of the department, members of the Advisory Board, visiting delegates, and members of the press were entertained at lunch and dinner by the members of the local Branch.

CONFERENCE OF NORTHERN YORKE'S PENINSULA BRANCHES.

The Northern Yorke's Peninsula Branches of the Agricultural Bureau, together with the Yorke's Peninsula Field Trial and Show Society, held their annual conference at Kadina on April 17th.

The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), Director of Agriculture (Professor W. Lowrie, M.A., B.Sc.), Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.), and Messrs. F. Coleman (vice-chairman), Geo. Geffrey, and G. G. Nicholls (secretary), of the Advisory Board, attended; and in addition the following delegates representing the undermentioned Branches :—Arthurton—J. Welch, W. R. Stephenson ; Blyth—E. C. Deland ; Kadina—H. Paterson, R. C. Price, J. H. Price, M. Quinn, F. G. Brinkworth, J. N. Pedler, R. Correll, R. Truscott ; Maitland—S. P. Smith, C. A. Pitcher, G. Bentley, H. G. Tossell ; Moonta—J. Luke ; Paskeville—P. A. Uren, G. H. Bammann, T. M. Forbes, R. D. Norris, F. H. Bussenschutt, H. F. Roch, A. H. Bussenschutt, A. F. Bussenschutt, E. G. Lamming, J. P. Pontifex, T. R. Brinkworth ; Pine Forest—W. Attenborough, D. Hanna, R. D. Goodridge, E. Hewett, J. Edwards, J. G. Beare ; Port Broughton—H. P. Whittaker, W. R. Whittaker, T. E. Pattingale, A. J. Fletcher, J. H. Fletcher, and H. M. Adams.

The chair was occupied by the President of the local Branch of the Bureau (Mr. R. Correll), who extended a hearty welcome to the visitors.

MINISTER OPENS THE CONFERENCE.

The Hon. T. Pascoe said he thought he would not be doing his duty to such an important conference as this if he neglected to be present. The two institutions which had combined for the purpose of holding the conference that day were of such a nature that they must run hand in hand in agricultural work. By field trials they would be enabled to secure those implements which were best suited for their land.

It was on Yorke's Peninsula that the stump-jump plough was first used, generally by the farmers, and in this way the Field Trial Society had done much in the way of solving the problems connected with farming in mallee and stony country.

This conference represented a greater number of old Branches of the Bureau than any other district conference. With one or two exceptions, those which were comprised in the district were formed in the 80's or early 90's. This showed that an early interest was taken in the educational side of agriculture. What was more, they had been able to keep up that interest, and it spoke well for the farmers that it was so.

ARTIFICIAL MANURES.

Not only had the lead been taken in the matter of stump-jump implements, but the practice of applying artificial manures was first generally adopted by Peninsula farmers. The names of Cudmore, Correll, and Parsons, and others known to the Conference were those of men who had enterprise enough to adopt manuring before the practice had been proved profitable. Statistics revealed the immense value of the use of manures and the adoption of more thorough methods of cultivation. In 1890 the average rainfall of Kadina (which was fairly representative of the average rainfall of the Lower North) during the growing period was 23·02in. The average yield of grain per acre was 5·7bush. In 1891 the fall of rain for the same period was 10·14in., and the yield dropped to an average of 3·21bush. per acre. Fourteen years later, in 1905, the rainfall at Kadina during the growing months was 17·09in., and the average yield 15·43bush. per acre. In 1912 the rainfall was 10·61in., and the average yield 13·33bush.—a very striking and significant fact, when compared with the 3·21bush. average of 1891, with a 10·14in. fall of rain.

Great as had been the improvement in the past, and satisfactory as had been the results, they should not rest content with their achievements. There were still agricultural problems for them to solve and practices which they could test, and it behoved them to maintain, at least, the enterprise that had characterised their work during the past years. Thus only could they maintain their reputation as leading farmers of their State and of the Commonwealth. He had pleasure in declaring the Conference open.

THANKS TO THE MINISTER.

Mr. J. Malcolm, in proposing a vote of thanks to the Minister, referred to the esteem in which the Hon. T. Pascoe was held. As had been said, the combination of the Field Trial Society and the Agricultural Bureau was a particularly happy one. He mentioned that arrangements had been made to hold a field trial at Bute in the near future, and he extended a hearty invitation to the Minister to be present. He moved a hearty vote of thanks.

Mr. J. N. Pedler seconded the vote.

Mr. Geo. Jeffrey (Advisory Board) referred eulogistically to the remarks of the Minister. Farmers throughout South Australia were not keeping the same number of sheep that they were 10 or 12 years ago. He admitted that the seasons had been against keeping sheep, but nevertheless he thought farmers were making a mistake. He was glad, as a member of the Advisory Board, to be present, and heartily supported the vote of thanks.

The Minister responded, and in reply to a question, gave some interesting particulars regarding the bulk handling of wheat, with which subject he had dealt fully at the Conference of Northern Branches held at Gladstone (*see* March issue, page 818).

IMPROVEMENT OF WHEAT

Mr. S. T. Barr, of the Pine Forest Branch, read a paper under the title of "Grading Seed." This will be found printed on page 992 of the April, 1914, issue.

Mr. F. Coleman (Vice-Chairman of the Advisory Board), said—"To a casual observer a flock of 100 stud Merino four-tooth ewes appear all alike, yet the breeder would say that not two of the ewes were exactly alike, and he would, if selecting some for show purposes, very soon have separated half a dozen that were better than the rest, and out of these one ewe that was a better all-round sheep than any other ewe in the flock. So, too, could he pick out very quickly a few that were distinctly inferior to the average.

"Quetelet illustrated this by comparing the height of 1,000 men of the same race : if ranged in line according to height, there were a few very tall men and a few very short, the great majority being only slightly higher or lower than the mean. This variation is inherent in all organic life. There are no two wheat plants exactly alike.

"Upon this inherent tendency to vary, the breeder, whether of Merino sheep or of wheat, bases the work of improving his stock. Australia, and South Australia, has done magnificent work in improving the Merino sheep ; there is a great field before us in the improvement of the wheat of the world, of which we already have grown the best.

"As there are breeds of Merino sheep adapted to certain climatic conditions, to soils and situations, so with the wheat plant, varieties from a cooler, heavier rainfall district, removed to a drier area take some seasons to become acclimatised. We may improve our wheats in three ways :—By grading ; selection and grading ; and cross-fertilising, selection, and grading.

GRADING.

"By grading we mean the re-cleaning of the harvest wheat of whiteheads, wild oats, chaff, straw, &c., and then sorting the cleaned wheat into three or four lots according to size, the first grade being the finest plump grain, the lowest grade consisting of the small cracked and pinched grains of wheat and foreign seeds, such as wild turnip, cabbage, drake, &c. Prof. Lowrie said, last year, that from 8 per cent. to 15 per cent. of these smaller grains could be removed, and that Dr. Cobb, of N.S.W., had shown by scientific tests that there was an 18 per cent. advantage in favor of sowing the larger grains; but allowing only 10 per cent. that would mean an addition of 2,000,000bush. to our annual wheat crop.

" The saving of the cracked grain alone for fowl or pig feed would in many cases justify the trouble of grading the seed. The drilling in of broken grain is pure waste of good food material. By grading, and sowing only the best and plumpest seed, our wheat will be kept from deterioration.

SELECTION.

" There has been unconscious selection from the very first; that yielding most value for food was given advantages. Productiveness insured survival, because of the greater chance of reproduction and of protection by man. Until less than a 100 years ago wheat was simply wheat. The names of Le Coutier who selected Talavera, of Shireff with his Squarehead, and of Major Hallet who raised his Nursery Pedigree wheats, are all comparitively recent. By means of selection the yield of wheat can be materially increased. The hand-picking of a crop to remove the strangers, or 'rogues,' or other plants not true to type, while often necessary when first growing a new variety of wheat, does not improve the wheat beyond securing a clean sample free from barley, &c. Plump grain alone may result from imperfect heads or poor plants; indeed the finest grain is often reaped from comparatively thin poor crops; hence the need for something more than simply the mechanical grading out of small, pinched, or defective grains.

" The most effective selection is in sowing year after year on separate plots the best grains from the best heads from the best plants; the best plants being judged in regard to yield, disease resistance, quality of wheat, retention of grain, and strength of straw. If the best 100 grains are selected from the best plant and this is repeated each year under rigorous selection, discarding unfitness in any direction, such as unevenness of growth, ripening unevenly, &c. seed from such plots will give an increase in yield and be pure and true to type. The seed from the small plot of 100 plants should give about 2lbs.; this seed used on the block seed plot of say a twelfth of an acre would give from ¾bush. to 1bush., and with this an acre could be sown the third season. Major Hallet, in 1859, from a head of wheat 4⅜in. long obtained 47 grains; by selection, he, in 1861, got from this wheat a head 8⅜in. long, with 123 grains, and 1,052 grains on one plant. In Minnesota an increase of from 22½bush. to 28½bush. per acre was secured in five years. The length of head, number of grains, and tillering power of the wheat plant can be largely increased by selection.

" The appearance of the crop is often deceptive. Federation, when I grew it first in 1901 with seven other wheats of Mr. Farrer's, I judged would come about fifth in order of yield out of 21 sorts all grown on exactly the same area of land; but somewhat to my surprise, as it has surprised many a farmer since, Federation came out well on top The practice advocated by Mr W. H. Hays in his Centgener system of small plots of equal size, each with 100 grains, the yield from which is carefully weighed, is a practical one. Selection has in South Australia given us such wheats as Dart's Imperial, Marshall's No. 3, Gluyas, Carmichael's Eclipse, Correll's Le Huguenot, King's Early, Viking, Petatz Surprise, College Eclipse, Leak's Rustproof, Baroota Wonder, Steinwedel, and many others. Selection is the most important part of wheat improvement. These points should be considered—(1) suitability to the district, (2) yielding capacity, (3) retention of grain, yet not too tough to thrash, (4) freedom from disease, (5) resistance to drought, (6) quality of grain, (7) good stiff straw, (8) early maturity in dry districts, and (9) resistance to bunt. If by selection we can get our wheat to yield only one grain more per head the yearly crop in South Australia would yield half a million extra bushels without effort or cost worth mentioning, in value some £100,000. Major Hallet increased the grain from 47 to 123 per head.

CROSS FERTILISATION.

"Chas. Darwin said 'Nature abhors perpetual self-fertilisation.' Wheat is normally self-fertilised, yet in cross-breeding we get increased vigor, breaks in the type, and wide variations, hence greater possibilities for selection. While the actual operation of cross-breeding wheat is not at all difficult, yet the judgment, skill, and experience required in selecting and fixing the type is a matter for experts and plant breeders, because of the time and attention this work involves at a busy time of the year. Probably our best wheat breeders do not average one cross in 100 that is worth persisting with, and from five to eight years are required to properly fix cross-bred wheats. I recommend the trial in small hand plots of new varieties to the district, and the careful inspection of his crops by the farmer about hay-cutting time ; an hour or so should be spent now and again marking with a stick the very best plants of the variety growing under normal conditions. Later, when ripe enough, he should cut these heads and thrash, clean, and sow the grain as a hand plot.

"Cross-breeding appears to have been practised widely only during the past 40 years or so. In America we have Pringle's Defiance; A. E. Blount's Improved Fife, Horneblende, &c.; Dr. Saunders' Preston, Stanley, and Marquis; A. N. Jones's Clawson and Winter Fife. Garton and Biffen, in England; Vilmorin, of France; Howard, of India; and in South Australia, Richard Marshall, claim front rank. The Agricultural Colleges and Experimental Farms are all doing excellent work; but above all stands the name of Wm. Farrer, of New South Wales, whose aim was to produce varieties with all the characteristic excellences of the very best of the old South Australian sorts, but yielding stronger flour ; to produce varieties which are equal to the very best grown in Minnesota or Manitoba in flour strength, but with mellower grain and of better appearance.

" In that aim he was wonderfully successful. Dr. Cherry, the Director of Agriculture in Victoria, said, in 1909, that Wm. Farrer had added in that season alone £250,000 to the value of the Victorian wheat crop as a result of his work."

Continuing, Mr. Coleman said Mr. A. G. Edquist, of the Education Department, had been doing a great deal of good work in encouraging the boys in schools in the agricultural districts to do something in the way of wheat selection. This work was begun in 1912, and the results thus extended over a period of two years. The average number of grains per head in Silver King variety had been increased from 26·4 to 50·9; in Federation, 32·7 to 41·35; and in Lotts, from 22·9 to 39·7. This was highly creditable. The work being done was not only valuable from the educational point of view, but the practical scientific value of the results was very considerable. Efforts in this direction were well worthy of encouragement, and greater support than had been given was warranted.

Some years ago Mr. Coleman had planted wheat with different spaces between the grains. The results were as follows :—

Space between Seeds.	Amount of Seed used per Acre.			Average Number of Heads per Plant.	Yield of Best Plant.		Yield of Grain per Acre.	
in.	bush.	lbs.	oz.		heads.	grs.	bush.	lbs.
3	1	19	0	3·43	6	156	49	27
6	0	19	12	8 22	14	462	37	50
9	0	8	12	12·5	19	627	25	35
12	0	5	0	16·0	38	1,254	18	25
15	0	3	3	19·21	33	1,089	19	21
18	0	2	4	29·94	41	1,353	15	33

These results were interesting, and indicated a means whereby a man who had only a small quantity of special grain from which he wished to raise seed for a larger area, could secure a greater yield by such very thin seeding as above.

DISCUSSION.

Mr. E. C. Deland (Blyth) said there was need for the selection and cleaning of seed. The great deficiency of the early wheats in this State was in their strength, *i.e.*, the amount of first-class flour that could be obtained from a grain of wheat. The old wheats, such as the old Purple Straws, yielded grain that was just about equal to the best Manitoban. The practice of selection carried out properly would benefit the whole State. Federation was one of the best wheats as an average yielder and for the quality of the grain. There was a great need for some farmers to clean their sample of grain better. Men who sold rubbish in their wheat were lowering the standard of South Australian grain in the markets of the world. The quantity of unsound grain in the average parcel of wheat put on the market in South Australia was about 2½lbs. per bushel. Millers could not make flour out of rubbish, but had to sell this back to the farmers in the bran and pollard. They thus paid the penalty, even within the borders of the State. With regard to the bulk handling of wheat, he had come to the conclusion, after careful consideration, that the State was not yet in a position to profitably adopt the system. The point was that, whether the wheat left here in bags or in bulk, it had to be bagged somewhere after the miller had dealt with it. The package must count in the cost. His opinion was that they could bag it more cheaply on the farms between times than they could in Port Adelaide or in London.

Mr. W. R. Stephenson (Arthurton) did not think farmers were so neglectful in regard to their wheat as had been suggested. On nearly every farm in this district the seed grader was to be found, and clean seed was put into the ground; but farmers were not careful enough in cleaning their wheat for market.

Mr. J. Malcolm (Wallaroo) said the quality of the wheat marketed in this State was not as bad as was represented, but if farmers knew the trouble millers had with barley in the wheat they would take more care to keep this out.

Professor Lowrie said improvement in the yield and the quality of wheat by individual effort on the part of farmers was a thing to be encouraged. He did not concur with the prevailing idea that because the wheat they were shipping was f.a.q., it was the wheat that should be shipped. If the f.a.q., standard were set at 61½lbs. when it could be set at 63lbs., they were not working in the best interests of farmers. As long as farmers brought down the f.a.q., and as long as they classed the grain with the rubbish that should be taken out, so long the reputation of South Australian wheat would suffer. His contention was that there would come a time when they would have two qualities of wheat offering in South Australia. The people who had 63lb. wheat should get the benefit of it, and nobody would lose. In regard to the selection of wheat the aim should be to start from the individual plant. If they picked a number of the best heads they did not get the constancy that they got by starting with one plant (the best that could be found) and working that up. They should take three or four instances, as they might not strike the particular plant that had the desired qualities in it. The work being done by Mr. Edquist was invaluable. It was by the multitude doing this kind of thing that they would get the improvement.

In biology there was a close correlation between the habit of growth of a plant and its habit of function. It could be modified by a long process of selection, but it was there in very strong force. Therefore it was necessary to get that characteristic that would carry with it high yield, tendency to withstand disease, and a plant that tillered well. Acclimatization had a strong effect on the yield of wheat, and if they had certain varieties that had stood by them, these were the ones to which they should give first attention in the matter of selection. They should not be too anxious to get hold of a wheat that was being talked about elsewhe

The strength of the wheat was very largely a matter of climate, and he did not think it wise to spend much time in cross-breeding with the idea of increasing this. On the question of grading they were practically all agreed; nevertheless it was not practised as widely as it should be.

AFTERNOON SESSION.

[The chair was occupied by Mr. A. Goodall.]

PEAS AND RAPE.

Mr. R. D. Norris (Paskeville) read the following paper:—"It has appeared to me that the good fallow in this district should produce more than a crop of wheat. With this idea in view, I selected a clean piece of fallow in September and prepared it for the drill, as would be done for a crop of wheat. The cereals which I selected to sow for early summer fodder were rape and field peas. In order to sow the rape evenly it was necessary to mix the seed with the super. I emptied the super., one bag at a time, upon a concrete floor, and mixed with this 10lbs. of seed. I then drilled it in at the rate of 80lbs. to the acre. The peas were sown at the same time through the oat and barley feeder, as thinly as the drill would sow them. I drilled them in on the 11th of September, and in about 15 days the seed had germinated. The growth was very rapid, and by the end of October the crop was almost 12in. high, scarcely any bare ground being visible. When the feed paddocks began to get thinned out in November the cattle and sheep were turned into it. They preferred the peas at first, but later ate the rape eagerly and did well on it. The quantity of feed which this crop yielded was surprising, well repaying the cost, and, in my opinion, as far as the peas are concerned, improving the land."

Mr. W. R. Whittaker (Port Broughton) had, from experience, come to the conclusion that rape seed could not safely be mixed with super. and left unsown for any time without the germinating qualities being affected. The better method was to drill in the super., allow the seed to fall on to the surface of the soil, and then just cover it. A crop of 11 acres of rape on his farm had carried 11 head of cattle, and in addition fattened 25 sheep.

In reply, Mr. Norris stated that he sowed rape on the same day that it was mixed with the super. The seed was put just below the surface, and his practice was to attach a small harrow to the drill.

STOCK ON THE FARM.

The Director of Agriculture (Prof. Wm. Lowrie, M.A., B.Sc.) said that in the districts represented by the Conference, where the average rainfall was about 15·8in., the problems that had to be solved in order to "keep up" the land were greater, for example, than those of the district represented by the Conference of the Northern Branches held at Gladstone. In that area the question, comparatively, was an easy one. The rainfall and the climatic conditions allowed of more elasticity in their methods than conditions here. Results from the point of view of profit might compare favorably, but there was not the choice of activities in this district. These lands were lighter on the whole, and in places were brushy, thin, and limestoney. On this class of land, if a man set out to grow one crop, say wheat, and grew it frequently, and thought to make up the soil with phosphatic manures alone, he would find that conditions would not respond as they had. The soil would become loose, especially if he ploughed it; there would be difficulty in consolidating the seed bed; the risk of the land drifting would be increased; and he would have to think hard for some method of carrying more stock on the country without diminishing his wheat yields, although diminishing his wheat area. The production of fodder for stock should receive more attention than was being given it. The size of the flocks of sheep in this and other areas was decreasing. This was largely explained by the fact that the State had experienced three bad seasons, from the point of view of lambing; at the same time the price of wheat was good, and farmers were encouraged to give this every attention. On some of the country they would have to alter this state of affairs. It would gradually be found that the same amount of work would result in smaller returns. The effect of fallowing at the present day was not equal to its effect 25 years ago. Some men were going to the extent of summer fallowing. The result was that they were doing away with nine-tenths of the feed that would have been on the stubble if it had been allowed to lie out. Fallowing was one of the best means of burning up the humus that was in the soil. That being so, and no means being taken to return the organic matter to the land, naturally it would lose its cohesion, its capacity to retain moisture, and the manures did not "tell" in it so well. This difficulty would come very slowly, and in some of the best land it appeared as though it would never come at all; but this would not be the case on the average mallee land.

STRAW.

It was a difficulty to know just what should be done with the straw. If they cut portion of it with the binder, and stacked it, the stock would consume part. But the expense in this regard was appreciable. On the other hand, it they ploughed it in the soil would become too open, and dry too freely. Therefore, this practice was not advisable on the light lands. If they burned it, for the first few years they would obtain better results, but he was strongly against burning stubble. A straw stack should be in every paddock, and when the feed was soft and watery, the stock would eat it at the stack. This was the means of getting rid of the straw, and at the same time preventing the loss of it as organic matter.

It would be found an advantage to put in a bigger proportion of oats. If this were done there would be less trouble with disease; for instance, takeall, Then it was worth growing a plot for horse feed; there was nothing that put more life into horses than oats. Following this crop also there was likely to be more feed in the stubble; the stock would do better on it, and when the time came for the paddock to remain out, it would carry more natural pasture.

PEAS.

The crop most to be desired, however, was peas. The objective was some means of restoring organic matter. In England, for example, this was attained by frequent growths of clover; in New Zealand, clover and peas were utilised, but here with a 15in. rainfall, clover could not be grown successfully. They could not hope to introduce such crops as tares, so peas practically constituted the only means at their disposal. He did not recommend green manuring, but would feed the peas off on the land. The results would not be apparent immediately, probably, but the effect would last in the land over a period of several years. They should have a certain area of the farm under this crop every year, and gradually work right round the farm. The more manure they put under the peas the more nitrogen they would get into the soil, and the advantage of the larger applications of phosphate would be shown in the succeeding crops.

SHEEP OR HORNED CATTLE.

Some few days ago someone in this district suggested that farmers should keep their young calves and artificially feed these. But there was no comparison between the returns to be secured from horned stock and those from sheep. He had noticed lambs from Bute selling in the market for 23s.; 16s. or 18s. per head for lambs would pay better than feeding cattle and selling them at £16 per head.

POORER LANDS.

For the poorer land in the district he advised the growth of rye. He did not think enough had been made of this crop. Five or six acres could very well be put under this, at the rate of about 2bush. of seed per acre. It would do well in the very dry seasons, would prove a good feed for stock, and very good thatching straw. White mustard might also be given consideration. There were large areas of country down the Peninsula towards Ardrossan that did not yield much that would give better results from a seeding of rye and white mustard to be fed off with stock.

One hesitated to recommend barley, he said, because of the alleged difficulty of keeping it out of the wheat. The danger was not very great, however, as the crop should be fed down early. The real difficulty that presented itself, however, was that of putting it in just when they were so busy with their general seeding operations. The question was whether it would pay them to keep an extra team of horses simply to put in a forage crop in the month of May. His opinion was that the matter would ultimately be solved by the utilisation of motor traction. With this they could plough from 12 acres to 20 acres in a day—whilst it was not being used the only expense was interest on capital. The practical solution, however, he thought, lay in the probability of owners of tractors contracting with different farmers to turn over a certain acreage on certain days ; the farmer meanwhile going on with his seeding. It would then be an easy matter for him to leave the seeding for a day whilst he put in the barley.

STABLE MANURE.

Another method of keeping up the humus content of the soil was by using stable manure. In this connection there was downright wilful waste on the part of many farmers. They were purchasing phosphates at £4 2s. 6d. per ton, and farmyard manure contained 6lbs. of tricalcic phosphate of lime to the ton. That equalled about 40lbs. of super. It contained about 12lbs. of nitrogen—as much as was in 1cwt. of dried blood ; it also contained from 6lbs. to 8lbs. of potash, the equivalent of ⅛cwt. of sulphate of potash, which was selling at from £16 to £18 per ton. Surely this was a source of humus that should not be neglected. If they put it on heavily it would cause the crop to be plethoric, and reduce the yield of wheat. They should get it on to the ground and work it in, and by this means full benefit would be secured.

QUESTIONS.

A number of questions were asked, and in reply to these the Director said the best way to put in peas was to plough the land, work it down, and put the seed on this. In the winter, the best results would be secured from farmyard manure by putting it on the fallows, even if it could not be ploughed in immediately. In the summer, however, this would result in a great deal of volatilisation. If it was intended to put wheat on land immediately following oats, it was advisable to put the stock on it in order that they might destroy any wild oats. In most cases it was best to allow peas to ripen before feeding them off. They then came in to carry and fatten stock when the rush of lambs was over and before the stubbles were ready. If rain fell early during April, and rape were planted, it would carry and fatten more stock than peas. If the land were at all stiff it would open it up below. On the other hand, when rains were late it would not do nearly so well. As a fattening crop it was the best that could be grown.

POULTRY-KEEPING.

Mr. P. A. Uren (Paskeville) contributed the following paper :—" Poultry-keeping may be profitably undertaken by farmers, either in wheat areas, where the second quality wheat may be turned into eggs or flesh, or as an adjunct to the orchard, keeping down the grubs and codlin moth and enriching the soil. Here they would find plenty of animal food, which is beneficial to the birds and increases egg production. On the dairy farm plenty of skim milk is usually available, and this takes the place of animal food and thereby increases egg production. On many farms the wives and daughters attend to this branch with the happiest results, most ladies proving very adept in mastering the details of successful chicken rearing.

" One has only to converse with some of the successful poultrymen (though many are difficult to draw, as they are somewhat loth to tell others how to equal or perhaps beat them at their own business) to realise that there are many who to-day are largely depending upon their fowls for a livelihood. To tell such men as these that poultry do not pay is to run the risk of being ridiculed. There is, of course, another side to this picture. While many are making a capital profit from their fowls, there are, perhaps, many more who are rapidly losing money, and who possibly see nothing before them but the loss of all or the bulk of their savings. It is a well-known fact that we invariably hear of the failures in life sooner than we hear of the successes. Bad news is never slow in spreading, and this is undoubtedly the reason why there appear to be so many more failures than successes in poultry-keeping. The statement, therefore, that poultry-keeping does not pay, may be, and frequently is, perfectly true; but, as a general statement, without qualification, it is altogether erroneous and misleading. I should like, as briefly as I can, to enumerate some of the causes of failure in poultry-keeping that I have personally come across, as it may be the means of preventing others from falling into similar pits. Actual management is not so often to blame as one thinks. Nevertheless, it is wellnigh impossible to devote too much attention to the care and wellbeing of the stock. It is perhaps in the details that a good many go wrong, *i.e.*, hatching too early or too late in the season, keeping a wrong sort, feeding unsuitable foods, or housing in badly constructed or insufficiently ventilated buildings. These points undoubtedly go a long way towards seriously reducing the profits and crippling the enterprise. Only in what may be termed exceptional circumstances is it wise to attempt running an establishment devoted solely and wholly to poultry. I know there are scores of such establishments in this country at the present time that are bringing in a comfortable living, but at the same time I believe I shall have the majority of practical poultrymen with me when I say that, except under special conditions, it is unwise to try to follow along these lines. It is better to begin in quite a small way, gradually developing as one learns which branch is best adapted to the locality, which varieties thrive best, and which class of work is the best and the most congenial. Lack of capital is a very common cause of failure. There have been many instances where, owing to lack of funds, a poultry farm has had to be closed just at the time when success was practically assured, providing the place could have been kept going a little longer.

" It is necessary that anyone who takes up this work should have enough to live on for at least a year or 18 months. No profit can be reasonably expected for a year, or even two years. I have known some men to start poultry farms who were doomed to failure from the very first. Some of these men were altogether unsuited to poultry-keeping, and others did not like the work, but merely went in for it because they had to do something. Unless one's heart is in the work it is doubly hard to succeed. Congenial work is a far more important factor than many imagine. Many people take up poultry-keeping because they have failed in other walks of life. Such men are not likely to succeed ; they would not succeed in any other business ; and it is surely unjust to blame the industry when it is really the man himself who is at fault.

" Very often the poultry-keeper is not to blame for the failure of his enterprise, but rather the location in which he is living ; and no matter how skilful or painstaking he or his manager may be, success is practically impossible. Some have attempted poultry-keeping in a cold, exposed, or in a low-lying, damp, situation ; others have tried to hatch and rear chickens during the winter in a very unfavorable spot ; and others again have started poultry-keeping miles from a town or railway station. In all such cases failure is almost certain from the first. The conditions, climate, &c., should always be carefully considered beforehand. There is no doubt whatever that the largest number of failures is due to inexperience. There are thousands who at this moment firmly believe that all one has to do in order to have a successful poultry farm is to buy a few hens, give them something to eat, provide them with some sort of a shed in which to sleep, and collect a continuous supply of new-laid eggs and a nice plump chicken for the table as often as required. How hopelessly mistaken this is only those who possess practical experience can fully realise.

" There is no branch of agriculture in which greater skill and knowledge are necessary, and there is certainly no branch in which constant care and ceaseless attention are more imperatively needed. I do not suggest that a fortune is to be made out of poultry, but I do say that when fowls receive proper attention and are looked after in a businesslike manner, they yield a larger profit in comparison with the amount of capital invested than any other farm stock. Until it is fully realised, however, that poultry-keeping is a business requiring skill, experience, common sense, and patience, plenty of hard work and constant attention, there will always be more failures than successes."

A number of questions dealing with details of management, &c., were asked and replied to by the writer of the paper.

EVENING SESSION.

TUBERCULOSIS.

The Government Veterinary Lecturer (Mr. F. E. Place, B.V.Sc., M.R.C.V.S.) dealt with this subject. With tuberculosis, especially in cattle in this State, there was no occasion for alarm, he said. Whilst inspecting cattle slaughtered for export he was impressed with the fact that the average incidence of the disease was one in two thousand.

The Head of the Stock and Brands Department had given a great deal of attention to this disease, and he had expressed himself as pleased with the small amount of tuberculosis that special inspection had revealed. Therefore, the idea of a scare could be dismissed.

So far as the consumption of milk from tuberculous cows was concerned, an adult might possibly freely take this without coming to much harm; the chance of a solitary tubercular bacillus attacking the inside of a human being was not great. However, with young children there was a risk of infection, especially when the milk was from one cow only, and that happened to be infected. The precaution of boiling the milk was frequently resorted to, but with this there was a great possibility of its digestibility being impaired, and pure milk from a healthy cow was much to be preferred.

EARLY PRECAUTIONS.

Tuberculosis was an insidious disease; it secured a firm hold on an animal before it was noticed. Precautions should be taken immediately an owner became suspicious that there was something wrong with a cow. Where doubt existed the Stock and Brands Department should be immediately notified. It was much better to sacrifice one cow than to perpetuate a disease that might result in very severe loss ultimately. The presence in the herd of the affected cow meant a direct tax of at least 10 per cent. on the herd. Generally throughout South Australia there was little trouble, but the disease was prevalent in confined herds, such as those of the dairies around the city of Adelaide. In a country where the cattle lived in the open air the disease would gradually stamp itself out, and this suggested the best precautionary steps. The cows should not all be crowded into one bail, but milking sheds and such appointments should be arranged with an eye to sanitation.

DIFFERENT DIAGNOSIS.

From the point of view of the farmer the disease caused by the tubercular bacillus was very difficult to recognise. In the case of a cow the animal affected would not look herself; she would, perhaps, be ailing on a misty morning, but on a bright morning nothing would appear to be wrong with her. In the early morning she would cough, especially if she were hurried. As the disease progressed the cough became convulsive. When these symptoms were apparent there could be little doubt as to the nature of the trouble.

Tuberculosis did not confine itself to the breathing passages or lungs. The small glands in the throat and neck became affected; thus they got what was known as " lumpy jaw " if the beast picked up the disease with its food, but tuberculosis was not likely to be confounded with actinomycosis, or true lumpy jaw. In the cow, the womb and its appendages were very often affected. When the disease settled in these parts abortion and ultimate sterility were likely consequences. It was certainly false economy on the part of the farmer to throw the internal organs of affected beasts to pigs. This would cause the sows to slip, and the suckers would waste, instead of fattening.

The lecturer described in detail the development of the tubercular bacillus inside the cow, describing the breaking down of the tissue to pus and cheesy matter, which ultimately became calcified.

INFECTION.

Infection took place through the air passages and by means of the food. When the glands at the back of the throat, the gland between the lungs, and that over the heart were all affected, infection had taken place through both channels. Grapey growths inside the lining of the chest or stomach were an indication that tuberculosis was general throughout the beast.

The tuberculin test was being used to determine the existence of the disease. In about 99 cases out of 100 this could be relied on. The method of applying the test was described at length, and stress laid on the fact that an officer of the Stock and Brands Department only must apply it.

A tubercular cow, whose udder was unaffected, could yield affected milk. When the udder became infected there was, first of all, a swelling ; this would continue and harden. The quality of the milk would suffer, but the quantity would keep up.

Experiments conducted during the past few years had revealed that calves from highly tubercular mothers had almost invariably been at birth free of the disease. If they were reared on healthy milk the trouble did not manifest itself in them, but if infected milk were fed the calves would quickly become highly tubercular.

ERADICATION.

He knew of no country where tuberculosis could so easily be got rid of as in South Australia. But to do this involved the owners taking notice of any deviation from health on the part of the cattle. Where there was the slightest suspicion the Stock Department should be immediately advised. It was much better to stamp it out in the earlier stages than to allow it to remain until it became a real danger. In this State the spread of the disease was largely facilitated by the practice of " buying in." The general method of replenishing the herd was to buy, and the risk of infection from the cows thus obtained was considerable, so that new purchases should be kept separate till their sound health could be established without doubt.

VISITORS ENTERTAINED.

The officers of the department and visiting delegates were entertained a dinner by the members of the local Branch and Field Trial Society.

THE WHEAT MARKET.

During April the local wheat market remained steady, not much business being done in either farmers' lots or shipping parcels. For growers' lots, quotations at the end of the month were 3s. 8d. to 3s. 8½d. per bushel, on trucks, Port Adelaide, or the chief outports, compared with 3s. 7¾d. to 3s. 8¼d. on the corresponding date in 1913.

"Two-thirds of the season 1913-14 are over, and (states *Beerbohm's Corn Trade List* of April 3rd), so far, shipments have been in excess of requirements, which we estimate at about 1,300,000 quarters per week for the whole season, or, taking into account the excess to date, and allowing an extra 1,000,000 quarters to be taken by Austria-Hungary, Spain, &c., than previously reckoned, 1,100,000 quarters per week for the remaining 18 weeks of the present season ending July 31st next. The exports to Europe in the 34 weeks ending March 26th have amounted to 48,325,000 quarters, or an excess over the requirements (estimating same at 68,000,000 quarters for the whole year) of 4,000,000 quarters, but as the quantity afloat is now 6,245,000 quarters, against 4,185,000 quarters at the commencement of the season, 1st of August, it follows that the actual imports have been about 2,000,000 quarters more than wanted.

"Twelve months ago we printed a statement giving the probable shipments to Europe for the remaining four months of the season, viz., 25,550,000 quarters, whilst the actual figure proved to be 25,180,000 quarters. Below we give an estimate for the remaining four months of the present season ending July 31st next.

	Exports to Date.		Exports April to July.	
	1912-13.	1913-14.	1913.	*1914.
	Qrs.	Qrs.	Qrs.	Qrs.
U.S. and Canada	18,410	20,520	9,520	9,000
Argentina	7,815	2,085	4,753	2,000
Russia and other Black Sea Ports	8,930	13,620	3,855	7,000
Roumania	4,940	5,135	1,330	1,250
India	3,970	1,920	3,643	1,000
Australia	2,645	4,100	1,669	1,500
Sundries	810	945	410	450
Total	47,520	48,325	25,180	22,200

* Estimated.

"Last season the total shipments to Europe amounted to 72,700,000 quarters, and this quantity was generally believed to be fully sufficient for all requirements, after allowing for the large quantity of wheat harvested in 1912 unfit for human food. The last crop of wheat in European importing countries was about 4,000,000 quarters larger than in 1912, or, allowing for the better quality, the excess in wheat fit for milling purposes was probably quite 8,000,000 quarters. The estimate of this season's requirements at 68,000,000 quarters, against 72,700,000 quarters last year, would therefore appear to be ample.

"The requirements, at 1,100,000 quarters per week for the remaining 18 weeks of the season, would amount to about 20,000,000 quarters, whilst the probable shipments, according to the above estimate, would be about 22,000,000 quarters. There would certainly appear to be ample supplies of wheat to satisfy all requirements.

"The world's visible supply decreased 895,000 quarters during March, against a decrease last year of 1,465,000 quarters, and an increase in 1912 of 370,000 quarters.

THE WORLD'S VISIBLE WHEAT SUPPLY ON APRIL 1st.

Steamer Freights.—(May 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 21s. 6d. per ton ($6\frac{9}{10}$d. per bushel) ; to South Africa, 20s. per ton (6⅖d. per bushel). Parcels. Port Adelaide to London-Liverpool, or Continent, 20s. per ton (6⅖d. per bushel) : Port Adelaide to Melbourne, 8s. per ton (2½d. per bushel) ; to Sydney, 10s. 6d. per ton (3¼d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 21s. 3d. per ton (6⅘d. per bushel) ; South Africa, 18s. 9d. per ton (6d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Government Produce Department reports on May 1st:—

Butter Factory.—The supply of cream is falling off, but owing to the much better weather experienced lately the quality is improving, and the demand for the butter is increasing. There was a drop in prices during the month; the present quotations being, superfine, 1s. 4½d.; pure creamery, 1s. 3d.

A. W. Sandford & Co., Limited, report on May 1st—

Butter.—Local supplies have been much below trade wants, so that importations from the neighboring States have been arriving to cope with the demand. However, the light general showers experienced in practically all parts of the State during the month will give a start to pastures and cause increasing quantities of dairy produce to come forward. Top values show slight fluctuations, while separators and store and collectors' lines have improved—" Alfa " is selling at 1s. 4d.; " Primus," 1s. 3d.; choice separators and dairies, 1s. to 1s. 1½d.; store and collectors', 10d. to 11d. per pound

Eggs.—An advance of 2½d. per dozen for new laid is recorded, and holders of refrigerated and pickled sorts are now taking advantage of the good rates ruling. Hen eggs, 1s. 5d.; ex-refrigerator, 1s. 2d. to 1s. 3d.; well preserved, 1s. 1d. per dozen.

Cheese.—Owing to export buyers operating on this market values have improved, and stocks here are being considerably reduced. Present quotations are from 7½d. to 8d. per pound for large to loaf.

Honey.—Purchasers for export have experienced difficulty in executing anything like their orders for prime clear extracted; local buyers are also operating freely. Prime samples, 3d. per lb.; beeswax, 1s. 2d. to 1s. 3d. per lb.

Almonds.—The trade are realising that the crop is not up to expectations, and are, therefore, taking up all offering at improving rates. Brandis are selling at 6¾d. to 7d. per lb.; mixed softshells, 6½d.; hardshells, 3½d.; kernels, 1s. 6d.

Bacon.—A very steady market has prevailed throughout the Commonwealth, there being no alteration to report in price, although the factories have been able to send in heavier consignments. Best factory cured sides, 9¾d. to 10¾d. per lb.; hams, 10d. to 1s.; lard in skins, 8½d.; bulk, 7d.

Live Poultry.—The penning before Easter was exceptionally heavy and quite equal in quantity to Christmas markets, but there was a tendency to lower rates. During the latter weeks of the month very much improved rates were obtained, and the market at the moment is good for all classes, especially quality. Good table roosters brought 3s. to 3s. 8d. each; nice conditioned cockerels, 2s. to 2s. 6d.; hens, 1s. 9d. to 2s. 3d.; ducks, 1s. 8d. to 2s. 6d.; geese, 3s. 6d. to 4s.; pigeons, 5½d.; turkeys, 5d. to 10d. per lb. live weight for medium to good table sorts.

Potatoes and Onions.—Fair parcels of good potatoes have arrived from the Millicent districts, but Mount Gambier deliveries were disappointing both in quality and quantity. Onions.—Good supplies offering from Mount Gambier and local sources, and as there has been no export inquiry the market has ruled steady. Present quotations—Potatoes, £5 2s. 6d. to £6 per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 6s. to 7s. per cwt. in the market. Onions—£7 per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 7s. to 8s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of April, 1914, also the average precipitation to the end of April, and the average annual rainfall.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

May 13th and June 10th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

MOUNT REMARKABLE (Average annual rainfall, 14·43in.).

March 18th.—Present: 12 members and three visitors.

Experimental Plots.—The Chairman (Mr. N. S. Giles, B.Sc.) undertook to conduct plots with the idea of producing a strong, well-selected, and prolific wheat plant. It was proposed to procure two varieties (one red and one white, if possible) each of early, medium, and late wheats.

Levers.—Mr. N. S. Giles, B.Sc., gave an interesting and instructive paper on "Levers: their Uses, Principles, and Application." Mr. Giles showed the practical application of the lever principle with reference to straining fences—that it was not sufficient to place one inner strut as the angle of two converging lines of fence. He practically demonstrated that if two tug-of-war teams were pulling upon a rope, there was no more strain upon the rope than if one team alone pulled the rope with the opposite end fastened to a post. Also, that by a little calculation a swing on an implement could be so arranged as to work a large and a small horse side by side by giving the smaller horse the longer end from the fulcrum, therefore the greater leverage. It was also demonstrated why a single cable round the tree to be uprooted by "The Forest Devil" should be as strong as the two cables fixed to the wheel which the lever operated.

QUORN (Average annual rainfall, 13·78in.)

April 11th.—Present: six members.

Pickling Wheat.—Mr. A. F. Noll contributed a paper on this subject, in which he said that there was little danger in sowing unpickled seed early in the season when the ground was dry and the seed free from smut. Seed sown late in the season, however, should be pickled. He used a cask of about 60galls. capacity, and into this put about 40galls. of water, and in this dissolved 4lbs. of bluestone by suspending it in a hessian bag just below the surface. In this manner it would dissolve in a few hours. A derrick with a swinging arm and pulley and rope attached was erected near the cask. A bag of seed was split into two butts, and tied loosely to allow the seed to swell. The seed was allowed to remain in the solution for about 3min. He then raised it to a draining table, which sloped back into the cask. A 1 per cent. solution was of sufficient strength for ordinary use. The pickled wheat should be left in the open air to dry and the bags turned every day to prevent mould. When dry the wheat could be stacked in the barn until required. Damp seed would not run freely through the drill. In the discussion which followed Mr. Britza said that by mistake he had allowed a bag of wheat to soak all night in the solution. He had sown the seed on boggy land, and the resultant crop was badly smutted. Mr. Brewster considered it advisable to pickle all wheat, whether sown on wet or dry land. The Hon. Secretary, however, considered it unnecessary to pickle seed if it were clean and sown before rain. The Chairman read an article on "Bunt" by Mr. H. Ross, Chief Inspector of Agriculture in New South Wales, in which was pointed out the mistake farmers made by using galvanized iron for troughs to drain the solution back into the cask. Mr. Britza made a practice of giving the iron three or four coats of water paint before use. In reply Mr. Noll said that the majority of farmers advised pickling the bags with the wheat.

TARCOWIE (Average annual rainfall, about 15¼in.)

April 12th.—Present: 15 members.

Pickling Wheat.—Mr. D. Butterick contributed a paper on this subject. He advocated the pickling of wheat with a 1 per cent. solution of bluestone. He preferred dipping the seed to the floor method, it being much quicker and easier. A hole about 4ft. 6in. deep and large enough to enable a large bag of wheat to be submerged therein should be cemented. A table top, with sloping sides, to allow the solution to drain back into the hole, should also be constructed. The bluestone should be placed in two sugar bags and submerged in the water. A bag of seed should be allowed to remain in the solution for from one to two minutes, after which it should be turned upside down so that the solution would drain back through the wheat. He believed in pickling in March, so that the wheat became thoroughly dry before being sown. It would then run more freely and evenly through the drill. The pickle would go through the bags much more quickly if they were fairly slack. They should stand for about 24 hours before being stacked. In the discussion which followed Mr. Breuer favored pickling a month before seeding. Mr. Symons thought early pickling was liable to destroy the grain. Mr. W. Ninnis preferred boiling the bluestone. The bags should not be tightly filled, as they were liable to burst. Mr. Travers preferred dry sowing. He had once sown a bag of pickled wheat in the centre of a crop which had been dry sown, and the pickled portion only was affected with smut. Mr. Butterick had kept a bag of pickled wheat for three years and the seed was in no way injured.

WILLOWIE.

April 17th.—Present: seven members and five visitors.

Shoeing Horses.—The following paper was read by Mr. F. Richter:—"The horse's foot in the natural state is almost round, and very elastic at the heel. The frog is broad, plump, and of a soft yielding character. The commissures are open and well defined, the sole concave, the outside crust from the heel to the toe increasing from a slight level to an angle of 45 degrees. Consequently, as the foot grows it becomes wider and longer on account of the amount of horn secreted, and narrower and shorter on account of wearing. If a shoe is fitted accurately to the foot after it had been dressed down well it will be found too narrow and short after the lapse of a few weeks. If an unyielding shoe of iron is nailed firmly to this naturally enlarging and elastic hoof it prevents its natural expansion almost wholly, and does not allow the foot to grow wider at the quarters as it grows down, consequently the foot is changed in shape by the continued restraint of the shoe, from a nearly round healthy foot to a contracted and unhealthy condition, as is generally seen in horses that have been wearing shoes for a few years. The principles which should govern shoeing are few and simple. It is surprising, considering the serious consequences involved, that it should be done with so little consideration. The object of the shoer should be, in trimming and preparing the hoof for the shoe, to keep the foot to its natural shape. This involves first cutting away any undue accumulation of horn affecting in the least its health and freedom, making the shoe the shape of the foot, fitting and fastening the shoe to the foot in such a manner as to interfere as little as possible with its health, growth, and elasticity. The preparation of the foot involves the cutting away of about the proportion of horn which, coming in contact with the ground, would have worn off, or which has accumulated since the last shoeing. If the shoes have been on a month the horn that was secreted in that time should be removed. Judgment must rest on the circumstances of the case. The stronger and more rapid the growth of the foot the more is it necessary to cut away . If little horn is produced it is advisable to remove as little as possible. There is generally a far more rapid growth of horn at the toe than at the heels or the quarters. More will, therefore, be taken off there than from the other parts. It is necessary to shorten the toe and lower the heels, until the shoer succeeds in bringing down the bearing surface of the hoof upon the shoe to almost a level with the horn of the sole. The toe should be smoothed down level with a rasp. Portions of the sole and frog detach by exfoliation, as they become superabundant. The sole, therefore, would not need paring were it not for the restraining effect of the shoe upon the general functions of the foot, which is liable to prevent such detachment of the horn. The bars should not be confounded with the substance of the sole, and set down to the common level with the sole. The bearing of the bars should be equal to the outside of the crust upon the shoe. They offer a decided resistance to the contraction of the heels. Cutting away the bars to give the heels an open appearance should never be done. In a natural healthy condition the frog has a line of bearing with the hoof, and by its elastic nature, acts as a safeguard to the delicate machinery of the foot immediately over it, and helps to preserve the foot in its natural state by keeping the heels spread. Permitting the heels to grow down, with the addition of high-heeled shoes, raises the frog from its natural position and causes it to shrink and harden, resulting frequently in contraction of the foot. If the heels are square and high, and the hoof presents rather a long narrow appearance, and is hollow on the bottom contraction has begun. It is advisable to cut away until the level of the line horn of the sole is reached. If the foot is weak do not cut it away too much. The foot should be so dressed down and the shoe so fitted that the bearing comes evenly upon the crust all the way around without the sole touching the shoe. The corners between the bars and crust should be well pared out." In reply to questions, Mr. Richter said that in shoeing a horse that brushed he would leave the inside of the hoof higher than the outside. The shoe should be left wide at the heel to allow of expansion. Generally portion of the frog had to be cut away. Burning did not damage the foot if all the charred horn were cut away. Messrs. D. and. L. McCallum thought it advisable for the farmer to learn how to put a shoe on a horse.

WIRRABARA (Average annual rainfall, 18·91in.).

April 11th.—Present: 18 members and three visitors.

Grubbing.—A paper on this subject was read by Mr. W. Bowman. In the winter, he said, the clearest and most convenient tree within reach of the edge of the timber should be selected for use as an anchor to hold the grubbing machine. The tree to be pulled up should be eased in front, in order that the taproot would not split up. If necessary, a few of the back roots should be cut also, but always far enough below the surface to ensure clearance for the plough. A pickaxe, round-mouthed shovel. and a good axe were the tools necessary. The trees nearest the anchor should first be pulled. The chain should be placed as high up the trunk as was possible without danger of it snapping. The hook, or ring, should be at the side of the tree, otherwise the strain was likely to break it if the chain were pulling from the centre of the tree. When the tree was about to fall, a log should be placed in front of the butt, this would then be lifted right out of the ground. The horse-power grubber with wire ropes was the best. In this district a machine should stand the test of 20 tons. Wire rope was more satisfactory than iron bars. A pulley block was a great advantage when heavy timber was to be dealt with. It was decided to hold a trial of the different grubbing machines to determine their relative merits.

CARRIETON.—Messrs. Bock and Kaerger were appointed to conduct experimental plots on behalf of the Branch.

DAVENPORT, April 2nd.—The Chairman (Mr. Holdsworth) summarised the information which had appeared in the *Journal of Agriculture* during the past few months on the subject of the immigration of farm lads. Members discussed the question, and commended the action of the Government in this connection.

MORCHARD, March 7th.—Fodder Conservation. The Chairman (Mr. J. Scriven) tabled samples of straw and self-sown hay, cut five years ago. Both were sweet and sound. Chaffed, and mixed with good hay chaff, this had been fed to horses, which did well on it. Mr. Kupke had made a practice of conserving cocky chaff and straw every year, this had been very valuable to him during the present season.

MORCHARD, April 11th.—Farm Outbuildings.—In a paper dealing with the erection of outbuildings on the farm the Hon. Secretary (Mr. B. S. McCallum) said that about this time was the best to give attention to such fixtures as the stables, barn, ensilage pit, blacksmith shop, fowlhouse, and pigsty. Stone and concrete would be found very suitable for making good strong walls. The concrete should be made from one part lime and three parts gravel, from which all the large stones had been sifted. After mixing it should stand for at least three hours. Planks 12in. by 2in., the length of the wall, should be placed in position, and about 2in. of concrete should be run between these. Stones should then be packed in; if these were of good face, tight against the planks, but if they were rough in the centre of the wall, between the planks. Concrete should then be run between the stones. Every second day an additional layer of this nature could be added to the wall. Whilst iron was more expensive for roofing there was less risk of fire with it than when straw was used. Mr. W. Toop preferred the concrete and stone walls as the cheapest if the stone and gravel were at hand. Stables should be well ventilated, but machinery sheds needed to be closed in well. Iron was best for roofing. Mr. W. H. Toop concurred, as straw roofs provided excellent nesting grounds for sparrows, In reply to Mr. E. J. Kitto, the Hon. Secretary said that stone and mortar building required an experienced workman, whilst concrete walls could be built by any handy man.

WARCOWIE, April 6th.—It was decided to conduct manurial tests on an area of fallow kindly offered by Mr. Telfer. Messrs. Donnellan, Ryan, Jarvis, and Feineler were appointed a supervising committee.

WEPOWIE, April 18th.—The delegates to the Upper Northern Branches Conference delivered interesting addresses regarding the proceedings of that gathering.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

BEAUFORT.

March 16th.—Present: 11 members and four visitors.

SEED WHEAT.—Mr. J. Sampson read a paper dealing with the "Treatment of Seed Wheat." He did not think either rust or takeall could be prevented by treating the seed, but 1lb. of bluestone in sufficient water to wet three bags of wheat would effectively prevent smut. The floor method of pickling was best. The best varieties for this district were Gluyas for early wheat, and Marshall's No. 3 and Federation for late. It was always advisable to put seed through a winnower to clean it of dirt and dust. The Chairman (Mr. W. W. Mugford) agreed. He noticed that red rust was more prevalent in wet years. Mr. A. Yard thought wheat drilled in when it was wet was more likely to be affected with smut. Mr. C. G. W. Underwood advised sowing rust-resisting wheats. A visitor mentioned that hard-strawed wheats were less subject to the rust fungus than the soft-strawed varieties. A 1 per cent. solution of bluestone was the best pickle for smut. It was pointed out that if there were enough moisture in the soil to cause the germination of the smut spores, but not the grain, the smut would die for want of a host plant.

CONSERVATION OF SOIL MOISTURE.—Mr. J. Nicholls, of the Nantawarra Branch, delivered an interesting and instructive address on this subject.

BEAUFORT.

April 9th.—Present: 11 members and four visitors.

SEEDING.—Mr. H. C. Underwood read a paper. He said "seeding operations should not be skimmed over. We are well into April, and those of us who are growing oats for hay should be on the move, so that we are ready to start on the wheat as soon as the first rain comes. One bushel of oats to the acre and about 56lbs. of second grade super. will grow a very good crop on stubble land. Wheat should be planted on fallow ground for the best results. After rain we should not be in too much of a hurry to get to work with the cultivator, especially after a heavy fall, but allow the weeds to come up and then work it to a depth of 1½in. to 2in. A light set of harrows is very good behind the cultivator if the weeds are very strong or the ground very uneven. The drill should not be let into the ground to its full depth, but so that it is running along nicely and covering all the seed. One bushel of wheat to the acre is enough, but if sowing in dry weather it might be sown a little thicker, because some of it may not germinate. The seed should be well cleaned and pickled with bluestone solution at the rate of 1lb. to 10galls. of water. Be very careful not to mix it stronger, or a bushel to the acre less at reaping time may result through a percentage of the seed not germinating. Marshall's No. 3 returns a very good yield when sown early, but it is rather late for this district, on account of hot winds. Gluyas is a very good early wheat to sow late. It is unwise to plant more of this than can be taken off quickly, as the first strong wind that comes along causes it to go down. Gluyas Late is a much thicker strawed wheat, and stands the weather better. Farmers in light scrub country should not give the land a heavy dressing of super. or the growth of the wheat will be so soft that the first trying weather will scorch it. The light scrub ground does not retain the moisture as the heavy soil does. On this class of soil it is not advisable to put on more than 90lbs. to the acre of Standard super. Those who are farming heavy country usually put on 1cwt." Mr. A. Yard thought that 56lbs. of super. on stubble ground for oats was too much; half that quantity was plenty. Sixty pounds of super. was sufficient to grow a good wheat crop. He always used high grade super. Mr. C. Wilson thought 50lbs. super. sufficient for oats, sowing about a bushel of seed to the acre. I.X.L. was a very good wheat, a little earlier than Marshall's No. 3, a good yielder, and very good for hay. Mr. J. Dahse thought I.X.L. rather light for hay, but a good wheat yielder.

The Chairman (Mr. W. W. Mugford) thought that where weeds were very bad it was a good practice to wait for rain before sowing. It was advisable to give the land a good dressing of super., as the benefit of it was secured in the feed if not in the wheat. Marshall's No. 3 seemed rather late in ripening. Gluyas, in his opinion, was the best wheat, but it had a tendency to go down very badly. He thought there was a great tendency for wheat to degenerate, therefore great benefit was derived from such places as the Agricultural College and experimental plots, as they all help to keep up the standard. Mr. G. Underwood agreed that 56lbs. of super. was the best dressing for oats. He had experimented with less, but had not had such good results. Oats should be cross drilled, putting on about 80lbs. to the acre. At seeding time it was not advisable to cultivate too deeply, as that only stirred up the subsoil that had been packed during the year. The skim plough worked about 2in. deep before the drill was the best weed killer, and it made a nice seed bed. Usually in starting seeding he put in some late varieties of wheat and left the early wheat to be put in later. It was better to sow a little of some early variety, such as Triumph, which stooled well and would prevent land from drifting, which would come in handy for feeding off. He thought Marshall's No. 3 a good wheat; also King's Early for an earlier variety. He had not had satisfaction with Gluyas. Ninety pounds of super. to the acre in his opinion would give the best results. Thicker sowing and cross drilling would pay well for the extra work. Mr. C. Veitch would cross drill wheat. He did not think farmers could put on too much super. It was a great advantage to cross drill oats. He had had the best crop of oats he had ever seen by sowing 1¼bush. seed and 70lbs. super. Mr. T. Warner had pickled barley with 1lb. bluestone to the bag and had no smut. Mr. A. Yard had smut in barley in abundance after using the same strength of pickle.

BEETALOO VALLEY (Average annual rainfall, 18in. to 19in.)

April 16th.—Present: eight members.

Intense Culture.—Mr. A. H. Jacobi read a paper. He said:—"Every acre of our holdings should be put to its best use. The ploughable land should be broken up and cultivated with wheat, oats, barley, and rye, as all these give a handsome return even in the poorest years. The rough country could be sown with wattles for bark. Sugar gums, pines, and other useful timber should be planted on the rough patches and creeks, as they will come into use later for fencing and building. Low-lying sandy flats may be put to a better use than any of the above mentioned. Fruit trees of any description should be planted and looked after. With a little care a large return will come from a few acres of these. Vines can also be added, and if wine cellars and a distillery were established here hundreds of acres which are too steep to culitivate could and would be planted with wine grapes. Where a plentiful supply of water is obtainable tomatoes, potatoes, melons, and summer vegetables can be produced in large quantities. I have been told by bee keepers that bees do exceedingly well here. With careful management both wool and lambs can be raised to a high standard by feeding them on lucerne. This district I consider is well adapted for poultry raising, and with a market like Port Pirie available they are worth far more attention than most of us give them."

Vegetables.—Mr. J. Ryan read a short paper. Vegetable seed he said, should be procured from reliable sources. The seed bed should be well manured and watered, and free from weeds before planting. Root vegetables should be put into soil dug to a depth of 1ft., and well dressed with stable manure. Fairly thin sowing was necessary in order that the plants should root well. Onions should be put into sandy soil, and kept well hoed up. Cabbages and cauliflowers should be put in about 2ft. apart in the rows, with 2ft. 6in. between the rows. Hoeing up and watering were necessary. Peas, tomatoes, cucumbers, and melons all did well in this district.

GEORGETOWN (Average annual rainfall, 18·32in.).

April 11th.—Present: 17 members.

Barbed Wire Cuts.—Mr. J. Fogarty dealt with the subject of cuts caused by barbed wire. The method of dealing with these, which he adopted, was to sew the edges of the wound together with a thin darning needle and strong thread, such as Belfast thread. He had tried all sorts of oils as dressings, and was quite satisfied that a light solution of bluestone was as effective as anything. Generally, members preferred a mixture of ½ dram of iodine and a bottle of methylated spirits.

Preparations for Seeding.—Mr. J. H. Buchan read a paper. Whilst it was admitted that different soils required different treatment, he said, the greater part of the land in this district was of a loose nature, and responded very well to summer fallowing. During one year he treated different portions of one paddock as follows:—One part was ploughed in winter, was cultivated twice, and then scarifier-harrowed. The other part was ploughed in summer, was harrowed, cultivated, and twice scarifier-harrowed. Although the former entailed extra work the crop from the latter was cleaner and better. Ploughing should be done in winter to a depth of 3in., but summer ploughing should be from 4in. to 4½in. deep. The land should be left as rough as possible, the weeds being kept under with sheep until the end of August, after which the harrows and cultivator should be used as frequently as necessary, in order to conserve moisture. He had found that harrowing from four days after drilling until a month after the plant was through the ground ensured a better crop than that from land not so treated. The best time to harrow was between four and seven days after the seed had germinated. All members favored early fallowing, but opinions differed as to whether the land should be cultivated at once.

GLADSTONE (Average annual rainfall, 16in.).

March 28th.—Present: 13 members and one visitor.

Depreciation of Farm Stock and Implements.—Mr. T. Hollitt read a paper. A team of, say, 10 horses, purchased at 4 years old at £30 per head, he said, would not fail in so far as work was concerned until they were about 12 years old, but their selling value would depreciate at the rate of about £2 per head per year. This would equal a loss of £200 in 10 years. The best practice to counteract this was to breed from the best mares, using a sound entire, and feeding the young stock well. Light work only should be performed by horses under 4 years of age. Shares of the ploughs and cultivators were the source of considerable expense; the best means of minimising this was to work the land only when it was in good condition. The wagon should be screwed up, painted, and oiled at frequent intervals, similar attention being given the drill, binder, harvester, and suchlike machinery.

LAURA (Average annual rainfall, 18·02in.)

April 3rd.—Present: large attendance of members.

Mixed Farming.—Mr. W. Stevens read the following paper:—"With such changeable seasons as we have in Australia it does not pay to rely only on one kind of crop. I have known some farmers put in 1,500 acres several years in succession and not reap their seed. In our own district there are still a few who rely on wheat and hay, but there are also a large number working on the three years rotation, which seems to be a good principle. Some have affirmed that mixed farming is a failure, but many of our wealthy farmers have been following it for years with success. Every farmer should keep a few sheep. A farm of 640 acres should be able to carry over 100 breeding ewes. It does not pay to overstock in a district where the growing of summer crops is not to be depended on. It will pay farmers to gather part of their stubble, as a stack of straw is always useful. Cropping the hay ground with early feed, such as barley or rape, or anything which will grow quickly, will prove beneficial, as with it, if early rains come, part of the ewes and lambs may be fattened. It will also pay every farmer who has stock to buy a few pounds of lucerne, and when drilling wheat sprinkle a handful of lucerne seed in the drill box with the manure when sowing a choice piece of ground. This in a good season will make good feed with the stubble. Every farmer with a family should keep about six cows, which, if fed well, will turn in a nice cheque every month for cream. The profits depend on the feed. It pays to have a silage pit which can be filled before the hay is cut. In favorable seasons a small plot of sorghum, maize, or thousand-headed kale is good, but it must be fed with care. Wheat chaff damped with hot water and molasses mixed with bran, oil cake, or crushed corn, makes good feed. From 50 to 100 hens of a good laying strain should also be kept. If these are well fed they will return a nice profit and can be looked after by the farmer's wife and family. One or two breeding sows with a litter or two a year sold at the present prices will prove very profitable. They can be fed with skim milk, any grain, and green feed. In addition to the horse stock necessary to work the farm there should be a few good mares for breeding. If two or three foals are bred every year they will come in very handy to replace losses or to sell. Young stock should be worked for a few years and sold in their prime. It pays to feed all stock well. A small plot of barley or oats will prove profitable. Some say that this involves too much work, but if done at the right time, one thing following another, the farmer can find work for his employés all the year round. Every farmer should have a small garden in which to grow vegetables for home use, but it will not pay to grow fruit, as the birds are so troublesome. A blacksmith's and carpenter's shop should be on every farm. On wet days a farmer can do a lot of repairs which will save considerable time and expense. An interesting discussion, in which Messrs. R. Lines, G. Bundey, E. C. Blesing, J. F. Roennfeldt, W. Wilson, and J. Sibly took part, followed the reading of the paper.

MOUNT BRYAN (Average annual rainfall, 15·81in.).

April 1st.—Present: about 25 members and visitors.

The Breeding of Ewes for Raising Freezers.—Mr. C. E. Birks, member of the Advisory Board, read the following paper:—"In writing on this subject I do not wish it to be thought that I claim to be an expert, but as one who has some practical experience in raising freezers on a small scale on the farm, I have a little knowledge as to what is required in the way of a mother for the fat lamb, and in so doing would offer you a suggestion for an improvement in the lamb industry so often advocated by Professor Lowrie, backed up by many experts in the handling of sheep, and which in New Zealand is a regular business in itself in certain parts of the country. It is very questionable whether there is anything in the way of stock more payable on the average farm than a flock of good breeding ewes, and to make the most of them too much care cannot be exercised in the breeding or selection of these ewes, so many things have to be taken into account to get the best return for the outlay, and the time has come when farmers are alive to the fact that every animal must produce its share of profit, and the more carefully the flock is chosen the greater that profit will be. Nothing puts a lamb buyer off more than a want of uniformity in the size of lambs; given lambs in the pink of condition, but uneven in size, I make bold to say that they would bring less than an even mob, whose actual weight was only equal to the uneven mob, to say nothing of the satisfaction to both buyer and seller in dealing in something that is a pleasure to look at. This point applies particularly in the case of the small farmer who has not enough lambs to draft up into, say, three grades. Of course, with the larger man he can sell according to size and quality to better advantage. Now, it is one thing talking about what we want in the way of ewes, but another to get them. We all know what competition a good line of breeding ewes draws when advertised for sale, and how farmers will go shillings per head more for an even well-woolled line as against the line composed of mixed sizes and shapes. *Where the ewes are to come from.*—It is practically impossible for the farmer to breed his own ewes and attain the high standard of type and uniformity that is required to send off in one line a big percentage of the lambs as freezers. It is in this direction I wish to throw out the suggestion to men whose holdings are on the edge of the farming districts, and who go in for, say 3,000 sheep and upwards, that they pick out as many of their big-framed, good constitutioned, well-woolled Merino ewes, mate them to the Border Leicester rams, or failing them, the Lincolns; keep the best of the ewe lambs and put them on the market as two-tooths to be mated on the farms to Southdown or Shropshire rams to produce freezers; or one can with advantage cross again with Border Leicesters, thus getting a three-part Border Leicester. The second-rate ewe lambs and wether lambs from the first cross can be disposed of as freezers or hoggets; but get them off, only keeping on each year with the Merino-Border Leicester or Lincoln. This cross makes a good framed and constitutioned ewe, a good mother, and just about the ideal ewe for producing fat lambs, and the wool will be as paying a proposition as any crossbred sheep you can name. In New Zealand a regular trade with these breeding ewes is done, and when a farmer wants to go in for fat lambs he can, by paying a high price (and it pays him to do it), buy ewes of the right sort to breed from instead of breeding from a mixed lot as to type, size, age, and breed. Very often from a good class of ewe bred in this way the farmer can safely rely in fair seasons, especially with the aid of some barley, oats, rape, kale, or mustard, on getting 90 per cent. to 95 per cent. of freezers, and he will be very glad to keep the other 5 per cent. to 10 per cent. for ration sheep. I trust this paper will be freely discussed and that some good may come out of the discussion, and not end at the termination of the meeting. There is money in it to the sheepfarmer, and it will supply a long-felt need of the farmer who only has room for 200 to 600 sheep, and the raising of fat lambs is a most profitable venture, especially from ewes of this class, whose wool, I might say, on the authority of Mr. H. Jackson, the Wool Expert, is of the best crossbred class and sells well at any time." A good discussion followed.

Bureau Work.—The Secretary of the Advisory Board (Mr. G. G. Nicholls) spoke on this subject. The man on the land, he said, was continually faced by more or less serious problems which had to be elucidated to enable him to make the fullest use of his opportunities. By meeting regularly together, stating their successes and discussing their difficulties, the members of the Bureau assisted each other tremendously. The Bureau had something more than a mere name to offer them. As an outcome of the Farmers' Congress in Adelaide in September, 30 odd Branches had undertaken to conduct various field experiments in their respective districts, and it was generally felt that much good would result therefrom. The Mount Bryan Branch had performed valuable work, but there was still a lot to be done. He advised the appointment of a programme committee to prepare a programme to cover the remainder of the year. Every meeting should be adequately provided for. Homestead gatherings should be encouraged; one meeting should be devoted to discussing harvest results and the means by which they had been obtained; and there should also be a "social night," which the ladies of the district should be invited to attend. They would find that by systematising their work as a Branch the effectiveness of the meetings would be materially enhanced, and the individual members would be greatly benefited.

NORTH BUNDALEER (Average annual rainfall, 16·15in.).

April 8th.—Present: 16 members and two visitors.

Pickling Seed Wheat.—Mr. W. Burgess read a short paper on this subject. He deplored the carelessness that characterised the treatment of seed wheat by many farmers. He advised the floor method of pickling with bluestone, mentioning that the practice of immersing the bag of grain in the solution by no means assured that every grain was thoroughly wet, which was the only means of ensuring the destruction of the smut pores. Mr. Pollard had for years used a 1 per cent. solution, but last year this was reduced to ½ per cent., and his crop was quite clean.

The Homestead.—Mr. Smart contributed a paper on the laying out of the homestead.

PORT GERMEIN (Average annual rainfall, 12·84in.)

April 18th.—Present: 10 members and two visitors.

Seeding.—Mr. Holman preferred sowing wheat after rain. The year before last he commenced sowing about the middle of June. That sown during the first fortnight went up to 21bush. If the rainfall were good it was better to sow wet. Usually dry sown wheat was subject to black rust or take-all. Mr. Stone also preferred sowing wet, or working the ground over to conserve the moisture. To harrow the fallow ground just after rain was a great advantage. Mr. Carmichael thought wheat sown after rain would produce a greater yield. Messrs. Deer and Crittenden also advised early sowing.

SPALDING (Average annual rainfall, 20·25in.)

April 11th.—Present: eight members.

Noxious Weeds.—Mr. S. Hennessy contributed a paper on this subject. He had come to the conclusion that where star thistles had obtained a good hold it was practically impossible to eradicate them. Sometimes he thought he had successfully cleared his land, as very few thistles had grown for about three years, when, after a heavy March rain, they again appeared in large numbers. Two years ago he had a large number of star thistles in his crop. He cut portion of the crop for hay, cutting the thistles also, and no seeds fell. The other portions of the crop he left for the harvester, and the weed seeds were allowed to fall. On the portion which had been cut for hay a large number of thistles grew the following year, and on the portion harvested there were very few weeds. He thought that the seeds remained in the ground and grew when the soil was in a fit condition. Where star thistles were in fallow, the more it was worked the more trouble they caused the following year. He advised fallowing it, harrowing, and then turning sheep on to the land. He usually waited for rain before putting it under crop. On pastoral land the star thistle made good fodder for sheep at this time of the year. To clear stinkwort from land intended for cropping the fallow should be cultivated in the preceding spring. Charlock did not appear to thrive in the district, but he made a practice of pulling it out of his crop each year. He had noticed a few patches of Salvation Jane about the roads, but it did not seem to spread. In the discussion, Mr. Campbell stated that the weed locally known as the star thistle was the Californian thistle, the former being almost unknown in the district. Members generally agreed with the writer of the paper, and thought that the stemless horse thistle should be placed on the noxious weeds list.

YONGALA VALE (Average annual rainfall, 13in. to 14in.)

April 4th.—Present: 11 members and four visitors.

Handling Wheat in Bulk.—Mr. Lock, of the Whyte-Yarcowie Branch, read the following paper:—Much has been written on this subject of late, and we are all fairly well acquainted with the pros and cons of the question. I have a few words to say, however, on the statement prepared by the departmental officers, and read at the Gladstone Congress by the Minister of Agriculture, as reported in the March issue of the *Agricultural Journal*. This statement goes into the cost of the two systems, and goes into figures to such an extent that I venture to suggest that the majority of farmers who have read it have been lost in a maze of decimals. In the end they have probably been little wiser as to how the conclusion is reached that the adoption of bulk handling in South Australia would cost approximately ·26d. or ¼d. per bushel more than the present system. However, that is the position taken up, and it would not be surprising if it proved to be right, considering the fact that it is usually a much easier and less expensive thing to stick to the old way than it is to initiate a new system, and one which we have to become accustomed to before it can be worked in the most economical manner. But before we accept the above statement as correct there are a few things to be considered. In the first place, they base their estimate on a 6d. bag, whereas the fact is that last harvest bags were as high as 8½d., and even if we say the average price was 7d., that will at once make up more than the difference of ¼d. per bushel, for we must remember that however high price we pay for bags we only get the same amount if we sell them as wheat. *Life of the Bags.*—Furthermore, there is the matter of the life of bags, which the report puts down at two years; well, every farmer knows that many, and even most bags will last considerably longer than that, without any very special care being given them, so that the life of bags might be fairly put down at an average of three years, which would again considerably reduce the estimated cost of the suggested modified system. Then, again, they base their estimate on a tied bag, which would hold 10 per cent. less than sewn. Well, why not sew them? It would cost very little more, and sewn bags are much more easily handled and safer to transport. *Effect on Marketing.*—They go on to say that the whole advantage of the bulk system appears to be (1) the saving of waste, and (2) in relieving the farmer from alleged disabilities imposed by the wheat buyer. This is a very short-sighted view, but probably the compiler is unaware that the adoption of bulk handling would entirely alter our system of marketing, as well as handling. In fact, the system of marketing thereunder is far more important than that of handling, for under it we would be able to export a clean sample of different certified grades, and each farmer would be able to sell on quality, and would get the full value of his product. As it is now, the farmer who cleans his wheat is really worse off than the other who sells a dirty sample, but up to the standard. The system of marketing on the f.a.q. sample, is not a quality system at all, as far as the farmers are concerned. It is certainly all right for the merchant, for he can mix the lot together, but that is no use to the farmer who grows the good wheat, and who takes the trouble to clean it well; whereas under the bulk system several grades would be recognised, and the farmer would sell on quality. *Facilities Needed on the Farm.*—Now, how can the farmer manage without using bags, providing that means are provided for transport and storage in bulk? Certainly, our system of harvesting, *i.e.*, the harvester, does not lend itself to the handling in bulk as well as the American—*i.e.*, the threshing machine; but the difficulties are very far from being insurmountable, and considering the big item, as cost of bags each year, it is safe to say that in, say, five years the farmer would find himself well in pocket after supplying proper and permanent means for dealing with wheat in bulk at home and in the fields. The cost of bags to a farmer who reaps 2,000 would be, at 7d., £60; for which he would receive, sold as wheat, about £12 10s., thus showing a loss of £47 10s. on one year's harvest, and on five years £237 10s., surely more than sufficient to provide facilities for handling in bulk, which would last considerably longer than five years. One essential thing would be a good barn—which most up-to-date farmers already have, and which would need only minor alterations and additions. Then a box wagon, which only means fitting sides and ends on to the present wagon or trolly, and which would, of course, be movable, as our hay frames are. Then, say, two receptacles of strong frame and galvanised iron on wheels to hold about 500bush. each, which could be run out into the paddocks adjacent to the crop, and into which the wheat would be deposited direct from the harvester, pending removal per box wagon to either barn or railway station on damp mornings, or any other convenient time. This would entail a little more travelling with the harvester, but the speed with which the harvester box would be emptied would make up for that. Of course, these receptacles would be portable, and when empty could be moved from place to place. Small portable hand elevators would be sufficient for use in the paddocks, whilst at the barn a larger elevator, worked by either horse or motor power, would be necessary. Some such scheme, I am sure, would be practicable, and would doubtless result in eventually saving the farmer a considerable amount on the cost of bags. *Progress, with Caution.*—Of course, if the price of bags were likely to go down to a reasonable thing, or wheat go up, there would not be so much need for attempting to do away with them, but such is not at all likely, for the cost of material and labor is increasing. Even so, the numerous advantages to be gained under the bulk system of marketing—which the older wheat-growing countries have certainly found to be to their advantage—would still be more than sufficient inducement for us to go for it. Now, I never did, nor do I now want to see South Australia rush madly into this alteration—although it must come sooner or later—yet I want to see the question receive the consideration it deserves, and not silenced simply by a departmental report which is, however, conscientiously prepared, pandering to the inherent conservatism of human nature, and simply preaching the doctrine of 'leave things alone,' they are good enough as they are, which, in a progressive country like ours, should not be tolerated. There appears to be a grave danger that the question of bulk handling may become a political party question; this must be avoided at all costs, for it is very much purely a farmer's affair, and has nothing to do in particular with either political party." Mr. Pearce, of the Whyte-Yarcowie Branch also spoke in favor of bulk handling. A strong point in favor of the system was that it would enable the farmer with the better sample of grain to secure a higher price for it. Mr. I'Anson contended that this could and should be done under the present system by grading the wheat into different qualities.

MOUNT BRYAN EAST, April 7th.—The Chairman (Mr. J. Thomas) delivered an address on the work and aims of the Agricultural Bureau, which was much appreciated by members.

MUNDOORA, March 20th.—Handling Wheat in Bulk.—Mr. G. M. Wilson read a short paper. This system, he said, was being successfully carried out in other countries, and South Australia was not up-to-date in the matter of wheat handling. Messrs. Browne, Button, Stephenson, and Clothier spoke in favor of the system.

NARRIDY, March 21st.—Messrs. W. F. Nicholls and R. Satchell reported on the proceedings of the Conference of the Northern Branches. The latter gentleman stated that he mentioned to the Dairy Expert the case of a cow kept in good condition through the dry summer, then turned on to good green pasture, and which died from dry bible within ten days. The Dairy Expert's answer, he said, was that the cow died from shock, which he characterised as ridiculous.

[The shorthand record of Mr. Suter's remarks shows that he said he could not hazard a guess as to what caused the death in cases where he had not seen the beast; it might have been due to shock or any other causes.—Ed.]

SPALDING, March 27th.—Selection of Farm Implements.—Mr. H. A. Gill read a paper on this subject in which the good and bad points of various implements and machines were compared, especially in view of their suitability for different classes of country. [We regret our inability to print this paper, as the use of makers' names would necessitate giving the former an opportunity of replying.—Ed.]

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16·46in.).

April 4th.—Present: 22 members and seven visitors.

Stock-Raising.—A paper on this subject was read by Mr. J. T. Harmer. The following is extracted therefrom:—"During the last 50 years greater results in the breeding of all farm animals have been accomplished and greater progress towards perfection made than ever before. Many farmers suppose that animals may be exposed to the storms of winter without serious detriment. No mistake could be more fatal to the stock raiser than this. An animal that barely survives the winter seldom more than regains during the next summer the flesh lost. No farmer should keep more stock than he can feed properly. One well-kept beast is worth more than three poor ones. In fact, if I go out to buy cattle or sheep, I can always rely on getting something good from the farmer who does not overstock his farm. The only profit there is in stock raising of any kind is made by keeping them steadily growing until they reach maturity. For once an animal is stunted in growth it never gains much weight afterwards. No money was ever made by neglecting or starving farm stock. It is better to get rid of some of the stock than to feed the pasture too close. Animals that have to busy themselves all day to satisfy their hunger never come out fat. If farmers have provided for contingencies by means of fodder they may, of course, stock their pastures closer than otherwise. It is just as cheap for the farmer who only fattens a few head yearly to make prime cattle as it is for the one who fattens hundreds. In fact a man who fattens but a few head should make better cattle. For the two purposes of milk and beef combined, I believe the milking strain of the Shorthorn cattle is the best. The cow that is not a good milker can be sold to the butcher, and as Shorthorns are mostly heavy-weight cattle one can always demand a fair price for them." Mr. McEwin mentioned the necessity for keeping the dual purpose cow in this district, and Mr. Pratt expressed a preference for the Shorthorn.

Experimental Plots.—A committee to supervise demonstration plots was appointed, as follows:—Messrs. W. and J. Pratt and J. Williams. Messrs. A. L. McEwin, C. P. Schuster, and H. Hamilton undertook to conduct manurial tests, and Messrs. J. T. Harmer and M. Williams wheat variety tests.

FRIEDRICHSWALDE (Average annual rainfall, 18in. to 19in.)

April 4th.—Present: five members and two visitors.

The Erection of a Homestead.—Mr. F. W. Duldig read the following paper on this subject:—"After purchasing an unimproved farm the first point to decide is a suitable place to erect the homestead. This should be put near a main road, as it is very inconvenient having a lot of gates to open, especially if a person is driving spirited horses. The house should be built of stone or brick, having high walls and plenty of ventilation. If possible the front should face north or even south, thus avoiding the sun shining on the doors and windows, and the rough westerly weather does not beat into the house. For the stable I prefer galvanized iron walls and a straw thatch roof. Gum forks, 8ft. high outside and 11ft. 6in. in the centre, giving a 3ft. 6in. pitch should be used. It is a big mistake to have a wide span between the forks. Stretchers, 5in. in thickness, and rafters 3in., with No. 8 wire drawn across are lighter and better than extra timber to keep the straw on. It is a good plan to attach a chaff house to the stable for convenience in feeding the horses. An implement shed should be five or six chains away from the stable. It is not advisable to have all the sheds connected, owing to the danger of fire. Cow yards and pig sties are best built apart from the rest of the sheds. The poultry shed should be of galvanized iron. The blacksmith shop and tool house may be built of stone or galvanized iron, apart from the other outbuildings. Water for the stock should be as handy to the homestead as possible, and always available. If stock have to be driven to water they very often have to go all day without sufficient drink, especially if worked on roads."

GAWLER RIVER (Average annual rainfall, 17in. to 18in.)

April 17th.—Present: nine members.

Fodder Crops.—Mr. P. T. Hill read a paper on this subject. Lucerne, he said, stood foremost as greenfeed. Variety, however, was an important point in feeding stock, and the best method of proving this needed consideration. "There are numbers of suitable fodders, such as rape, kale, silver beet, barley, oats, Egyptian clover, &c.," the paper continued, "but for this locality with its, say, 18in. rainfall annually recent experience seems to point to rape as deserving a place second to lucerne amongst food plants. It may be described as a member of the cabbage family, growing from, say 10in. to 15in. in height. It is renowned for its crisp and succulent nature. It is not a deep-rooting plant, therefore does not stand the heat as well as lucerne. If eaten close to the ground during excessive heat many plants die, and most likely if stock run on it it will require replanting after the second year. It is much liked by stock, and does not in any wise taint milk or butter. In winter, when lucerne makes slow growth, the rape is the most vigorous, consequently in Europe, notably in England and Germany, it is freely grown for cattle. Oilcake made from it is well known for its fat-forming qualities. Last year on a Gawler River farm a few acres were sown with rape which gave splendid results, for whilst most dairy cattle in the district were reduced to skeletons owing to the scarcity of feed those favored with the freedom of the rape paddock were fat and sleek. The crop mentioned was, through necessity, fed down too closely, and during the heat of the dry summer following a dry winter much of it died. Last year's crop upon the river flats was such a marked success that the same alert farmers are this year planting a much larger area on the higher lands. It cannot be expected that the higher, lighter, and drier lands will yield a crop to compare with that upon the better soil of the flats upon the river frontage. Last year two small plots were sown on the dry land back from the river about a quarter of a mile. No. 1 was not watered artificially and yielded a light crop late in spring, but suffered severely from the summer heat and died down, but fully one-third of the plants sprang into life after the rains of February 27th, and at the beginning of April yielded a moderate cutting. No. 2 was watered with Barossa water, and during the same period gave five fine cuttings. Only 5 per cent. of the plants succumbed to February's heat. The tenderness of those plants was such that poultry devoured them greedily. It was fed in rotation with lucerne and kale, and the decided success attending past operations strongly recommends it for the future."

JULIA (Average annual rainfall, 18in. to 19in.).

April 11th.—Present: 13 members and three visitors.

Wheats for District.—Mr. G. Gaerth contributed a paper on this subject, in which he stated that farmers should take careful notice of the soil and climatic conditions of the district when selecting wheat for seed. They should retain over harvest more wheat of both early and late varieties than they were likely to require for sowing. When the season opened they should select the varieties intended for sowing, with due regard to the conditions which promised during the year. Seed should not be discarded if it did not prove successful in the one year. For testing new varieties a few acres were sufficient. The standard of the seed would be well maintained if farmers made a practice of selecting the best of heads from their crops and sowing these to provide future seed. He thought Federation the best variety for this district, and Florence, a newer wheat, promised well. For late varieties he favored either Yandilla King, Bluey, or Marshall's No. 3. Early varieties were best for hay. King's Early, Gluyas, and Baroota Wonder were very suitable.

Harrowing after the Drill.—Mr. C. Nash read a paper on this subject, in which he said that harrowing after the drill was a practice which, in this district, should not be neglected, especially where land was infested with destructive weeds. If this harrowing were made a regular practice it would no doubt prove a great success. It was necessary for each farmer to test the practice, however, as on one farm it might be suitable and not on another. He thought the best time to harrow was two or three days after drilling, but if land were being drilled during dry weather, this was not so necessary, but if it were wet or sticky the drill did not cover the grain as it should, and the grain was liable to perish if not harrowed. The best way to remedy this was to attach the patent self-adjusting harrows to the drill, which would be little trouble where the land was clean and free from rubbish. Should the weather prove favorable, however, the common harrows should be used, and the ground reharrowed across the drilling.

NORTHFIELD (Average annual rainfall, 19in.).

April 7th.—Present: eight members.

Harrowing.—Mr. D. Rowe read a paper. He said—"In the case of land which does not clean from the plough it is questionable whether the edges of the furrow should be broken to cover rubbish, or whether the harrow should be loaded to pull the rubbish to the surface. I am in favor of the former. The first harrowing should pulverise the soil, break the lumps (if any), and work to a depth of 1in. or 1½in., leaving the cultivator to make a seed bed. The reasons for this are that the ground has been ploughed when wet, and if harrowed when the surface is in proper condition, viz., the top a little dry, it covers the rubbish with earth. Rain following causes the rubbish to decay. If harrowed again two or three weeks after the rain the rubbish is too decomposed to be an annoyance. I am not in sympathy with loading the harrows, because it is too much like doing unnecessary work. Harrows, if loaded, frequently pull up lumps or clods, besides rubbish, which remains to be a nuisance for some time. I have known roots of bulldogs and stinkwort and branches of the same to remain in this way for 12 months after being pulled up. I have not seen any extra crop for the extra weight and work put into the land. Harrowing after the grain has been drilled has a good deal to do with the return of our year's labor. If we are fortunate enough to harrow when the ground is too damp for the dust to rise, and not wet, and dry enough to kill the rubbish, and we have a light rain of about 20 or 25 points six or eight days after sowing, and the plant gets strong before a heavy rain comes the prospects are good. Harrowing in the early part of the season can be done three or four days after sowing and prove very successful, and later, six or eight days after sowing." Messrs. Dall and Williams firmly believed in the usefulness of the harrows. Messrs. Kelly and Goldney preferred the cultivator.

SALISBURY (Average annual rainfall, 18·57in.).

March 24th.—Present: 15 members.

Experimental Plots.—Arrangements were made for manurial tests to be conducted by Mr. E. Tate, and variety tests to be undertaken by Mr. E. Moss.

Harvest Results.—Members presented reports of the harvest just completed. Generally it was agreed that the outstanding feature of the season was its exceptional dryness. Mr. E. Tate fallowed his land in June and July, scarified it twice before harvest and once again before drilling. Baroota Wonder wheat was sown on May 20th with 120lbs. of super. per acre; the average hay cut was 1¼ tons. Mr. W. W. Shepherdson ploughed during August; broke the land down well in the spring with the cultivator, and again in February after a heavy fall of rain. Wheat and oats mixed with 1¾cwts. of super.

was sown during the last week in May. The germination was irregular. The yield of hay equalled 15cwts. per acre, and but for a fall of rain in October, would have been worthless. The wheat was badly affected with red rust. Mr. E. Moss fallowed in August, harrowed, and later scarified his land three times. Heavy rains in February and March set the ground very solid, and it was scarified deeply in April, and harrowed before sowing at end of May, and rolled and harrowed after crop was up. Dart's Imperial wheat alone was sown on a small portion, and the same variety of wheat and Algerian oats on the balance. Mineral super. was used at the rate of 1¾cwts. per acre. The yield was about 25cwts. per acre. Some patches came up in due time after sowing and the rest from one month to two months later. Rust affected the wheat very badly, but the oats were free from it. Where wheat only was sown the rust was so bad that the hay was almost worthless. Where oats were mixed the wheat was not so badly affected and the hay was very palatable. Where there was wheat only the crop was good enough for 35cwts. to the acre. On this ground peas were grown two years ago instead of hay, and the difference in growth last season was very marked. Mr. F. C. Fleet fallowed to a depth of 3½in. in July, 1912. Part was harrowed twice before the cultivator in September. The harrows again followed, and the wheat was drilled in with 5cwts. of gypsum per acre during April. Portion was cultivated and harrowed, and drilled on June 10th with about 3cwts. gypsum, the harrows following; Dart's Imperial wheat and oats mixed were sown. The result was a cut of 15cwts. hay per acre. Mr. J. A. Short fallowed in July and August, scarified during September and October, scarified shallow in February and drilled with 1cwt. Thomas' phosphate and shells mixed. The greater part was sown in May with oats ½bush., Baroota Wonder ½bush., and Le Huguenot ½bush. mixed, a total of 1½bush. with 1cwt. of guano super. to the acre. One small paddock was sown with Majestic and one with King's Early and Golden Drop mixed. Germination was very uneven, some of the wheat malting and some germinating very late. The mixed oats and wheats gave a much better return for hay than that sown with wheat only. The wheat sown by itself was affected with red rust, while wheat mixed with oats was practically free from rust. Mr. H. Bussenschutt ploughed in the winter, cultivated two or three times in the spring, and again just before seeding. Baroota Wonder and Le Huguenot wheats mixed with oats were sown in May, with from 1cwt. to 3cwts. of bone super. per acre. Shells had been put on part of the area sown twenty years ago, the cost of the shelling being £2 per acre. The portion so treated gave the best results this year. Mr. T. H. Judd commenced fallowing in July to a depth of from 4in. to 5in. The land received frequent working prior to seeding. Baroota Wonder, Correll's, Dart's Imperial, and Le Huguenot wheats were each sown with oats, about 1½bush. of seed per acre. The part fallowed early yielded about 35cwts. hay per acre. and that fallowed later from 15cwts. to 20cwts. Land on which Le Huguenot wheat had previously been grown did not yield so well. Dart's Imperial and Correll were badly affected with rust, Baroota Wonder was slightly affected, but the fungus did not affect the Le Huguenot. Mr. W. J. McNicol's cropping area was ploughed between June 20th and July 30th, cultivated in August and October, and part again in November. Seeding commenced in the first week in June, and finished in the first week in July. Baroota Wonder, 1¼bush., mixed with oats. ¼bush.; King's White, 1¼bush., and Golden Drop, 1¼bush., mixed with oats, ¼bush. were sown. Super. at the rate of 125lbs. per acre was applied, except to the King's White, which received 100lbs. The harvest, which yielded three-quarters of a ton hay per acre, and 6½bush. of grain (King's White) was the poorest experienced for 16 years. Baroota Wonder did best.

SALISBURY (Average annual rainfall, 18·57in.)

April 7th.—Present: 12 members.

Sheep and Forage Crops.—The address delivered by the Director of Agriculture on this subject, reported in the March issue, 1914, page 856, was read and discussed. Members thought that hay at 35s. per ton could be more profitably fed to stock than sold. Whilst this would entail more work the stock would improve the land. Sheep would fatten on chaff. Mr. Neal fed 1,000 sheep during a drought by sprinkling clean wheat on the ground, a little being fed at first. The sheep were kept in good condition and reared lambs. Peas was thought the best crop for fodder in this district. The land was too hard to break up early for rape, except in the case of fallow. Mangolds paid better than sorghum and similar crops.

MALLALA, April 7th.—**Veterinary Science.**—In the afternoon the Government Veterinary Lecturer, Mr. F. E. Place, B.V.Sc., M.R.C.V.S., gave a lengthy and very instructive demonstration at Mr. Kongig's farm. Over 80 persons were present. A horse for demonstration purposes was provided by Mr. McCabe. Several horses and a cow were brought in for inspection, and their ailments explained and treated. In the evening Mr. Place delivered a lecture on "Stomach Troubles and their Remedies."

NANTAWARRA, April 8th.—DRIFT.—Members advised applying super. to the soil when barley was sown with the object of preventing drift. Mr. J. H. Nicholls preferred wheat to barley for this purpose. Mr. Smith and Mr. R. P. Uppill recommended either wheat or oats, sown with super.

STOCKPORT, March 23rd.—FODDER CROPS.—The Chairman (Mr. R. Whitelaw) thought vetches and tares would make good fodder in this district. Mr. Cant recommended sowing lucerne with the wheat. Mr. Watts thought barley was best in this district for feed, even when sown late in the year.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

MAITLAND (Average annual rainfall, 20·08in.).

April 4th.—Present: 10 members.

HANDLING WHEAT IN BULK.—Mr. F. Wundersitz read a paper, as follows:—"Whilst the bulk handling of wheat is the best system for a State which is sufficiently developed, that is, so far as railways are concerned, the wheat-producing areas of South Australia are not sufficiently connected with railways to warrant the introduction of the system at present. In the first place, most of our wheat is taken to port during about eight weeks. If we had one elevating plant alone it would mean endless complications in the few weeks during which the wheat was being handled. We would still have to provide bags for harvest. One might send in all new bags, and his neighbour secondhand bags. When the empties were returned probably the former would get the secondhand bags and the other man the new ones. About four elevators would be needed in different parts to handle our wheat successfully. More railways and new rolling-stock would be required, and in addition, each wheat-buying station would need a weighbridge. This would mean a considerable outlay." Members generally agreed that circumstances were against the success of the system in this State.

MINLATON (Average annual rainfall, 17·46in.).

March 12th.—Present: 12 members.

POULTRY-FARMING.—Mr. J. A. O'Brien read a paper in which he said—"A poultry farm in full swing should have at least 1,000 laying hens, for preference, White Leghorns, averaging from 170 to 190 eggs per head yearly. The laying flock should be obtained by culling out and breeding only from tested hens, either by trap nests or the single pen method. Careful attention to feeding and cleanliness is quite as important as 'strain,' for no matter how good a laying strain, if the birds are not properly and systematically fed, their pens and quarters not kept in a clean healthy state, payable returns will not be secured. The best wheat, pollard, bran, meat meal, maize, peas, oats only should be fed, and greenfeed and plenty of grit should always be in the pens. One of the most important items is pure, fresh drinking water in utensils which must be thoroughly cleansed every day and kept in the shade, otherwise sickness is sure to follow. The first meal should be given not later than 7 a.m., and should consist of a mash composed of two parts pollard and one of bran, lucerne chaff, and meat meal mixed with hot soup and worked with the hands into a crumbly mass (not sloppy), and served at the rate of about 4ozs. or 5ozs. per bird. Each bird should get enough to provide the machinery with sufficient to produce condition to the body, strength to the feather, and energy and power to lay eggs. The quantities required must be determined by observation, as a bird will not eat more than is necessary for its needs. The whole of the feed given to the fowls should be cleaned up by them, and none of the mash should be allowed to lie about to become soured. At noon chaffed greenfeed should be supplied, and at 5 p.m. grain, generally wheat. In cold weather peas, maize, or oats may be used with advantage at the rate of about 2ozs. per bird. The grain should be scattered in the litter to keep the birds in exercise, always keeping a good supply of grit and charcoal handy. Pens to hold about 50 hens, with warm shelter houses, scratching sheds, and dust baths are advisable. Hens provided with warm houses will give a much larger percentage of eggs than those allowed to roost in trees. An established farm should also have equipment, such as incubators, incubator houses, brooders, and chicken runs, and turn out 1,500 chickens to keep the flock up by replacing all hens over 2 years old and culls. To prove that poultry-farming in the hands of an energetic, careful man, carried out on the lines such as I have just suggested, will pay, I cannot do better than quote the figures of the last Roseworthy competition, which shows a profit of 10s. 10·2d. per hen over the cost of food. Besides marketing eggs a poultry farm must produce a good quality table bird—I would suggest the Faverolle-Indian Game cross—sending to market good 4-months-old plump cockerels and pullets from 4lbs. to 5lbs. live weight, returning an average of about 2s. per bird. It is absolutely necessary to keep two or three good cows, so that the fowls and chickens can have a supply of skim milk, the cream being sent to the nearest butter factory. Any surplus milk could be fed to pigs. The sale of cream and pigs during the year would more than compensate for the extra cost. I am not in a position to give the figures for cream, but the pig market at present is really good, and I feel sure that there would be a further margin of profit, which would, perhaps, bring the income up to about £650. From this amount the wages of a lad are to be deducted, leaving the net income, or wages, for the proprietor at about £600."

YORKETOWN (Average annual rainfall, 17·47in.).

April 11th.—Present: six members and one visitor.

Harvest Report.—Mr. J. V. Davey (Hon. Secretary) read the following report of the season's cropping:—"The season just passed has been of an unusual character, and, therefore, any reasoning from the behaviour of crops grown will necessarily be of somewhat limited application. The rainfall registered at Yorketown for the year was 4·36in. below the average, and where I reside the deficiency was even greater, especially during the earlier part of the year. Grubs destroyed a good deal of the wheat that did come up. Perhaps the most striking feature was the failure of germination in a great deal of the seed. The grain did not appear to malt very quickly. Some of my early sown wheat came up two months afterwards. Grain sown shallow fared the best; where the seed was buried to a depth of 3in. or more the plant never developed sufficient strength to force its way to the surface. It simply ran along under the crust, and after a time died off. The best germination that I had was a piece of Cape barley sown broadcast and harrowed once, the super. being drilled in beforehand. This came on comparatively well from the start, and yielded about 12½bush. As regards varieties of wheat, Federation and Marshall's No. 3 yielded about equal returns, but King's Red was not so good. Forty-six acres of Federation was cross drilled with 100lbs. super. and ½bush. of seed each way, the land being rolled between the two drillings. The crop returned about 10bush. per acre. Thirty-nine acres of similar land alongside, drilled once with 100lbs. super. and 1bush. seed (Federation) yielded 7½bush. This result of 2½bush. extra from the cross drilling can scarcely be called profitable, although it demonstrates that the land responds to some extent to the extra manuring, even in the driest seasons. I also cross drilled 34 acres of Pryor's barley with 100lbs. super. and ½bush. of seed each way, and the crop yielded 7½bush. per acre. Thirty-one acres alongside, drilled once with 100lbs. super. and 1bush. seed returned 6bush. Both of these pieces of crops were badly damaged by grubs. I am inclined to think that in such a dry season much of the super. sown remains in the soil, and my intention is, if possible, to give those two pieces of ground very light surface cultivation only and sow them with barley again this year, using about 80lbs. of super. per acre on each, and reap them separately in order to see if there is any improvement the following year from the heavier dressing of manure used in cross drilling."

MINLATON, April 9th.—Papers were read by the President (Mr. J. W. Griffiths) and Mr. H. A. Chester. Unfortunately these are not available for publication. In the course of discussion members realised that farmers had benefited greatly by agricultural research and scientific education. Farming at the present day was not dreary, but full of interest. The man on the land had to adapt himself to his environment, and the variations of conditions demanded that he should solve many problems for himself.

MOONTA, April 11th.—**Working Fallow.**—Mr. B. Ferguson had worked his fallowland immediately after harvest last year and had obtained a record return. The soil was light. Mr. J. Brinkworth favored this practice after rain, but not if the ground was dry. Mr. C. Nankivell had worked his fallow directly after harvest for two seasons, when the ground was wet, and had received very poor returns. He favored summer fallowing and working back during the following season, following which he had received an increase of fully two bags to the acre.

Double Manuring.—Mr. W. J. Brinkworth advocated this practice. He applied 50lbs. of super. when fallowing and 50lbs. when drilling in the seed. By this means the manure became thoroughly mixed with the soil. Unfortunately last year he had drilled his doubly-manured land too early, as the early rains were light and some of the wheat in the heavy land was thin. He had received best returns from the sandy soils.

WESTERN DISTRICT.

ELBOW HILL (Average annual rainfall, 11in. to 12in.).

April 4th.—Present: 10 members.

Continued Applications of Super.—Mr. H. Wheeler wished to have the opinion of members as to whether continued applications of super would have a detrimental effect on the land. The Chairman had applied super. for several years on the same land without any detrimental change being noticeable. At the same time he thought it was advisable to change the manure from phosphates to guano. Members agreed with this opinion. [If members have any doubt as to the effect of continued dressings of super. on mallee lands, they should study the reports of the Roseworthy Agricultural College Farm, where heavy dressings have been applied longer than anywhere else in the State. If further information be needed, the Principal, doubtless, would readily furnish it.—Ed.] Members generally applied the same quantity of super. for oats as for wheat.

Exhibit.—Mr. A. Chilman tabled a fine sample of lucerne of the Hunter River variety. The plot had been sown three years ago and had grown about 12in. since cut three weeks ago. It had withstood the dry weather remarkably well, and he was of the opinion that this crop could be grown extensively in the hills. The Chairman had noticed several plants growing in his paddocks. These had been sown over five years ago. Mr. F. Spence stated that some farmers sowed lucerne with wheat as food for stock. Members generally agreed that lucerne would do well in this district.

KOPPIO (Average annual rainfall, 22·40in.)

April 9th.—Present: nine members and one visitor.

Experimental Plots.—The following wheats were chosen for the variety tests to be carried out on Mr. Gardner's farm:—Early—Bunyip and Dart's; Mid-season—Federation and Cooper's; Late—W.A. Crossbred and Yandilla King. The plots were to be half an acre each in extent, fallowed and worked similarly, and all sown on the same day with 1bush. of seed and 1cwt. mineral super. per acre.

Fodder Crops and Stock.—A paper by Mr. Sprigg, read before the Morphett Vale Branch (*see* page 881, March, 1914, issue), was read by the Secretary. Members were of the opinion that the paper was an excellent one, and much of it would apply to this district. Mr. Gardner had grown kale and rape sucessfully on fallow. Barley was considered one of the best early fodder crops; sorghum had been tried last year, but with only moderate success. An excellent sample of lucerne was tabled by Mr. Gardner. It was about 18in. high, the result of three weeks growth from the last cut, and had not been irrigated. Samples of ungraded and graded wheat with the rubbish taken out by the grader were tabled by the Secretary (Mr. R. Richardson).

MILTALIE (Average annual rainfall, 14·55in.).

April 4th.—Present: 12 members and six visitors.

Farmers' Difficulties.—A lengthy paper was contributed by Mr. W. E. Hier, in which he dealt with causes which sometimes led to the failure of farmers. In the matter of share-farming, he said, many young men did not secure a properly drawn up agreement before commencing work on a block. A verbal undertaking was usually most unsatisfactory. Failure on the part of the man who had put by a certain amount of capital, and had taken up land from the Government, was due to different causes. There was too often a tendency to take little account of the possibility of adverse seasons. When these occurred immediately the farmer had taken up his land, quite likely his capital would be found insufficient. Horse stock involved a considerable outlay; clearing and fencing were expensive; and wire netting loan, land taxes, and district rates all helped to swell the expenses. As a general rule, unimproved land was not worth the value that was put on it. He suggested that land taxes should not be collected until the farm was yielding some return on the outlay. The practice of erecting sheds and providing water tanks that had been adopted by the Government was a good one, but they might go further, and roll about 200 acres of mallee, ready for the farmer to burn and clear, and thus enable him to get a crop in 12 months earlier. Such matters as want of seasonable rain, high price of labor, quick growth of shoots and scrub, high price of bags, and living expenses, and distance from markets all militated against the success of the settler. Some who had taken up land in this district had paid altogether too much for it. The construction of a railway in this district would, he thought, greatly improve the conditions under which settlers were laboring. The Chairman (Mr. P. G. Wilson) thought there should be a more equitable distribution of the good land in the district when allotted. Mr. J. P. Storey attributed the present unsatisfactory conditions in some cases to the high prices paid for land some few years ago. The Government was doing quite enough for the farmer. Mr. A. M. Wilson did not think the Government should be asked to clear the land.

MITCHELL.

March 28th.—Present: 11 members and two visitors.

Horses' Shoulders.—Mr. G. Jericho read a paper on this subject. The chief preventive measure, he said, should be to keep the animal's shoulders clean. Sweat should always be brushed off. Immediately a sore appeared the collar should be examined; a lump inside this might be the cause. If so, a bran bag should be placed under it. If no improvement were noticeable, the lining should be cut and portion of the stuffing removed. If the animals were kept in good condition, little trouble should be experienced. When they were working hard, a few pints of oats in their feed was advisable. Flies should be kept from sores by the application of blacklead finely powdered and mixed with oil, or some such preparation. Well-fitting collars were essential.

The Farm Homestead.—Mr. E. C. Jenkins read a paper, as follows:—"In selecting a site for a homestead on a scrub farm care should be taken to pick on a spot situated near the centre of the block, so that any part of the farm may be conveniently worked from the homestead. Of course, the water supply is one of the main factors to be considered, but in a country such as this, where most farmers have to rely on dams for their water, a person can usually find a suitable spot for a dam somewhere near the middle of the block. If a well of fresh water is to be found, make the homestead near this. It is better to have the farm buildings on the east side of a hill and the dam on the west. Then the drainage of the stable will be away from the dam. Build the homestead on land of a sandy nature, as it never gets boggy and muddy. Should I again start farming on a scrub block where it is doubtful whether water can be secured by sinking, I should thoroughly explore the block before putting up the house. If I could find a sandy rise with a red flat of good holding ground to the west and a good catchment for a dam situated near the centre of the block, I should place the homestead there."

PENONG (Average annual rainfall, 11·93in.)

April 11th.—Present: five members and two visitors.

Preparation for Seeding.—The member responsible for a paper was not present, and had not forwarded the paper. Regret was expressed at this, as it had a tendency to discourage members who took a keen interest in the Branch. In the expectancy of hearing a paper members did not come prepared to initiate a discussion. Mr. J. C. Steggants, who was farming in stumpy country, preferred the disc harrow to the plough for preparing his land for seeding. A cultivator only was necessary on fallow. The Hon. Secretary (Mr. J. Oats) advised early fallowing. The weeds could be killed with the cultivator, or fed down with sheep. Fallow would benefit by being harrowed occasionally. This would conserve the moisture, and perhaps tend to prevent drift, which was so likely to occur in range country. He preferred the disc plough for working stubble. The Chairman (Mr. A. Shephard) favored early sowing. The disc harrow had the disadvantage of making the land uneven.

ROBERTS AND VERRAN.

April 8th.—Present: eight members and three visitors.

Pickling Wheat.—Mr. J. C. McCallum contributed a paper on this subject. He had tried various solutions for pickling wheat, such as formalin, sulphate of copper (bluestone), with varying results. The success of bluestone depended largely upon the manner in which it was utilised. Into a 1 per cent. solution (1lb. of bluestone to 10galls. of water) in a cask, a thin bag, such as a bran bag, holding about 1½bush. should be placed and allowed to remain for three minutes. It should then be shaken vigorously and the solution allowed to drain back into the cask. If wheat were badly affected with smut a solution consisting of 1lb. of bluestone to 6galls. of water should be used. The object of pickling was to destroy the tiny spores or seeds of smut which adhered to the grain. In the discussion members generally favored sowing the seed three or four days after pickling, Mr. Masters preferred dipping the seed into the solution to the floor method. If the wheat were dipped in a solution of lime after pickling it would germinate better, although it would not run so freely through the drill. Mr. W. Kunst favored the floor method of pickling. Mr. W. Sharman also adopted this method and was seldom troubled with smut. Mr. Masters considered formalin a preventive of black rust, but thought the wheat did not germinate well if left too long before being sown. He preferred pickling all seed, but would only sow dry seed in dry weather before rain.

YABMANA (Average annual rainfall, 17·14in.).

April 4th.—Present: six members and two visitors.

Bulk Handling of Wheat.—Mr. Robertson expressed the opinion that the introduction of this system would result in a great saving of bags and do away with the practice of "docking" on inferior samples. Mr. Schumann thought wheat in bulk would not realise the same price as that bagged. Bags would not stand refilling many times, and unless sufficient to hold the season's crop were purchased, extra teams would be necessary to cart the wheat as it was harvested. Mr. A. McCallum agreed. Mr. F. A. Beinke suggested a trial shipment in bulk.

YADNARIE (Average annual rainfall, 14·09in.)

April 4th.—Present: 12 members and four visitors.

Stubble-Burning.—The following paper was read by Mr. W. L. Brown:—"On this matter there are numerous conflicting ideas. My experience is that the crops which have to follow on stubble without the advantage of burning off have in every instance been greatly inferior to that sown on the burnt land. Burning off improves the fertility of the soil by the deposit of ashes which result and also by the heating of the soil. It destroys the low forms of animal life which feed upon the nitrate producing and nitrogen transforming organisms in the soil. As a result the bacteria increase in numbers, and make more nitrogen available. There are two systems of farming. There is the one adopted by the pioneers, who have to clear the virgin land of all timber, stumps, stones, &c. Not until it is clear of all such obstacles can the farmer work his land on the most up-to-date methods. The most approved way then for the man who is fortunate enough to have his farm in such a condition that he can go in for working his land on the second system is to subdivide the farm into four parts, one devoted to fallow, one to wheat after the fallow, one to Algerian oats for grazing, and one to be left out to the natural grass. If this plan is followed all stubble is enabled to revert to the condition favorable to the increase of bacteria, which makes more nitrogen available in the soil. I am firmly of the belief that a lot of expensive machinery can be done away with when a farm is thoroughly clear. A farmer then could do the bulk of his harvesting with the binder. By using a header a large quantity of the straw could be saved to mix with the hay. The portion not fit for that purpose could be converted into stable-yard manure. A simple way to conserve farmyard manure is to make a foundation of a good bed of dry earth. Manure placed on this should be covered occasionally with a light protective layer of earth. Preserved in this way the manure has been found by analysis, after six months, to have lost but 2 per cent. of its quality, whilst a similar mass without the protective cover of earth lost 23 per cent. of its most valuable ingredient—nitrogen. The action of stubble in the soil is the same as that of new stable manure. It is of no benefit to the growing crop. My experience is that take-all has been more troublesome in a crop following on stubble, especially in a wet season. A good fire over the land does it a great deal of good, and there is less difficulty in putting in the crop."

COLTON, April 18th.—The Chairman (Mr. E. A. Whitehead) commented upon the dilatory spirit among members generally. He mentioned the work and efforts of life members of the Bureau, and expressed the sanguine hope that more interest would be taken in the Branch.

COORABIE, April 4th.—Stock Troubles.—Members continued the discussion, which had been carried on at the last two meetings, relative to stock troubles. A number of particular cases of complaints in horses were reported and referred to the Government Veterinary Lecturer for opinion and advice.

GREEN PATCH, April 6th.—Sorghum.—Samples of sorghum, amber cane, and kaffir corn were tabled by Mr. E. M. Sage. These had been grown in limestone soil to a height of about 7ft., without irrigation. Both in ironstone and limestone soils he had grown this crop for fodder for some years, sowing about 3lbs. of seed per acre in the late spring on well-worked ground.

MANGALO, April 11th.—DEMONSTRATION PLOTS.—It was decided to conduct experiments with different methods of cultivation, wheat variety tests, quantities of seed, quantities of super., and kinds of super. A committee was elected to arrange details.

MITCHELL, April 11th.—Mr. McCormack read a paper on castrating colts. Mr. Timble advised leaving the operation until the animals were three years old.

YALLUNDA, April 5th.—QUESTION BOX—*Ploughing*—Mr. G. Provis considered from 3in. to 4in. a fair depth to plough, but Mr. Forrest strongly advised setting the plough according to the nature of the soil. The depth of the soil in this hilly district varied considerably, and he did not favor turning the subsoil to the surface. Where takeall was troublesome shallow ploughing had proved to be beneficial.

STUBBLE-BURNING.—Mr. Fairbrother had found that cereals yielded well after a stubble burn, but the Chairman and Mr. W. Cabot considered it advisable to plough in the stubble if possible.

FRUITS.—Several members had found that apples grew well in this district. Mr. Fairbrother said that peaches, although they appeared to thrive well at first, seemed to give out when about eight or nine years old. Grape vines had proved well adapted for this district, both as to qualtiy of fruit and hardiness of plant.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

CLAYPAN BORE (Average annual rainfall, 16in. to 17in.)

April 8th.—Present: 10 members and two visitors.

EXPERIMENTAL PLOTS.—Mr. S. Hill undertook to conduct manurial and variety tests, and a committee consisting of the President (Mr. J. Gray), Mr. M. Robinson, and the Hon. Secretary (Mr. L. McCormack) were appointed to supervise.

HARVEST RESULTS.—Mr. J. Gray reported that he had sown oats on part fallow land and part stubble. The fallow land was ploughed for seeding in 1912, but left for fallow, ploughed in October and again in April. The stubble land, which was mostly sand, was ploughed in April, the heavier land being cultivated before seeding. It was sown during the first week in May. Part cut for hay yielded about 1¼ tons per acre. On stubble land, ploughed after March rains, cultivated with tine cultivator before drilling, 1bush. of Viking wheat and 60lbs. super. were sown. The result was 10bush. per acre. Stubble land ploughed in March after rain, cultivated before drilling, part with tine cultivator and part with light Norman disc. was sown with 1bush. Gluyas wheat and about 60lbs. super. per acre. This yielded 11bush. per acre. One hundred and eighty three acres were fallowed in August, and the greater part of the field was tine cultivated in October and ploughed again in April and May. Two sandhills included in this area were cultivated with the tine cultivator. This field was sown partly with Federation wheat and partly with Golden Drop. On the flats oats and Le Huguenot and oats mixed were sown; 1bush. wheat, 1½bush. oats, and ¾bush. each of oats and wheat mixed were the quantities of seed sown, and 60lbs. to 70lbs. super. The flats and as much of the sand as possible were cut for hay, yielding about 1 ton per acre. One sandhill was very badly affected with takeall. Portion of this which was reaped yielded from 1bush. to 2bush. wheat of poor sample. Federation was badly affected with rust, and some portions appeared to have been frosted. It yielded 9bush. of grain of rather pinched sample. One sandhill that had grown three crops of Algerian oats in succession returned about 12bush. per acre of Golden Drop wheat. A 300 acre field, containing about 100 acres heavy sandhills, was fallowed in August and September. Only a small portion of it was worked. It was heavily stocked with horses to eat off self-sown wheat, and ploughed in June and July before drilling. One part sown to Golden Drop in June produced a fine looking-crop, but it was badly damaged by high winds; it yielded 10bush. per acre. A large part was sown to Gluyas wheat in June and July. It was badly knocked down by the wind, and yielded 10bush. per acre. Another portion sown to Viking wheat was badly affected with rust. It yielded 8bush. per acre. A small part sown with Bunyip during the last week in July yielded 8bush. One and a quarter acres sown with 2bush. peas in last week in July yielded about 9bush. per acre. About half the crop was left on the field. There was a poor growth on sand, but on heavier land the growth was good." Mr. S. Hill cultivated portion of his cropping area in May, 1913. At the end of June it was ploughed shallow, and drilled with 50lbs. wheat and 80lbs. super. Germination was slow, but a good dark-green growth resulted in a return of 15bush. per acre. One hundred and fifty acres ploughed and drilled with 60lbs. wheat and 80lbs. super., harrowed after the drill, yielded slightly over 7bush. per acre. He believed, from the experience of the past that careful working of the land would ensure fair returns in this district.

COOMANDOOK (Average annual rainfall, 18·01in.).

April 4th.—Present: 13 members.

Fodder Crops.—Mr. Legallez contributed a paper on this subject, in which he stated that up to the present the object of settlers in this new district had been to grow wheat and destroy the mallee. The blocks were too large to be entirely devoted to cereal growing, and it would, he thought, be wise for farmers to experiment with fodders. Leguminous crops were best for the land, and he thought lucerne would prove the most profitable in this district. It should be sown early in autumn on good sandy loam, which had been manured, ploughed deep, and cultivated to eradicate the weeds. Hunter River seed, guaranteed free from dodder should be mixed with super. at the rate of about 8lbs. per acre and sown immediately, or the super. might impair the germination of the seed. As an experiment a plot should be irrigated with the waste water from the bore. If it were intended to provide grazing in the stubble paddocks, seeding at the rate of 3lbs. or 4lbs. per acre would be ample. It should be put in with the earliest sown wheats, which would nurse the tender plants. He thought that autumn sown lucerne would do better than that sown in spring as, if it germinated early, it would not suffer from the winter frosts and would get through the first summer more easily. Field peas were valuable for fattening sheep, and vetches also made wonderful growth and would stand grazing. In normal seasons such fodders as prairie grass, Italian rye grass, cocksfoot, &c., would grow successfully. Rape and mustard sown together made splendid growth of valuable fodder. Silver beet was worthy of a trial, although it would require cultivation, such as hoeing. In the discussion which followed, members agreed that experiments should be conducted to ascertain which fodders were the best for the district. Lucerne was the most favored plant. Rape did well. If this were sown with mustard there was no danger of stock becoming blown when put on it.

COONALPYN (Average annual rainfall, 17·49in.)

April 10th.—Present: 12 members and four visitors.

Horse-Breeding.—Mr. Wall read a paper. Draught horses, he said, could be bred more cheaply than they could be purchased. Light horses, however, which were more liable to accident from barbed wire, &c., should not be bred on the farm. Good feeding was an essential, and brood mares should be in first-class condition when mated.

Dairying.—Mr. J. Angel read a short paper. He preferred Shorthorn cows, he said, because they were good milkers and good beef animals. Lucerne and oats were very suitable for feeding to milch cows, and summer fodders such as maize or sorghum should be grown. Regular milking and enclosing the animals at night in a warm yard were advisable.

LAMEROO (Average annual rainfall, 16·55in.).

April 11th.—Present: 12 members.

Windbreaks.—Mr. C. Wray read the following paper:—"There is a want of something of the nature of windbreaks in this district. This matter was brought before the Advisory Board by Mr. Bonnin. The report of this gave me the impression that the members of the Board thought all the land here would drift. I would like to refute this impression at once. There are sand ridges which will drift if fallowed, and drift badly, but there is also a class of land which will not drift, no matter how often it is fallowed. In support of this I might instance a paddock I have fallowed this year. Apparently it is all drifting, but on examination it will be found that the harrow marks are still visible, and that a fine dust has drifted from the rises on to it, which gives it the appearance of drifting. In regard to breaks, one cannot treat all blocks alike to the best advantage. To have breaks running right through a paddock in many cases would mean that they would run through a lot of good arable ground. In other cases the ridges run right through the paddock; then it can more easily be dealt with. To leave the ridges in their natural state is to provide a great harbor for vermin. Where these ridges have been cleared, and are not producing much, they could with advantage be planted for shelter, but where there are blocks which have sand ridges and good flats alternately, it is harder to deal with them without spoiling the squareness of the paddock and creating a break in the middle of it, which would make it awkward at seeding and harvest time. Even taking these things into consideration, however, there are in many cases ridges of sand which do not pay to crop. I have rises which are only a few acres in size, and I feel certain it would pay me to grow something besides wheat on them, because of the heavy working and the small returns. It is on these small rises that the majority of us could grow something for shelter and for breaks, and also beautify the farm. But what are we to plant? I have not experimented in anything of this kind, but sugar gums grow well, look well, and make a nice shelter. The thought has occurred to me, however, that we might grow something that would be of value during dry seasons for food for stock. Sheaoaks might grow here, and sheep are very fond of these. Wild hop bush would also grow." Mr E. J. Trowbridge advised planting the wattle, but Mr. Townsend said this tree, when grown in this district, produced a low percentage of tannic acid, and did not live for any considerable time. He thought the gum more suitable. Mr. J. Kakoschka would plant gums in the corners of paddocks. Mr. A. J. H. Koch agreed, and advised planting when the crop was growing, as it would then protect the trees. Gums which he had planted six years ago had now reached a height of 25ft., and afforded splendid shelter.

POTATOES.—Mr. Leckie reported very successful results with Pinkeye potatoes.

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).

April 4th.—Present: 19 members and four visitors.

NOXIOUS WEEDS.—Mr. R. E. Anders read a paper, in which he dealt with weeds that were now growing in the district. He said—"The Scotch thistle, which was formerly under the Noxious Weeds Act, but taken off in 1890, is spreading very rapidly. Some claim that it is good feed for stock, but I have never seen stock eat it, except if nibbling is called eating. Some paddocks are now completely covered with it. Rolling Jack is another very fast-spreading weed, and can be found almost everywhere. Stock do not seem to care for it. The paddy melon is also spreading very fast, and although stock will eat it, it is harmful to horses, which are known to go blind if they eat it in any quantity. Farmers should be careful not to let them get a hold on their farms, or they will be difficult to eradicate. Nightshade is a new plant to the district, and landholders should destroy it at once, as it is very poisonous. I would like this Branch to take steps to get the Scotch thistle regazetted. It is very difficult to kill. If it is not dug up by the roots it will shoot again and grow a bigger bush than ever. It is also very troublesome in the crops when stripping, as it grows up higher than the wheat." It was resolved to request other Branches to discuss the advisableness of placing the Scotch thistle under the Noxious Weeds Act. Some members thought sheep would keep rolling Jack in check, as they were very fond of it when it was young. The plant would only grow where sheep were grazing.

MORGAN (Average annual rainfall, 9·29in.).

April 11th.—Present: six members and one visitor.

HORSES AND HARNESS.—Mr. O. Hausler contributed a paper on this subject. He stated that the price of horses had fallen largely lately, on account of the falling off in demand, which was very strong just when new areas were being opened up, and the fact that this demand had given the breeding industry a considerable impetus. This animal was practically indispensable on the farm, and farmers were strongly advised to keep only the best. Regularity of feeding was essential, little and often being the rule. Clean, dry stables should always be provided. Harness should be carefully protected from the weather; and for preference each set should be hung near the horse on which it was used. Collars should be stuffed once a year, and all leather should be oiled frequently.

PARILLA (Average annual rainfall, 16in. to 17in.).

April 9th.—Present: 14 members and one visitor.

FARM HORSES.—Mr. John Lee read a short paper. He preferred the medium draught for this district, as being more active and easier to keep in condition than the heavier animals. Good food should be regularly given in small quantities. Rock salt should always be kept in the mangers. The horses would do better loose in a yard than tied up. Well-fitting hames and collars, kept clean and soft, would go a long way to prevent sore shoulders. Mr. P. W. Lewis preferred the heavy draught horse, as it was stronger and more saleable for breeding purposes. Mr. M. Shannon said that in many cases sore shoulders were caused through bad blood. The horse's blood should not be too hot, and this depended largely on the feeding. After harvest, when horses were turned out on stubble, they picked up sand. Before being worked they should be stable fed for a week or two, and given plenty of bran. In the summer a roof over the horses would be sufficient, but it was necessary to have good warm stables for the winter. If they were accustomed to being in a yard together it was unnecessary to tie them up. In case of fire they would then have a chance of escaping. They should not be given water immediately after a big feed, especially of corn. Mr. G. Neindorf stated that if the bit were left in the animal's mouth when it came in from work, it would not then drink too quickly. Mr. A. J. Stevens favored tying up the horses, as the stronger robbed the weaker of their feed. Bran was a good remedy for sand. To prevent sore shoulders well-fittting collars were necessary, and it was better to have them too tight than too loose. Two packets of Epsom salts per week in the feed would keep the blood cool if the animals were being fed on oats or heavy feed. Mr. J. Roachock contended that horses should have freedom at night, and that a water trough should be kept in the yard. To prevent sores the shoulders should be washed with cold water immediately the collar was taken off. A tablespoonful each or carbonate of soda and ground ginger mixed with a pint of new milk made a very effective drench for sand. Mr. C. E. Moyle tied the animals up when feeding, but left them loose at night. It was a good plan to have the stable stalled off, as this prevented fighting and made it unnecessary to tie them up at night. If horses were tied up they should be bedded down with straw. A tight collar was liable to give the horse a sore neck, which was possibly worse than sore shoulders. Light horses should not be given a drink for an hour or two before starting on a journey. They could be given a good drink on their return. Horses on stubble should be given one feed daily. They would not then be so likely to pick up sand. The shoulders should be carefully washed each morning, and also, if possible, at dinner time. Mr. R. M. Shannon preferred warm water for washing the shoulders. Mr. G. Neindorf always soaked a new collar in water. It would then adapt itself to the shape of the horse's shoulder. Applications of vinegar were good for the shoulders of young horses. Mr. Gregory contended that horses would do better if they were fed in small quantities at frequent intervals. When turned out on stubble they should be given a couple of sheaves of hay per day. This would prevent sand and they would be ready for work when required. They should not be worked too hard after coming in from the paddocks. Mr. E. J. Kerby advocated the use of vaseline, if sores appeared on the shoulders. Mr. C. Foale favored re-padding collars each season.

Manure for Mallee Land.—Mr. M. Rush read a paper, in which he recommended the following treatment for new mallee land:—Fifty pounds super. should be harrowed in after the drill; the land should be ploughed the second year, and 70lbs. of manure applied. After drilling sand rises, he had applied a further 30lbs. of super. per acre when the wheat was well up, and the returns were better than those secured from the flats. Fallow should be well worked and sown with 100lbs. super. and 60lbs. wheat; good working was essential to get the best results from the super. He would not put more than 100lbs. of super. per acre on red flats, as the crops thereon had a tendency to blight after frosts and hot winds; 120lbs. per acre could be applied to sandhills. Mr. Shannon thought it a good idea to apply more super. to the sandhills than to the flats. Too much super. on the flats was liable to cause the wheat plants to blight off. In dry weather 70lbs. of super. on the flats and 100lbs. on the sandhills was sufficient. Mr. Roachock believed in harrowing after seeding. Mr. C. Foale had applied 65lbs. of super. on a plot of fallow land, and alongside had applied 130lbs. The heavily manured plot yielded 2bush. more per acre, was not so badly affected by the hot winds. The amount of feed which came up subsequently was quite double that on the lightly manured plot. Mr. E. J. Kerby thought 80lbs. per acre the best quantity of super. to apply. Guano super. was good on sandy land. Mr. H. G. Johnston had obtained his best crop from land on which he had applied 40lbs. of second grade super.; 40lbs. more could be safely applied to flats than to sandhills. Mr. J. Lee thought it a good idea to roll the land shortly after the wheat came up. This set the sand tight and conserved the moisture.

WILKAWATT (Average annual rainfall, 16in. to 17in.)

April 4th.—Present: 15 members and three visitors.

Preparation for Seeding.—Mr. D. F. Bowman read a short paper. He mentioned that excellent weather for stubble-burning had prevailed, and thus the growth of the mallee shoots should have been effectively checked. The only way of killing the shoots, he thought, was to plough out the stumps. It was too early to sow just at present, unless the land was particularly clean. The practice he recommended was to work the land with the idea of encouraging the weeds to grow, then destroy these with the cultivators, and follow closely with the drill. Members thought the fire-rake went a long way towards ridding the land of the green growth of mallee.

BORRIKA, April 11th.—Present: 26 members and five visitors. Members discussed various matters dealing with seeding operations, such as ploughing, pickling, &c. Mr. Sandercock, of the Northfield Branch, addressed the meeting, urging members to foster the Branch in every way as a most valuable institution.

SUTHERLANDS, April 4th.—Arrangements were made for Mr. A. M. Twartz to conduct experimental plots on behalf of the Branch.

SOUTH AND HILLS DISTRICT.

CHERRY GARDENS (Average annual rainfall, 35·03in.)

April 7th.—Present: 12 members and several visitors.

The Agricultural Bureau.—Mr. C. Beaumont delivered an address. Te be successful, he said, Branches must have live and energetic members. A large membership did not always denote this. The men who were most willing to help their fellow members were those who took most pains to better their own conditions. It was not expected that all could contribute papers with equal success, but they could lend their assistance in other directions. Members should take note of any new subjects which were likely to be of interest to others; helpful discussions were in this way initiated. Mr. Beaumont was asked and answered a number of questions dealing with fruit pests, etc.

CLARENDON (Average annual rainfall, 32·67in.)

March 16th.—Present: 10 members and one visitor.

Selection of Seed.—Mr. J. Spencer read a paper. Last year, he said, he purchased wheat for seed from another district. The variety was supposed to be White Tuscan, but it contained from 20 per cent. to 25 per cent. of another wheat, which was inferior. This only grew to a height of 3ft. 8in. when the White Tuscan was 5ft. 2in. high. He considered this depreciated his crop to the extent of from 6cwts. to 8cwts. per acre. For several years he had been trying field peas from different districts with various fertilisers at the rate of from 1cwt. to 4cwts. per acre. The seed sown each year was carefully selected, but a change of seed seemed to be the best method of securing a heavy yield. This year peas from seed grown near the sea yielded 29bush. per acre, an adjoining block sown later averaged 18½bush., but locally grown seed did very poorly. Seed potatoes were secured from Victoria last year, and some of these appeared to have been dug before they were matured. These yielded a much inferior crop to the thoroughly matured tubers. His conclusion was that it was necessary to exercise the greatest care in the selection of seed. Samples of hay and potatoes were tabled. Members generally favored the practice of pickling seed wheat.

FOREST RANGE (Average annual rainfall, 35in. to 36in.)

April 9th.—Present: eight members and two visitors.

Orchard Cultivation.—Mr. J. Green read a paper. In the early stages of the growth of an orchard, he said, it usually received fair treatment. The soil was well broken, the trees were well pruned, manures applied, and such crops as peas and swedes grown between the trees. When the practice of growing these crops was discontinued sorrel immediately took possession of the land, to the detriment of the trees. This could be best destroyed by running a cultivator through the orchard. The land should also be cultivated once or twice during the summer to keep the soil loose and conserve moisture. Mr. F. Green agreed with the idea of growing peas between the trees. If the cultivator were used frequently the land would become lumpy. If the orchard were ploughed in spring and harrowed the same day, the soil would remain loose throughout the summer. Mr. Schultze did not approve of autumn cultivation. He preferred to allow the grass to grow during winter, plough it in September, and harrow three weeks later, both ways. Mr. E. Rowley would grow white peas and manure them well. In autumn it was possible to plough more deeply than in spring, as deep ploughing would then injure the roots. The harrows should follow immediately after ploughing, and again after rain. Mr. A. Green favored ploughing under crops of sweet peas. Mr. McLaren preferred deep ploughing, and recommended growing potatoes between the trees and ploughing in the tops. Mr. F. Rowley had autumn ploughed some very wet ground, turning the furrow towards the trees, and leaving a furrow in the centre between the trees to drain off surplus water. In reply, Mr. J. Green said he ploughed in the late spring and cultivated as late as January. He would plough wet ground early in the winter, leaving a furrow down the centre to allow the water to drain off.

HARTLEY (Average annual rainfall, 15in. to 16in.).

April 8th.—Present: 16 members and one visitor.

Farm Lads.—Under this heading a paper was read by Mr. S. Beavis, dealing with the question of farm labor generally. The best workmen of all, he said, were the farmers' own sons, who had an interest in the farm, had been accustomed to stock, implements, and general affairs all their lives, and looked forward to taking over their father's properties, or other farms later on. The occupation of farming as a pursuit for educated men was now more generally recognised, and having the opportunity of gaining some technical knowledge at agricultural schools and colleges, the present day farmers' sons were the

right men to keep on the land. Hired lads, as a rule, he thought were not so satisfactory, although some of them were good lads, honest and enthusiastic. The immigration of English lads for farm work did not commend itself to him. Practical farmers, with sufficient capital to take up land, were more to be desired. For those farmers whose holdings were sufficiently large to warrant it, the solution of the labor problem was to employ a married man who could live on the farm. A good man on a good farm could always command good wages.

IRONBANK (Average annual rainfall, 33in. to 34in.)

April 11th.—Present: seven members and two visitors.

Poultry Raising.—Mr. R. Coats read a paper on this subject. The site for a poultry farm, he said, should be selected on a sunny slope, preferably one with a covering of scrub and timber. This provided shelter, and also food in the form of insects which abounded in the decaying leaves. The yards should be netting fenced to a height of 6ft. or 8ft. The bottom wire, of which there should be four, should be barbed, and be at least 4in. under the ground. The netting should be fastened to this. The top wire should support the top of the netting, the next should be half-way down the post, and the third half-way between this and the bottom. Roomy houses of galvanized iron, and facing north, should be provided. If it were found necessary to use wood in their erection, all joints and cracks should be tarred. The perches should be about 3ft. from the ground, and movable. Once a week the woodwork should be sprayed with kerosine, and the ground sprinkled with lime. Ducks should on no account be allowed to run with hens. Drinking vessels should be scalded at least twice a week, fresh water being supplied daily. The paper continued:—"Add a pinch of Epsom salts to the drinking water at intervals in the hot weather to keep the birds in a healthy condition. If the yolks of the eggs are rather pale, drop a few rusty nails into the water. Keep the water in a cool place. The morning meal should consist of a mash—pollard mixed with the kitchen scraps or a little bran. Make it into a fairly stiff paste. In the cold weather add a little pepper and meat meal, or boil some meat and mix the soup into the mash. Always keep a supply of shell grit, so that the fowls may get at it as they require it. At mid-day a supply of green feed such as chaffed lucerne, lettuce, cabbage, or any such green feed should be given. The evening meal should consist of grain. Maize and peas are best for cold weather, but they are too heating for summer feeding. For breeding stock pick out the strongest and best birds from the flock and feed them well. The male birds should not be related to the hens. Hatch the chicks early, and so dispose of the roosters early; the pullets will lay when eggs are scarce. Ducks and turkeys are also best hatched early. If a duck is fed well from the beginning, at 10 weeks old it should be ready for market, but a chick should be ready at from four to six months old for market purposes. Cox's chickvital gives the chicks a good start, and they will make rapid growth on it. Give them this till they are about three weeks old, when they should be changed to the ration previously recommended. Geese involve very little trouble. When hatched they feed on grass, and no work is needed with them until they are fit for market. Turkeys are more delicate, they require more attention, and a good supply of green feed. When turkey chicks are hatched they require a warm coop. Feed them with one part of hard-boiled egg, two parts of dry oatmeal, two parts of parsley, cress, or lettuce, chopped very finely, three times a day. When setting hens seek a sheltered corner; there dig out a hole in the ground big enough to make a nice nest, sprinkle a little new lime in the hole, then put in some clean straw, sprinkle a little more lime to make sure that vermin will not trouble the hen. After a fortnight renew the nest and add more lime. Do not have the setting pens too small, for the hens need exercise. Also have a good dust bath. Feed her on wheat, and see that fresh water is always available." Members thought it preferable to use 1in. mesh netting for the lower and 2in. mesh for the higher half of the yard fences; thus obviating damage to the combs of the birds.

INMAN VALLEY (Average annual rainfall, 26in. to 27in.)

February 2nd.—Present: 16 members.

Exhibits.—Mr. H. J. Jagger tabled some fine Brown Spanish onions, the average yield of same being about 20 tons to the acre. Mr. V. G. Tugwell tabled some large potatoes of the Carmen variety. One tuber weighed 2¼lbs. The Hon. Secretary (Mr. H. M. Parsons) tabled some Indian corn (gram). The Hon. Secretary thought this a much hardier plant than the field pea. It had withstood the severe frosts of last winter, and had been eaten off three times before October. It did not blossom until November, and would perhaps suit the Northern districts.

Irrigation.—Mr. G. McCoy read a paper. He said:—"Differences in soil, climate, and natural features of the country will not admit one system of irrigation being definitely laid down. Few of the great irrigation schemes that exist in all parts of the world, and especially in Australia, can be said to have passed completely beyond the experimental stage. We hear of wonderful crops of fruit, vegetables, fodder, &c., as the result of irrigation, but the financial part of the process is not carefully gone into by disinterested people, and the producer himself too often is willingly blind to the cost of production so long as he has the pleasure of gazing on green fields and beautiful orchards. As an indication of how much we are in the dark yet, I might state that there are scarcely any published works on irrigation. I do not wish for one moment to suggest that irrigation is a failure, or a financial trap to catch the unwary. Far from it. Under easy conditions there are few things more profitable and certain to bring in a handsome return for one's outlay and labor. The first irrigation scheme with which I had anything to do started in 1887. It was the first in this colony—Renmark. I made the survey, and consequently have taken notes now and then of the progress made. Owing to want of capital by the originators of the scheme the early settlers were confronted with apparently insurmountable difficulties, but the Government came to the rescue, and now most of the growers are in comfortable circumstances. In the first few years some of the growers thought they had planted the wrong sort of fruit. At that time there was not much demand for lemons, so some lemon growers rooted up their trees. The very next season there was a scarcity of this fruit, and the price rose to 3d. each. There were several instances of that kind even with other fruits. It is a great mistake to think that because a certain product is not saleable one year that it will never pay to grow it. The fluctuations in the demand for all produce are simply due to a glut in the market. *Orchard.*—When selecting a piece of ground for orchard irrigation take care that there is only one slope, and that a gentle one. On no account choose undulating country. It is very expensive to work, so much channelling to make and a lot of extra running about when watering, and the planting has to be arranged in order not to interfere with the channels. The usual plan on the River Murray is to make a main channel of concrete along the highest boundary of the block, with a fall of 2ft. to the mile. Sub-channels can be made from the main channel, with an outlet for each row of trees. A deep plough furrow is then run along both sides of each row of trees, and the water directed into these furrows. When the water has sunk into the ground the furrows are filled in again. This prevents evaporation, and the trees get the benefit of all the moisture. This is done from three to five times a year according to the season, and considerable judgment is required as to when to apply the water. Sometimes a heat wave comes along and lasts perhaps a fortnight. The growers all call for water at exactly the same time, and sometimes the last man to get served has the misfortune to see a lot of his fruit falling off the trees. Fortunately this does not occur very often, and they now generally are able to cope with emergencies of this kind. *Lucerne.*—As with orchard land, a block for lucerne-growing should never be on undulating ground. If a slope is unavoidable see that it is a very gentle one. The ground should be kept absolutely clear of all growth of every kind right through the autumn and winter. Lucerne does not like bad neighbours when first planted. It wants the ground to itself, though when thoroughly established it will flourish in spite of much bad treatment. It should be ploughed with the slope, not across it, and drilled in the same direction. The reason for this is to give the water an even flow. If the ploughing is across the slope the water lingers at every ridge, and consequently takes a long time to get down to the end of the patch and the top side is getting more than its proper allowance. As before stated the slope must be very gentle or the water will rush down to the end of the paddock and form a large pool. Never make an earth channel with a fall of more than 4ft. to the mile or a washout is likely to occur. If a slope is more than that the difficulty can be got over by making steps. That is the system adopted in the drainage works of the South-East. Always sow lucerne thick. Do not imagine that because it comes up thin owing to want of the proper quantity of seed the gaps can be filled up later on. It must all come up the first season. There is no better illustration than with lucerne of 'the survival of the fittest.' Old plants will not let young ones grow alongside of them, even if planted by hand. When once established it submits to a lot of hard treatment, but overstocking will, of course, kill it. Brackish water is not detrimental to lucerne. It likes a certain amount of salt, though of course very brackish water will kill it in time. On LeFevre's Peninsula, near Port Adelaide, a resident had a small patch of lucerne growing on a low-lying piece of sandy ground. It was doing well, when an abnormal flood tide flooded a great part of the Peninsula. Part of this patch of lucerne was under water for two or three days. In a few weeks the patch was as luxuriant as ever, and the portion that had been under water longest was the most luxuriant and a beautiful dark green. In one part of Holland they grow fodder that will stand periodical waterings with salt water, and in the Isle of Jersey seaweed is applied to the soil in immense quantities. The channelling for a lucerne block is the same as for an orchard, but care must be taken to see that there are no dry patches left. When the ground is level the most favored proceeding is to flood it, using light 4in. to 6in. galvanized piping connected with canvas joints. These can be disconnected and moved about easily, and a big flow of water kept going. *Rape, Maize, and Vegetables.*—Rape and such like can be treated in much the same way. Maize is generally planted in rows that can be cultivated. Sprinkling appears to be the most natural way of irrigating, but it is very expensive, and also very slow. The sprinklers need constant attention, lifting them about and keeping them level. They are best suited for lawns and small gardens. Nothing is easier to irrigate than vegetables. If rows are convenient distances apart it is simply a matter of directing the water. Care must be taken not to overdo watering. Provided that one escapes frosts and such pests as snails, vegetable growing pays handsomely. But of course there is more work attached to this branch of irrigation than with fruit, lucerne, &c. Mangolds and such like can be treated as vegetables. Field turnips and silver beet grow best in winter and spring, consequently they do not need irrigation, and the best way is to sow them broadcast. I would never advocate raising water more than 40ft. above the supply, that is to say, above the spring, well, or river from which the supply is obtained. I know of some large schemes where the water is raised 150ft. or more, but this requires enormous engine power. The best system in this State so far is on the Murray in the neighbourhood of the Bridge, where the swamps have been reclaimed. They are level, no pumping is necessary, and all one has to do is to let the water in as it is required. However, nearly all these swamps need sweetening. There is a sourness in some and a salty nature in others that must be eradicated before a compensating return can be expected for the labor and outlay. In some places, where there is every appearance of promising soil, seeds actually refuse to germinate. I know of a reclaimed swamp higher up the river that has been cultivated once or twice, and grows magnificent oats over 7ft. high, but there is something in the soil that gives the hay a poisonous nature. No doubt with continuous cultivation this bad quality will disappear. For centuries these swamps have been feeding ground for immense flocks of wildfowl, and it is quite possible for the mud to have become impregnated with too much poisonous matter, which though not prejudicial to the growth of vegetation may affect its quality. *Local Irrigation.*—There are flats in this district that cannot be beaten for irrigation. The purest water can be got at shallow depths in unlimited quantities. The lift would not be much more. The soil is as suitable as any in the State. What it lacks in salt, lime, &c., can be cheaply applied. Even without these it is rich enough for most things. I would advise anyone who has 10 acres of such country to get an engine of say six to 10 horse power and a suitable pump and intensely cultivate that area. I am confident that the result as a paying venture would be surprising. The engine is purely a matter of choice. I prefer steam, because in this district wood costs nothing. If anyone takes the trouble to work it out he will see that after all there is not very much to choose between all the engines, and it is significant that steam, petrol, and oil engines are still being manufactured in the same proportion as usual. If there were any great difference in the cost and working expenses the engine wanting in these advantages would speedily disappear. One advantage I can see in the quick-running engine is that there is no loss of time getting up steam, but as for the statement that they require no further attention, that is ridiculous, and when anything goes wrong an expert is generally required to put it right. We learn lately that large ocean vessels have adopted the crude oil engine, but one reason is the fuel is much cheaper than coal, can be handled easier, and packed in a smaller space. There is no engine easier to understand than steam, and one can regulate the power and speed, which one cannot do with most petrol and oil engines without adding very materially to the cost of working and wear and tear. I do not like windmills for irrigation. It is a powerful mill that will keep one acre irrigated, and when the wind fails in hot weather it is not a success. They are all right for a house supply and flower garden or watering stock, if one has a storage tank, but as 1in. of water over an acre of ground means about 23,000galls. the cost of tanks to hold this for irrigation would buy an engine that would pump the quantity in a few hours. *Returns.*—The question might be asked—What is a fair return to expect from irrigation? A well-tended orchard of mixed trees in full bearing under favorable conditions might be expected to yield a net profit of £100 per acre. I have heard of some extraordinary returns much higher than that, but am speaking from notes taken personally. This is assuming that a market is easily accessible. With lucerne one could expect 4 tons to the acre, cut five times a year, and grazing for fattening stock. Vegetables pay better than anything if the conditions are all right, but the work is correspondingly much greater. The produce is perishable, and a market must be handy. In these estimates I have taken care to keep well within the mark. Doubtless there are some present who can tell of larger returns; for instance, one grower on the Murray told me he cut his lucerne 12 times in one year. To that I would say he cut it too often, and was doing the very thing to kill it. No plant will stand that sort of thing for many years. There seems to be no soil more suitable for irrigation than a deep red sandy soil over red clay. For oranges especially this soil is ideal. It will stand continuous working, never sets hard, and retains the moisture. Fertilisers are easily applied, and the fruit has a glorious deep red color. In this soil oranges will produce a crop in four years. All sorts of fruit flourish in ground of this nature on the Murray settlements. It seems to contain all the necessary ingredients for producing fruit of the first quality. One of the most successful orange growers at Waikerie never allowed the surface roots of his trees to come within 8in. of the surface. These are the fruit supplying roots, but he kept them down by ploughing deep, and he was justified in doing this by the result, for better oranges have not been grown in Australia. The branches shaded the butt of the trees, as they were allowed to hang to the ground. Of course all superfluous inner growth was pruned out to let in the air and a certain amount of sunshine. By keeping the surface roots down he did not allow them to get scorched. Thorough cultivation seems to be responsible for most success on an irrigated block. Although oranges will grow in this district they do not come to the same perfection as on the River and at Salisbury, north of Adelaide. But other fruits, such as apples, pears, plums, peaches, apricots, and nectarines cannot be beaten if they receive proper attention. They do not need irrigation in an ordinary season. It is astonishing how even poor soil can be made productive under irrigation by continuous working, sweetening, and the judicious use of fertilisers. With soil of a stiff clayey nature, such as we have here in places, it is an excellent thing to cover it with sand, even to the depth of 1ft., and plough it in. Sea sand will do as well as any if close at hand. It keeps the ground open and porous."

INMAN VALLEY (Average annual rainfall, 26in. to 27in.)

March 18th.—Present: 10 members.

POULTRY.—Mr. H. G. Allert read the following paper:—"The first consideration is the yards, the smallest of which should not be less than 10ft. wide by 40ft. long, and divided into two. The fowls can occupy one yard for 12 months whilst the other is dug over and sown with gross-feeding plants, such as kale, cabbage, rape &c., which causes the ground to become sweet and clean. Shade and shelter can be easily supplied by a framework of wood covered by galvanized iron, the latter being covered by a coat or two of King's Compo. in the summer. Poultry houses should be built of the best material possible. The timber should be hard wood, not given to crack in drying, such as jarrah or red gum, preferably the former. The roof, sides, and ends should be of galvanized iron, the front should be netted, the weather end of the front being partly closed in with, say, two sheets of iron. About 3in. of the back, just under the roof, should be open for ventilation. The weather end of the house must contain the roost and perches, because if built as here recommended there will be no draughts. The other end will constitute the scratching part of the house. It is here the fowls are fed when the weather is wet. The scratching and roosting parts are separated by a jarrah board 12in. high and 1in. thick. The same kind of board runs around the bottom of the whole house; a door must also be provided. A house 10ft. long, 4ft. 6in. wide, 5ft. high at the back and 6ft. in front, will accommodate from 20 to 25 hens. One 16ft. long, 6ft. 6in. wide, 5ft. at back and 6ft. in front, will be large enough for 40 to 50 hens. The perches should not be higher than 18in., so that the birds may not injure their feet or legs in their descent. I prefer them to be about a foot off the ground. They should be 2in. by 2in. jarrah, square, with the edges slightly rounded. They may be hung or fixed, but in any case should be movable in order that they may be cleaned. At least once a fortnight the roosts should be well scalded and cleaned with boiling soapwater, and when dry painted over with kerosene. The scratching shed floor should be well covered with straw, wheaten chaff, or other clean litter, and the grain food buried therein. This will keep them warm, as well as give them healthful exercise. Nests should be on the ground, and so made that they should face the wall, as a laying hen likes privacy. Water should be given several times a day. Let it be clean and cool. See that the dishes are cleaned every day, and once a week at least with a good disinfectant, after having boiled them in water and soap. The washing copper may be utilised for this purpose after the weekly washing is done. Tin or iron utensils must not be used, good earthenware is the best. Shun patent fountains, as well as those of home manufacture, because they are harbors of disease. Douglas mixture and other chemicals which must occasionally be utilised, cannot be used in them. Place the drinking water high enough to prevent the fowls scratching filth into it. Good sharp grit should be supplied every day, also shell grit, old mortar, and charcoal. The latter I consider of the utmost importance, as I have found that, given plenty of charcoal, poultry can easily be kept in good health. Cleanliness must be strictly observed. Droppings of poultry make a valuable manure and should be removed often; daily if possible. In fixed houses, with just the the natural floor in them, remove a little of the surface every time the house is cleaned, and replenish with fresh dry earth sprinkled with slaked lime and wood ashes. *Feeding.*—When feeding for egg-production give the best grain procurable. Wheat, oats, maize, and peas can be used, mixed or separately. I mix wheats and oats in the proportion of three parts of wheat to one of oats, and have found this very suitable. About twice a week I mix very coarsely-crushed maize and peas with the wheat and oats. This gives a good change and supplies them with an extra amount of protein necessary for egg-production. I give the same amount of food always after first having found out the amount necessary to every individual fowl. By handling individual fowls daily one can soon find out whether they are over or underfed. Maize and peas fed daily are too fattening and cause the fowls to cease laying. In table fowls maize produces a very coarse, unpalatable yellow fat, and it must be judiciously fed; but it is necessary on account of the oil it contains. My experience teaches me that it should be given in small quantites in summer, whereas in winter a little more may be used. Peas on the contrary contain a high percentage of protein, but are deficient in fats and oils. When mixing maize and peas with the daily ration of wheat and oats I used one part of maize to two parts of peas. Feed grain to fowls twice a day, morning and evening. Two mornings in the week I give them soft food, consisting of one part of bran and two parts of pollard. With the soft food I also mix a little linseed, bonemeal, salt, and meatmeal, with just enough boiling water to mix the bran and pollard to a crumbly consistency. I also add about one-third of the whole bulk of chaffed greenstuff and sufficient charcoal dust to slightly color the whole. All this, well mixed together, is given in feeding pans, which must be kept scrupulously clean. With the soft food I also mix any medicines or tonics which must be occasionally given, such as sulphur, Epsom salts, ground ginger, &c., as this food forms a convenient vehicle for administering these. Ginger should be given in winter, when the weather is cold and frosty. The feed of stock birds should be simple, but nourishing, so that the supply of eggs is moderate. Grain should be the principal food, with soft food occasionally. Torrified grain is very good at this time. Coarse bonemeal, shell-making material, and plenty of green food are necessary. A fortnight before incubating mate the hens with the male birds, which should at other times be kept alone. This will keep them healthier and stronger, and the eggs for incubation will yield sound and healthy chickens. Eggs for market should never come from mated fowls. Do not give rainwater, as this does not contain the necessary salts. If a fowl is not looking perfectly healthy take it away from its mates, keep it by itself, and attend to it separately at some distance from the others. It does not pay to doctor poultry as a rule. Generally it is advisable to destroy and bury deeply the sick fowls."

KANMANTOO (Average annual rainfall, 17·90in.).

April 4th.—Present: 14 members and one visitor.

Treatment of Ewes.—Mr. A. Mills read a paper on this subject. Ewes should not be too fat when the rams were put with them, he said. One ram should be given between 50 and 60 ewes for about six weeks, after which a "picker up" could be put in the flock to impregnate the "stragglers." Careful note should be kept of the time that the rams were put in, so that the flock owner should know when to expect the lambs. The ewes, when carrying the lambs, should have an abundance of good drinking water, and their eyes should be kept free from wool. Three weeks before lambing commenced they should be mustered, left in a yard overnight, and then crutched. The left arm of the operator should be placed well down on the animal's neck and around the brisket. The off hind leg should be seized with the right hand, and drawn forward. The sheep should be gently lifted, and deposited on its rump, backed up with the operator's legs, and have its head doubled to the left. The eyes should be well cleaned, and then a commencement made at the lower edge of the belly, cutting away the grease tags to allow the lamb to locate the teats. The cut should follow down to the tail, leaving a clean track, so that the afterbirth and urine did not collect and encourage the attention of flies. Care should be taken not to cut off the tip of the vagina. During lambing the sheep should not be moved to strange paddocks, or there would be a danger of the young mothers leaving the lambs, and wandering about. Careful watch should be kept, and in the case of false presentation assistance should be given; otherwise the ewes should not be disturbed. When assistance was necessary, violence should not be used, but the animal would bear a good deal of force. If it were necessary to cut away the lamb, a blunt-pointed knife should be used.

If the womb still protruded it should be washed with warm water and carefully placed in position. A couple of stitches should then be put in the lips of the vagina. Trouble of this nature would almost assuredly recur at future lambings, so the animal should not again be used for breeding. When sore teats occurred powdered borax and honey should be well rubbed into the affected parts; a solution of alum should be applied in cases of inflammation of the udder. Lambs could be tailed at a week old; a clean, sharp knife being used in preference to the searing iron. Castration should take place a little later. The ewes should not be changed to very rich feed, or mortality would occur amongst the lambs. Epsom salts, or a similar purgative might well be used in this and similar cases. The flock owner was well advised to spend a few pounds for feed for ewes during dry seasons.

LONGWOOD (Average annual rainfall, 37in. to 38in.)

April 11th.—Present: six members and three visitors.

Homestead Meeting.—The meeting was held at the homestead of Mr. J. C. Blakeley. An irrigation scheme from a spring in a hillside was much admired. In the orchard the trees looked healthy, and although only in their third year were carrying apples. These trees were not planted in holes. Some members thought that unless the ground adjacent to the trees was kept well stirred the trees would fail in a few years time. The usual method of planting trees in this district was to dig holes 4ft. square down to the clay, and loosen the subsoil well with a bar.

MEADOWS (Average annual rainfall, 35·52in.).

April 7th.—Present: 11 members.

Bee-Farming.—Mr. H. Thorn read a paper, as follows:—"The climate here is not suitable to make bee-keeping a really profitable industry. The winters are too cold, long, and we have too much rain during the swarming season. Most of the bees in this district are hybrids. The first cross between the Italian and the common black bee is in many cases equally as profitable as the pure Italian. I tried the Cyprians here about five years ago, but they proved a failure. They were very hard to shake off the combs and very vicious. The black bees are not so particular as the Italians in defending their hives against the wax moths. They also swarm too much; I have known a hive to send out four swarms in about six or seven weeks. Queens should be reared in the strongest colonies, so that they get every possible attention from the workers. It is of great importance that the young queens are well fed in all stages. The bees should be gathering honey while queen-rearing is going on. Queens are at their best in the second year. They are often kept far too long; three years is quite long enough. A good many are then past their profitable age. This is the reason we have so many small useless colonies in our apiaries. I use the double Langstroth hives in my apiary, but do not have the excluder between the boxes. One great drawback is that it closes half the ventilation space between the boxes, with the result that a large force of bees is employed fanning at the entrance to keep the hive cool. When the hives are badly ventilated the bees show a great desire to swarm. The excluder is very useful in transferring bees from common boxes into hives, however. Turn the box upside down and place the hive on top of it, drive the bees up into the hive. Then place the excluder between the boxes. The bees will hatch out the young brood in the lower box, and the queen will start to lay in the top hive. In 21 days the brood will all be hatched out of the lower box. This should then be removed. This plan will give good results if carried out when there is a flow of honey coming in. Foul brood is a germ disease of a very infectious nature. The treatment is to drive the bees out into an empty box and keep them enclosed until the next day, then hive them on starters of foundation. The hives and frames should be boiled. With paralysis, which I found in my apiary some eight years ago, the bees crawl out to the entrance of the hive, seeming to have lost nearly all power of their legs and wings. The treatment I adopted was to destroy the queen and put a younger one in her place. The hive recovered."

MOUNT BARKER (Average annual rainfall, 30·93in.).

April 8th.—Present: 53 members and three visitors.

Sheep or Cows on a Small Farm.—Mr. A. B. Blades read a paper. He said—"A man will have the most success in dealing with cattle or sheep as they appeal to him most. We all have our likes and dislikes, and he who naturally likes cattle will do better with them than the man who naturally likes sheep. Now, to treat the subject in a more concrete form, I will take as a basis of our discussion a farm of 200 acres in this district, comprising for the most part good land with a small portion of roughish gravelly soil which, however, will grow a little grass, and which, if fenced off, will prove a most useful change paddock for sheep. We crop 100 acres of our farm annually, leaving the other 100 under grass. In putting the utility aspect of sheepfarming I would draw your attention to the fact that the United Kingdom maintains an average yearly total of about 25,000,000 sheep. Throughout the whole country these animals are regarded as the most important of livestock, because they fulfil the onerous task of paying the rent. This part of the question, of course, is not so vital to us, as our lands are not of such high values as in the old country. Nevertheless, it must be admitted that an animal upon which devolves the task of paying the whole cost of the use or interest on the value of the land, and succeeds in doing it, must be of a very high utility value. Now comes the question, which breed of sheep is of the highest utility value to us in this district ? Without any hesitation I give the place of honor to Comeback ewes. These are among the very best as mutton sheep and wool producers. Mated with a good Shropshire ram the progeny will be the very *beau ideal* of a lamb. Sheep, under good management, can be depended upon for three sources of income, viz., the fleece, the lamb, and the carcass. *Management.*—Under the heading of management comes the question of feeding, and this taps a source of immense possibilities. Now, I doubt very much if there is another country in the world where the natural grasses will keep and fatten stock as in Australia, consequently the practice of hand-feeding has not received the attention here that it has in the colder climates. For about six months the English farmer has to handfeed his sheep, and the system of artificial feeding has been brought almost to perfection. In the art of feeding animals we cannot 'hold a candle' to the English farmer. I have seen, in the middle of winter, on farms where the sheep have not had a bite of natural grass for months, Oxford Down sheep rolling fat, which made between £3 10s. and £4 per head. What is the secret of this ? In a word—good management. This question has, as I say, received scant attention in Australia ; but the growing of feed for sheep is bound to come, and under the able advocacy of Mr. Henshaw Jackson, the wool expert, who has been doing experimental work for years, sheep men are slowly but surely realising that there is something in it. I am convinced that when the practice and art of artificial feeding are understood it will mean thousands of pounds into our pockets. The Advisory Board is anxious for Branches to undertake experimental work. Here is some work that can be undertaken by this Branch. In stating the case for sheep, I do so on the assumption that the animals are given reasonable care and attention, and also that in the winter, when there is little natural feed about, artificial feeding is resorted to. I can hear the dairymen saying, 'No ; you cannot put your feed into a better animal than a cow.' Well, they are entitled to their opinion ; but I would point out that 25 sheep do not rob the soil of as much fertility as the cow fed for milk production, and, unlike the cow, return what they borrow, so to speak, in the shape of readily available manure evenly and widely distributed over the land. When this point is carefully considered it opens up vast possibilities that may mean the salvation of a lot of farmers whose paddocks are dirty and sick. With regard, again, to the actual feeding of the animals, Sir J. B. Lawes, the leading agricultural experimentalist of the world, has conclusively demonstrated that sheep may be fed with a profit of 50 per cent. more than cattle. In the dairying industry the silo has proved its worth as a factor in maintaining the condition and very often increasing the milk flow of cows. There is not the slightest reason why sheep should not be fed on ensilage. Where one cow could be kept one could keep seven to 10 sheep, and the net return would be much in favor of the latter. Another argument against dairying is the work that it entails. Dairymen taboo this, but it must be admitted that if kept on the farm in season and out of season, Sundays and holidays, a man will become stale, and his nervous condition will be in such a state that a change will be necessary. To employ labor to milk cows does not pay at the present rate of wages—to keep a boy or boys is very unsatisfactory. Almost everything produced on the farm can be marketed on four legs by feeding to sheep. We know what peas will do ; we know also that oats possess an even more valuable feeding quality than peas. In last week's *Leader* there is an interesting article on the subject. The writer says that ½lb. of oats per day will maintain a sheep in good condition ; 1lb. will fatten any healthy store, and 2lbs. will top up a big wether for the prime fat stock market. Potatoes are relished by them also. Of the value of lucerne it is almost superfluous to speak, suffice it to draw attention to a statement that on 14 acres of lucerne at Messrs. Morphett's Woods Point Station, 3,500 were grazing. They were kept two days on a paddock and then shifted to a fresh one. Briefly, then, to summarise—25 sheep do not rob the soil of as much fertility as one cow. Sheep maintain and increase the fertility of the land, also they keep the paddocks clean. Where one cow is fed one can feed from seven to 10 sheep, returning a profit of £1 per head. The cost of attending to the sheep is much less, as one man can do it easily. Sheep make better use of the food given them and do not show their likes and dislikes in such a pronounced fashion as cows. The work of tending sheep is less laborious and infinitely more attractive than milking cows. In this district we are only just beginning to realize what our resources are. Not so very long ago no one thought of feeding his crop of peas to sheep. Here we can grow almost anything, the results varying a little according to the season, and it is my humble opinion that the farmers must keep sheep." Mr. J. Thomas said—"For the purpose of comparison I intend to restrict myself to a property of, say, 300 acres. On this land, under systematic farming (not the style we can see in our midst daily), I consider that 60 cows could be kept. By the term 'systematic' I mean the growing and conservation of fodder, keeping good cows, and properly controlling breeding so that each cow will have from six to eight weeks' rest before again coming in. Two months' rest will allow of the cows each being in the bails for something like 10 months, hence a herd of 60 cows will be necessary to insure 50 in milk. In addition to the herd of 60 milch cows, the dairy farmer should rear annually from 15 to 20 selected heifers, which in time would be used to replace the old or useless milkers. I would not recommend keeping bull calves, as I consider it more profitable to feed any surplus milk to pigs and a few selected heifers. Heavy milkers only should be kept, *i.e.*, cows which will yield from 550galls. to 700galls. per annum. Taking it at the low yield, viz., 550galls. per cow, this means 27,500galls., which, at say 6d. per gallon, gives a return of £687 10s. In estimating this amount I am valuing the milk for butter or cheese making; but if the farmer were living within reasonable distance of a city, his income would be about three times as much by the sale of milk. The separated milk or whey from cheesemaking would go a long way towards the upbringing of heifers, which should be worth from £2 to £3 when 12 months of age. If 20 heifers were reared each year I have no hesitation in saying there would be a profit of £50. In addition, I see no reason why a farmer could not have, say, four breeding sows which could easily be fed from the refuse of the dairy. These, having two litters a year, averaging say at least seven, would give 50 pigs, which should realise £2 10s. at six months old—a return of £140. From these three items, viz., milk, heifers, and pigs we have the handsome return of £877 10s.. Against this we must debit the labor required for running a dairy, for which I allow three hands to assist the owner to milk and feed the heifers and pigs, for which I apportion £2 per week each, which means an expenditure of £312 per annum. Added to this expenditure I will allow the farmer £50 for the purchase of food for topping off his pigs for the market. After deducting these two items the dairyman should come out with a profit of £515 per annum. If the sheepfarmer can show a greater profit than this he is a lucky man. I do admit that the dairyfarmer has to invest more money on his land in the purchase of implements, &c., but notwithstanding that he will at the end of the year show a substantial balance in the bank." Mr. L. Frame assumed the case of a farm of 300 acres of fair average land in this district, one-third of which could be profitably cultivated. This 100 acres should be divided into four paddocks of 25 acres. The balance of 200 acres should remain as permanent grass land. The following rotation could be adopted on the cultivated area:—Peas, wheat, Cape barley, or Cape oats on the wheat stubble to be fed down with sheep, and natural grass for the fourth year. Whilst it would be preferable to allow it to remain out for two or three years, if well cultivated and heavily manured one year's rest would do. He would purchase from a reliable breeder 200 four or six tooth Merino ewes off shears. About March 1st these should be mated with Shropshire rams, the lambs being dropped at the end of July or August. By this time the oats or barley should provide good feed to keep the flock through September, at the same time saving the grass land until the oats or barley was done. This grass should keep the sheep going until the peas were ready to feed off and the lambs fit to wean. Part of the pea crop should be cut and stacked, as the damage by a heavy rain to the standing crop was too great to risk. Two hundred ewes should yield 160 lambs in a fair season, 150 of which should be put on to the peas. They should be ready for market during February or March, and if in prime condition should return 15s. per head in an average season, equal to £112. Wool from the ewes should return 7s. per head, a total of £70, making a grand total of £182. The advantages with these animals in so far as the farm was concerned, were that they destroyed weeds and wild oats, increased the fertility of the soil, and they involved little labor. Mr. B. Stephenson had had 25 years' experience of cows. A good animal would yield at least 600galls. per year, which, at 6d. per gallon, equalled £15. One man could easily milk 10 cows. When the cow became stale it could be topped up and sold for about £10. and a springer purchased for about £4 5s. Sheep had to be sent to the city to be marketed, and the prices varied considerably. One hundred acres should carry from 10 to 15 cows. Mr. J. Pope thought that if sheep were given the same care as cows they would return much more. Crossbred ewes were more profitable than Merinos.

One man, on 300 acres, could easily look after sheep; but four men at least would be required for cows. There was a great future for sheep in this district. Mr. G. Cleggett advised keeping the Shorthorn or Holstein if milk were the objective; but if cream were wanted the Jersey was the best breed to keep. Mr. W. Stephenson preferred sheep to cows; tuberculosis interfered very much with the latter. An experiment showed that certain ewes, which cost 8s., when fed on 1lb. chaff and 1lb. peas per day, in six weeks returned 13s. each. Mr. Monfries said 80 acres of mustard and rape fattened 1,500 sheep and showed a net profit of £450. Cows must be kept up. Sheep could be sold in the winter and more bought when the feed came. Mr. H. Jones thought oats were very good for feeding sheep, especially when they cost 1s. 7d. and peas 4s. 3d. per bushel. Sheep would clean up oat stubble before they touched the peas. Cattle did not like green oats. Mr. J. Pope said sheep were useful to turn back a rank crop. Mr. W. Stephenson had fed off his crop twice with sheep and the resulting crop was a heavier one still. Mr. Henshaw Jackson (Wool Expert) said the dairy cow could not be done without. There were dairy men and sheep men, each special people, and not to be compared. The result of experiments showed that 25 sheep per acre could easily be kept by intense culture. The fertility removed from the soil was the greatest in the case of the cow and least with the sheep. Fertility returned to the soil—most by the pig, then the sheep, and the cow least of all. The sheep returned to the soil from 70 per cent. to 90 per cent. of that which it took out. The cow removed from 25 to 30 times as much as the sheep. Sheep had never been treated as systematically as cows. The great point was the feeding. Chaff, peas, oats, and all grains were good, but the profit was missed if their ration were not balanced. In this district oats should be fed to the sheep. The animal should be credited with ¾d. per day for its manurial value. Sheep had been fed on 1lb. chaff and 2ozs. oilcake per day for 200 days, a daily cost of ·6d. per head for the ration. These animals returned a profit of about 5s. per head.

BLACKWOOD, April 20th.—THE FEEDING OF DAIRY COWS.—The Dairy Expert (Mr. P. H. Suter) delivered an address on this subject, and illustrated it with lantern views. At the conclusion Mr. Suter answered a number of questions asked by members.

MACGILLIVRAY, April 7th.—VINES.—Consideration was given to the question of cultivating vines. It was thought that the Doradilla would be suitable for local planting, as splendid fruit had been gathered from young vines of this variety during this season.

MYPONGA, April 8th.—IRRIGATION.—The Chairman (Mr. G. Hunt) contributed a paper on this subject, in which he dealt chiefly with the possibilities of irrigation in this district. He advised growing fodder crops and vegetables, and mentioned an instance of 64 cows being kept on 18 acres of irrigated lucerne. Mr. J. Müller delivered a short address on the various irrigation schemes, and dealt chiefly with the large plants on the River Murray. Members considered that the system adopted by gardeners along the Torrens Valley, where the land permitted of open drains, was the best, but in land which was liable to crack, sprinklers were favored, although these were hardly workable on a large scale.

PORT ELLIOT, April 18th.—EXPERIMENTAL PLOTS.—Mr. W. E. Hargreaves undertook to experiment with different quantities of manure and lime on fruit trees.

PEAS AND OATS.—Some members thought May the best time for sowing peas; others preferred June or July. Scotch Grey and Cape oats were thought the best for this district.

SOUTH-EAST DISTRICT.

COONAWARRA.

April 7th.—Present: 10 members and one visitor.

FARM IMPLEMENTS AND CULTIVATION.—Mr. L. Stapleton read the following paper:—"With our varied classes of soils and very mixed conditions of agriculture and horticulture, each class of implement is sometimes the best under that particular set of conditions. *Ploughs.*—The stump-jump is the most popular plough here, but this is so, not because it does the best work, but because it is the easiest to manipulate. From my own experience and from extended observation it appears to me that there are more faults than virtues in this class of plough. As far as I have seen, speaking of working in our stiffer soils—red, black, and chocolate—few seem at best to get an average depth of more than about 3in., and in a large proportion of cases about 1in. less than this. Then, because in this stiff compact soil the ploughs are always more or less on the jump they make poor work of inverting the furrow-slice, because the mouldboard is shaped to properly turn the sod only while the mouldboard is in the horizontal position. For this same reason these ploughs cannot properly pulverise the soil. The mouldboard loses all semblance of shape after a few yards have been gone over in our sticky soils. Set mouldboard ploughs are, speaking generally, the best if the nature of the ground allows their use, *i.e.*, freedom from stumps, roots, and stones. My own experience has been mostly with disc ploughs. They have a few faults and many virtues. Unless the scrapers are adjusted so that they scrape properly and keep the discs quite clean, allowing not even a thin film of soil to adhere to the discs, they cannot work properly. Ploughing with dirty discs bears the same relation to ploughing as a dirty and sticky spade bears to digging. Disc ploughs can be used when the soil is fairly wet, because, unlike the mouldboard ploughs, there is nothing to slide on the ploughed furrow and so compact it to dry into hard clods. If the scrapers are properly adjusted the draught is very much less than with other ploughs ploughing the same depth in stiff, compact, and sticky soils. Stubble can be ploughed in much more easily than with other ploughs, and this ploughing in of plenty of straw and rubbish is, I think, a great need with our stiff and so easily compacted soils in order to make them more mellow, more easily worked, and to allow of better aeration and surface drainage. They are, however, more difficult in turning if the ground is being ploughed in lands; and they vary greatly in the width and depth of cut according to the varying nature of the soil. *Harrows and Drills.*—The zig-zag or diamond harrows makes a level, but very shallow, surface on the ground, and is easily choked up with rubbish. Stump-jump harrows are light of draught and do not collect rubbish. Lightness of draught in harrows is, however, in my opinion, not a good point; as it is proof that they are not doing much work. I find the lever harrows best, if under all conditions the teeth are set more or less slanting in a backward direction. They seem to go into and comb through the soil better than either of the other two kinds mentioned. They are not so rigid as the zig-zag, but more so than the stump-jump. The rigidity of the first seems to make them lively and jumpy, while the slackness of the stump-jump makes them offer little resistance to obstacles. The lever harrows are 'dead' and comparatively heavy of draught, but do good work in pulverising the soil, and in dry weather can be used successfully on pretty rubbishy ground. The hoe drill is the better under general conditions. The make of hoe drill that I have been in the habit of using successfully negotiates rubbishy ground if the ground is dry enough on the surface to be in proper order for drilling. *Cultivators.*—With cultivators my experience has been limited mainly to disc implements, and as far as I have seen there is no implement to take their place for making a finely pulverised and mellow bed; but unless used only when the soil on the surface is dry the discs get a coating of moist soil on them, and then the implement is useless for good work. When a crop is to be put in early in the season I think a tine implement should be used, because it leaves the soil more or less lumpy on the surface, and so it does not set down so hard after long-continued wet weather. If the crop is fed off a roller and then harrows may be put over this lumpy surface, and a good new top put on the ground again to assist in carrying the crop through a dry spell in the spring. The tine cultivator, with the tines arranged along a diagonal beam, one behind the other, does not choke with rubbish so easily as the others. Spring-tooth cultivators are not of much use on the stiff compact soils in a general way, but are very useful for summer and autumn cultivation of fallow ground, especially for destroying sorrel."

GLENCOE (Average annual rainfall, 38·84in.).

March 4th.—Present: five members.

Farm Fences.—The Hon. Secretary (Mr. G. F. Ferguson) read a paper. He said—"It may be taken for granted that fences erected will be influenced by the timber available. In some districts it is almost impossible to get timber suitable for posts, and in these circumstances iron posts are the best kind to use. In our district, however, we are supplied with stringybark timber of good quality. Care should be exercised in selecting the trees for splitting. The quality of the timber is of far more importance than the size of the post. Young timber has so much sap wood that when the post has been erected a couple of years and the sap wood has rotted away, the post is quite loose in the ground, and it is a difficult matter to tighten it. A post measuring 6in. by 4in. at the small end is large enough and will last as long as one 8in. by 4in. In days gone by fences were unnecessarily high, but we have gone to the other extreme now, and a great number of fences are too low. Consequently stock reach over them and damage both the fence and the crop. There are practically only two kinds of fences erected in our district, namely, sheep-proof fence of five plain wires and one barb, and rabbit-proof fence of wire netting with a barb above. The question in the first place, is—what height can we make a fence with six wires and still have it sheep proof ? A fence 3ft. 9in. high with a gauge as follows, is suitable:—Height of first wire from the ground 8in., and the spaces between the other wires 6in., 6in., 7in., 8in., and 10in. respectively. Some may object that a wire 8in. from the ground will allow sheep to crawl under, but if with a single furrow plough we throw a furrow against the fence, not only does this close up any low places under the fence, but the furrow is in such a position that the hind legs of a sheep would be in it if the animal attempted to push through. We would have a much better fence by using two barbed wires instead of one. Cattle will very often reach between the fifth plain wire and the barb on top of the fence. An inch hole should be bored for the second barb, and by just running a plain wire through the holes and attaching the barbed wire to this a horse can draw it in quite easily, without injury to the barbs. Do not use staples to attach the top wire. If the fence is on undulating land they are always drawing out and are a source of trouble. Bore a hole 2in. from the top of the post, put a length of No. 12 galvanized wire through and twist this round the barbed wire on either side of the post. No. 8 galvanized wire and 12 x 3 barbed wire are the most serviceable. The 14 gauge barb wire is too light, and is easily broken. Be careful to note the quality of the 12 gauge barbed wire when purchasing, as there are some brands with barbs so short as to be of very little moreuse than a plain wire. The question of using netting of 17 or 18 gauge, 36in. or 42in., 1¼in. or 1½in. mesh is a matter that has to be decided according to the nature of the land and also according to the state of one's finances. Doubtless we all prefer the higher quality material. If using netting of 36in. width I would fasten it to a plain galvanized wire on top and put a barb wire a few inches above it, allowing for the netting being sunk 6in. into the ground. It means that if a barbed wire is put at the top of the netting and another on top of the post, the fence can only be 3ft. 6in. high when a space of 12in. is left between the barbs, and that is too much. For that reason I would attach the netting to the plain wire and put two barbs above. If we should be careful to use sound and matured timber for posts, we should be even more careful in the selection of the strainers and corner posts. I believe in having plenty of timber in them. A post 18in. to 2ft. or more at the small end, sunk 3ft. in the ground and securely rammed will not pull over easily with the constant strain of the wires. I prefer split posts for strainers with struts 12ft. long and 6in. in diameter at the small end. We are making a mistake in not using more droppers in our fencing operations. If we used three posts to the chain with three light droppers 5ft. 6in. apart between each, fences would be more cheaply erected, there would be less damage done to the wire in case of fire and repairs would be cheaper to effect, and all without lessening the sheep-proof qualities of the fence. Good fences mean good stock and help to promote that friendly feeling that should exist between neighbours, while bad fences are indicative of careless farming and are a source of trouble and irritation to all concerned. But do not erect good fences and then have a barbed wire entanglement for a gateway." In the discussion that ensued Mr. W. Holloway said that he believed in putting four posts to the chain with one dropper between each. He did not like the gauge for the wires as indicated in the paper. He placed the first wire 6in. from the ground, and the next three wires each 6in. apart. He thought the sheep would crawl through if the spacings were greater. Mr. F. A. Telfer considered that dropper fences were all right in grazing country, but not in Glencoe. The droppers caused the fence to sag. He preferred all posts 8ft. apart. Mr. A. Dow had found 14 gauge barbed wire unsatisfactory, and was replacing it with 12 gauge. Mr. T. F. Gratwick considered that it would pay to use 17 gauge netting rather than 18 gauge.

KEITH (Average annual rainfall, 19·20in.).

March 7th.—Present: six members and one visitor.

Sowing and Harvesting Wheat.—Mr. Lill contributed the following paper:—"The farmer should take the utmost precaution in the selection of seed wheat most suitable for the land in which it is to be grown. Some varieties of wheat will yield better on some classes of ground than others. The most popular varieties in our district are Federation, Bluey, Clubhead, and Bunyip. The first three, sown properly, will yield up to expectations on any class of soil. Bunyip, although a good yielder, is not a good standing wheat, and, in my opinion, seems to do better on the heavier ground. Every care should be taken with the seed. One year's seeding means several years' weeding if good, clean wheat is not sown. With regard to manure, nothing less than 100lbs. should be used on the sandy soil, and from 70lbs. to 80lbs. on the heavier land. With good seed on clean land and the quantity of manure stated above, the result is almost assured. The next question is harvesting. The harvester, both as a time and labor-saving machine, has been a great success; now the reaper thresher has come to take its place. The average cost of a harvester is about £90, against £130 for the thresher. Is the extra cost necessary, when for a much smaller sum we can get a machine to do the work equally as well? The only advantage with the thresher, as far as I can see, is amongst star or Scotch thistles, and in a badly tangled crop. The first two, if farming is carried on as it should, ought not to be there, and the best way out of the last difficulty is to sow wheats that are not liable to go down. There are plenty of varieties, such as Federation or Bluey, that will yield as well and stand for weeks. Another question raised in favor of the thresher is that of saving grain; whether such is the case I am not in a position to say. The thresher, no doubt, will do good work in, say, a 30bush. crop of average height on good ground, but to do good work on bad country and in a poor crop is just a bit too much for it. The harvester will work equally as well in a 5bush. as in a 35bush. crop, and is much better suited to our class of country." Mr. Shannon thought the reaper thresher wasted less grain than the harvester, and was lighter in draught. Members advised the application of from 40lbs. to 100lbs. of super. per acre, according to the nature of the land.

MOUNT GAMBIER (Average annual rainfall, 32in.).

March 14th.—Present: 15 members.

Life Member.—Sympathetic reference was made to the death of Mr. J. C. Ruwoldt, a life member, who, during his lifetime had done a great deal in the interests of the Branch.

Agriculture, Past and Present.—Mr. C. T. Major contributed a lengthy paper, in which he contrasted conditions of working the soil 50 years ago and at the present time. Within the last two decades, he said, the application of chemistry to agriculture had done a great deal. The newer ideas of farming aimed to increase, or at least to maintain, the fertility of the soil. On the higher class lands the importance of this had hardly been realised. It was doubtful whether the richer soils in this district were used to fullest advantage, whether the sheep on the mixed farms were of the best quality, and whether the dairymen took the trouble to test their cows. There might be room for the extension of mixed farming, and no doubt fodder crops could be profitably grown on land that was now carrying grain crops. The future promised good prices for fat stock. In discussing the subject Mr. J. Botterill said dairying was more behind than any other department of agricultural work. Mr. Buck agreed. More rigid inspection of dairies was advisable. Mr. Sassanowsky said there was room for intense cultivation on the poorer lands of the district. Large areas could be improved 50 per cent. by the use of manures. Mr. Fowler mentioned that approximately 850 tons of seed potatoes had been imported last year. Their methods of keeping seed were somewhat lax. Mr. Major, in reply, mentioned that about 10 years ago he tested a herd of 12 or 15 cows. The results of the tests showed that his opinion of the value of the animals before they were tested was quite wrong.

MOUNT GAMBIER (Average annual rainfall, 32in.)

April 11th.—Present: 13 members.

Conference of South-Eastern Branches.—Mr. A. A. Sassanowsky, who had attended the Conference as a delegate of the Branch, delivered a lengthy and interesting report of the proceedings. Discussion followed with reference to growing fodder crops in the district. Mr. E. F. Crouch said that generally turnips would not do well in this district, although they might be grown on the damp land. He had grown good crops of rape in the district, but only when heavy December rains fell. Kale and chou moullier had both done well, but they were somewhat late. Italian rye grass was practically useless in the second year.

NARACOORTE (Average annual rainfall, 22·60in.)

April 11th.—Present: nine members.

Experimental Plots.—Mr. S. H. Schinckel undertook to conduct wheat variety tests on behalf of the Branch.

South-East Conference.—The Branch's delegate to the Conference of South-Eastern Branches, held at Millicent (Mr. W. E. Rogers), delivered an interesting report on the proceedings. In discussing the subjects raised, Mr. C. Bray mentioned that he had tried fodder crops, *i.e.*, rape, kale, sorghum, and maize, with rather indifferent success. Lucerne, however, had done splendidly. Mr. Schinkel had put in chou moullier last year.

It fed three and a half sheep, besides cattle and horses, to the acre, and did not interfere with the following crop. On the stubble four sheep to the acre were fed on chou moullier and kale. He had sown one or two crops of rape, but not with success. Mr. W. H. Smith mentioned that he had some fine self-sown plants of chou moullier, which had reached a height of 2ft. 6in.

Rope Making.—Mr. C. Bray contributed a paper. He had made a practice of utilising binder twine, after it had been cut from the sheaves, for the purpose of making rope, on such days in the winter as were too wet for ordinary work. He undertook to demonstrate to members the method of manufacturing the rope.

Life Members.—Messrs. A. Caldwell and S. H. Schinckel were congratulated by members on their appointment as life members of the Bureau.

WIRREGA (Average annual rainfall, 19in. to 20in.)

March 11th.—Present: six members.

Common Ailments of Horses.—Mr. C. Meier read the following paper:—"The most important point in connection with farm horses is the treatment of mares at foaling time, as often a little attention at this time may save pounds. In my opinion mares should be worked lightly well up to foaling, but never in shafts or the centre of a team, always on the outside. Within 24 hours of foaling wax appears on the teats of the mare. She should be kept away from other horses, especially from colts, as she is liable to get kicked or otherwise knocked about. If the mare in the act of foaling has difficulty in passing the foal help should be given, and the foal pulled gently, but firmly away, always pulling downwards, never upwards. Foals should be watched for the first few days. When the foal is unable to pass any manure the fingers should be dipped in salad oil, inserted in the foal, and the hard lump of manure pushed backwards. After it was released the oil would allow the manure to pass. In cases when the navel cord does not come away from the foal, it should be thrown and the cord tied tightly about 2½in. from the animal's belly with a piece of clean thin twine, then with the sharp scissors the cord should be severed about 1in. the other side. When horses gripe through such causes as over quantities of green feed, change of chaff, &c., give them a drench consisting of one and a half tablespoons of baking soda in a bottle of milk. Sand is shown by the horse grabbing intermittently at his stomach. Give a drench of ¼lb. coffee, boiled and strained, to which is added two spoonfuls of baking soda. Give to the horse just warm. In the case of barb wire cuts, when not too big to stitch, wipe them over with a feather and a little kerosine, then on top of that apply a little bluestone solution, about the same strength as for wheat pickling. Before the above treatment cut away any loose hanging lumps of flesh with sharp scissors.

WIRREGA (Average annual rainfall, 19in. to 20in.)

April 8th.—Present: four members and two visitors.

Mallee Shoots.—Mr. H. Rogers read a paper, in which he said that to cut mallee shoots between the months of June and December was only to clear the land for the time being. They should be cut between the middle of February and the end of March, as the sap was then in the stems and the roots received a setback. Sheep had been found to eat the shoots just as they appeared above the ground, and for this reason it was advisable to get stock on to the land in this district as soon as possible.

KALANGADOO, March 14th.—Dry Bible.—Mr. T. Bott reported that he had treated an animal affected with dry bible with 1 pint of Stockholm tar mixed with 2 pints of fresh milk as soon as the trouble was noticed. The results had been satisfactory.

KYBYBOLITE, March 5th.—Manures.—Mr. Hahn initiated a discussion on the merits of A and B grades of manures. He had used both under similar conditions, but there had been no apparent difference in the crops. Mr. Bradley, also, had had the same experience. He would like to see the matter tested at the Kybyholite Experimental Farm. Mr. Schinckel preferred the A grade, because of the better analysis. He had never, however, tested them. The extra cost per acre, sowing at the rate of ¾cwt., only meant an additional 3d., and an extra 4lbs. or 5lbs. of wheat per acre at harvest would cover this cost. He contended that the better quality of the manure would produce this. He did not think this slight difference could be noticed in the standing crops. Mr. Scholz also favored the A grade.

Minister of Agriculture

POINTS FOR PRODUCERS.

Agricultural Machinery in Siberia.

A very important feature in the colonisation of Siberia is the organisation throughout the country of stores for the sale of agricultural machinery to the peasant population. From a small beginning in 1898 the organisation has rapidly assumed large proportions, and at the end of 1912 there were, at various centres east of Tchelyabinsk, sixty-seven depôts and 120 sub-depôts and agencies. The annual turnover continually increases, and attained in 1912 the sum of 8,438,000 roubles. The purchases of machinery in the same year were for an amount of 5,970,000 roubles, and the value of the whole stock on hand was estimated at 11,424,000 roubles, says the *National Review* (China). The machinery is sold on long and easy terms of credit, and the amount due from purchasers rose from 4,554,000 roubles in 1911 to 4,754,000 roubles in 1912. A good system of organisation minimises the number of bad debts. As far as possible, machinery of Russian manufacture only is sold by these stores, but the amount of modern machinery dealt with by them is very large.

Manuring of Malting Barley.

As a result of experiments carried out in connection with the Agricultural Institute of Giessen University, the following principles are put forward in a bulletin summarised in the *Journal of the Board of Agriculture* in regard to the manuring of barley for malting purposes :—" To obtain the best quality nitrogen should be available in minimum quantities ; this end may be most safely attained by the omission of nitrogenous manuring and by a liberal manuring with potash and phosphates. If the highest yield is desired it may be considered advisable to apply a nitrogenous manure. It should be remembered, however, that the largest yield is not consistent with the best quality ; there is nevertheless a point up to which nitrogenous manuring may increase the yield without leading to deterioration in quality. The attainment of this aim is dependent upon suitable manuring with potash and phosphates.

Veterinary Surgeons in England.

The President of the British Board of Agriculture (Mr. Runciman), speaking at a gathering of farmers held at Cambridge on March 28th, said one of the greatest rural problems they suffered from in England was the scarcity of veterinary surgeons. This was due to parents refusing to put their boys into the profession because of a belief that motoring had killed it, which was not true ; and the Government proposed to offer encouragement by remunerating more fully the cleverest of the young men who might come into the veterinary profession.—*Mark Lane Express.*

Agricultural Co-Operative Societies.

In 1901 there were some 25 agricultural co-operative societies in England. These increased in 1907 to 170. In 1913 the number of affiliated societies reached 530, or an increase of 385 societies in the six years.

Fruits, and Where They Come From.

In the course of a lecture recently delivered, Mr. E. A. Bunyard, F.R.H.S., is reported to have said that no traces of the fruits we now had were found among the debris that had been dug up at various ancient places, except the stone of the sloe. The plum, apricot, and fig, he continued, had come from Asia, *via* Greece, Italy, and France. The introduction took a long time, and in one instance it was 1,400 years from the time a fruit left its native country until it was cultivated in England. The fig was the oldest known fruit, but its origin was unknown. As to the strawberry, it was a mistake to suppose that it was a cultivated form of the wild fruit, for one could cultivate the wild strawberry and never be able to grow it any larger than it was at present. The improved form of the strawberry came to us from Peru, South America, although it was in the first instance taken out from the East.

Pig-Keeping by School Children.

The subject of agricultural education is at present very much alive in Kent, writes the *Agricultural Gazette.* Recently a county agricultural organiser was appointed to supervise courses of instruction throughout the county, and the Kent Education Committee constituted a special sub-committee for the purpose of supervising rural classes, and for the consideration of steps which may be necessary to increase the facilities for agricultural education in the county. But the most novel movement is that which came before the committee from Chevening, a parish near Sevenoaks, in which Earl Stanhope's demesne is situate. The managers of Chevening School had forwarded to the committee a proposal to establish a scheme of "co-operative pig-rearing," to be carried on in the school playground," but not to be included in the school curriculum, and the committee approved of it to a certain extent, but strongly objected to the scheme being brought into operation in the school playground. Sir Mark Collet, Bart., was, however, able to inform the committee that there was a misunderstanding, and that instead of the playground being used for a number of pigs only one was to be kept in the garden adjoining. With this information before them, the committee withdrew their objection to the scheme, and it will now in all probability go forward.

Dairy Instruction.

The rapid growth of the dairy industry in Ontario is due largely to the excellent system of dairy instruction maintained by the Government. There is now in force a system of sending specialists in cheese making and butter making to factories and creameries during the manufacturing season to assist the makers in the production of a better and more uniform quality of cheese and butter. Among the duties of these specialists is to inspect sanitary conditions and to give advice on the care and handling of raw material. The Provincial Department of Agriculture bears the expense of a staff of thirty-five dairy instructors, whose functions relate both to producers and manufacturers, and whose duty is to see that a uniformly high quality of dairy material goes out to the market. The method of dairy instruction now given in Ontario, the appointing of special officials to deal with udulteration of milk, and the holding of factory meetings and district dairy meetings have brought about a great improvement in a progressive and prosperous field of labor.—*Agricultural Gazette.*

Longevity of Goats.

The useful life of a goat, says the *Agricultural Gazette,* depends on its constitution, and also on the way it is looked after and fed. Good goats can be kept from 15 to 17 years, and even breed at that age. Yet we may state that these are exceptions which only prove the rule that goats may attain an old age if properly fed and well looked after. The Alpine goats give an average of from 900 to 1,200 pints of milk per annum, and, although not fattening up as readily as sheep, the goat is a fleshy animal whose value as a slaughtering proposition is not to be neglected. We must, in conclusion, say that the goat is a very useful adjunct on any well organised and conducted farm—(1) For her production of milk ; (2) for the quality of that milk in the rearing of infants ; (3) for the conversion of that product into cheeses and the creation thereby of a real and genuine industry ; (4) for the great help cattle breeders will derive therefrom in the rearing, at a small cost, of their calves when their cows' milk is insufficient.

Fighting Insect Pests.

More than half a million of dollars is expended annually in the work of endeavoring to control the scale and other insect pests that infest the southern California citrus groves. This amount includes only what is actually expended in fumigation and spraying and does not, says the *California Fruitgrower*, take into consideration the loss of fruit from improperly treated trees, or trees not treated at all. Furthermore, each county maintains a horticultural commissioner, and many of them a corps of inspectors, primarily on account of insect enemies.

Australian Handbook of Meat Inspection.

Received the "Australian Handbook of Meat Inspection," by Dr. J. Johnston, M.D., C.M., D.P.H., &c., of Melbourne. This is a well-bound volume of handy size, and its contents, which should prove exceedingly useful to candidates for certificates of competency as meat inspectors and others interested in meat inspection, are effectively illustrated and concisely arranged. The inclusion of sections of various Acts relating to meat inspection in Australia should enhance its value as a textbook to those intending to qualify as meat inspectors in the Commonwealth.

Imports and Exports of Fruits, Plants, etc.

During the month of May, 1914, 1,496bush. of fresh fruits, 5,948 bags of potatoes, 128 bags of onions, 14,494bush. of bananas, and 82pkgs. of plants, seeds, and bulbs, &c., were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Of these, 972bush. of bananas and 40bush. of oranges were fumigated, and 446bush. of bananas (over-ripe) and 88 bags of potatoes (diseased) were destroyed. Under the Federal Commerce Act, 3,130bush. of fresh fruits, 1,010pkgs. of dried fruit, 124pkgs. of preserved fruit, 53bush. of lemons, 13pkgs. of plants, and 14pkgs. of seeds were exported to oversea markets during the same period. These were distributed as follows :—For London, 1,035bush. of apples and 5pkgs. of dried fruit ; for Vancouver, 600pkgs. of dried fruit ; for South Africa, 405pkgs. of dried fruit ; for India and East, 2,095bush. of apples and 108pkgs. of preserved fruit ; for New Zealand, 53bush. of lemons, 13pkgs. of plants, 14pkgs. of plants, and 16pkgs. of preserved fruit. Under the Federal Quarantine Act, 3,639pkgs. of plants seeds, bulbs, nuts, &c., were examined and admitted from oversea markets.

Of Interest to Sheep Growers.

Mr. Henshaw Jackson writes :—

A farm without sheep may pay well, but the farm with a flock will pay better.

No matter what breed of sheep you keep, it is your business to see that it returns the maximum of profit.

A profitable sheep for the farmer is one that combines a growth of wool and mutton, making the most mutton with a good grade of wool.

When you send low-grade mutton to the Abattoirs you do not know how it will pan out ; but if you send the best, you do not have much uneasiness about account sales.

A nice round body, pink skin, with a clean face, and clear, bright wool, and sportive humor, are good indications that your lambs are doing well.

When you start in to improve your flock, do it systematically. Careful selection and proper handling will produce a higher standard for wool and mutton.

Breed only to first-class rams, and remember that while a sheep may be of the purest blood, its form and fleece may be so deficient as to render it unfit for breeding purposes.

Strict and careful attention to the improvement of sheep is repaid when you have produced a flock carrying high-grade fleeces and showing a well-developed carcass. When you have got this, you possess just about the most profitable animal in the world for his inches.

* * *

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

Replies supplied by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.

"G.," Nantawarra, had a mare which after being ill a week died. The animal was in good condition, had smooth coat, and apparently suffered little pain. The dung was very dry, and on day of death she seemed in great pain, and did not want to lie down. Frequently passed very dark urine. Post-mortem showed all bowels surrounded by dirty fluid, with bits of matter floating in it. The contents of water gut were hard and dry; a little sand was found, and place of contact with sand seemed rotten and inflamed.

Reply—If the horse possessed an appendix this mare would have died of appendicitis; as it was she died from perforation of the caecum, the puncture of the bowel induced peritonitis, the fluid and matter, which resulted in the acute pain before death. Possibly a sharp strain had taken place before the illness was noticed.

"H.," Coorabie, drenched some horses with linseed oil. They coughed while being dosed, and laid down and gasped. They eventually recovered, but for several days after lumps of solidified oil came from nostrils.

Reply—Heads held too high while being drenched. Oil went into lungs. Discharge was not oil, but clotted fibrinous matter. Very lucky they recovered, generally die. Never keep on drenching a horse that coughs.

"J. A. H." has some sheep suffering from pizzle disease. He asks for a remedy.

Reply—This disease is the result of crystals blocking the urethra, the irritation causing a gleety discharge, all resulting in the swelling noticed. Sheep are more or less a nuisance to drench, but if they are few benefit will follow 20 drops of tincture of camphor given twice a day either in a tablespoonful of milk or smeared on the tongue with a little molasses. The pizzle should be well bathed with warm water and soda or lysol, and a little glycerine, 20 or 30 drops, injected up the tube. A lick of sweet bonemeal three parts, saltpetre one part, will assist in preventing the disease.

"W. J. K." had a draught gelding which was found one morning after a warm night tucked up and shivering, especially in hind quarters, the urine was scanty, high colored, and offensive. He improved after dose of warm brandy and saltpetre, gradually came on feed, and after a spell in paddock resumed work, but had slight relapse, which again yielded to saltpetre. He asks—(1) Cause of trouble ; (2) what is the correct dose of saltpetre for horse, and how often can it be repeated ; and (3) cure for horse suffering from chronic cough.

Reply—(1) The symptons point to congestion of the liver, indicated by the urine and mopiness. The treatment was correct, but it would have been better to have given two drams of chloride of ammonia instead of the saltpetre, and repeated it twice a day for a few days. (2) Saltpetre—A full safe dose for a horse is ½oz., which may be repeated in 24 hours, but it is better to give two drams (a heaped teaspoonful), and this can be given twice a day for a few days. (3) Probably due to broken wind, for which there is no real cure, although many are advertised. Relief may be afforded by feeding chaff and bran only well wet and in small feeds, with once a day 2ozs. (a wineglassful) of raw linseed oil in it. Sometimes improvement follows the use of 10 drops aconite morning and evening for a month or so.

A member of the Northfield Agricultural Bureau seeks advice concerning a pony which went off its feed, it breathed heavily and catchy, its nostrils were distended, and tips of ears very cold, it was restless but quiet ; pawed, laid down, and groaned, and its eyes were dull. It received nux vomica and arsenicum with little relief, but recovered.

Reply—The symptoms are those of congestion of the lungs ; the treatment was correct, but possibly carbonate of ammonia, one dram, twice daily, would have helped.

"N. B.," Nangkita, has an aged horse which backed over a bank and grazed its flank on the top of a low post ; since it has fallen away, is very weak and easily exhausted. It had urinary trouble, but that is now better. Two front teeth in top jaw are broken and black. He asks for treatment, and should teeth be removed.

Reply—The teeth need not be removed ; in fact would be better left. The accident has no doubt bruised and possibly ruptured an internal organ, possibly the liver or spleen. The following tonic might improve matters :—Sulphate of iron, 1dr. ; powdered nux vomica, 1dr. ; gentian, 1dr. ; sulphur, 1dr. ; sugar, ¼oz. ; making one powder, to be given once daily in the food for a fortnight.

" G.," Coorabie, has (1) a yearling gelding with soft swelling below stomach as big as a football; and (2) a stallion with scurfy hind fetlocks, worse in wet weather.

Reply—(1) This is a navel rupture, probably too big to be successfully operated on. Feel how large the hole leading into the stomach is, if less than 2in., operate as follows :—Starve colt for 24 hours, cast on back, push swelling (bowel) into belly, gather up loose skin and pierce with two wire skewers crosswise, tightly wrap about 3ft. of strong waxend round loose skin between skewers and belly, and leave to slough off in about eight to 10 days, when sufficient inflammatory tissue will have closed the rupture hole. If, however, it is larger than 2in. the procedure will probably result in the bowels coming out and the death of the colt. (2) Probably due to a mange mite (*Chorioptes*). Try dressing the legs daily with benzine one part and linseed oil four parts. Also give daily in the food about 1oz. of sulphur (a tablespoonful).

" M.," Coorabie, asks treatment for a filly foal with swellings on stifles as big as oranges. Swellings are hard when standing square, and soft when legs are relaxed. There is apparently no pain, but a stiffness and difficulty in rising. The foal was benefited by rubbing; trouble is worse on cold mornings. Is it muscular rheumatism ?

Reply—Probably rheumatoid arthritis, commonly spoken of as joint evil. If the swellings have not broken and discharged, which is possible, rub them daily with this liniment :—Camphor, one part; olive oil, two parts; oil of turpentine, one part.

" W. B.," Grange, seeks information as to artificial food for calves.

Reply—A standard meal and milk diet for calves is—milk, 3½qts.; water, 3½qts.; wheat flour, 10ozs.; ground malt, 10ozs.; potassium carbonate, ¼oz. Preparation—The flour is boiled with the water and half of the milk to form a porridge; when this is cold the other half of the milk, with the potassium carbonate dissolved, is added, and the malt stirred in. The mixture stands for half an hour in warm place, and then is boiled up again and strained. As milk is stopped off, 1oz. linseed to one pint of separated milk may be substituted; and later, as separated milk is lessened in quantity, the following meal may be boiled up to take the place of each quart of milk :—Rice meal or wheat starch, 1oz.; crushed linseed, 2ozs.; maize meal, 2ozs.; pea meal, 1oz.; commercial extract of malt or ground malt, 1oz. If prepared in bulk omit malt and add as the prepared fluid is cooling off.

" P. B.," Lyndoch, asks treatment for cows which changed from grass feed on to soursobs lost power of hindquarters, otherwise they appear well.

Reply—The paralysis probably arises from the action of the oxalic acid in the soursobs on the blood, so that the brain and spinal cord do not receive the nourishment they require from that fluid. Probably benefit would follow, the administration of 2ozs. twice daily of syrup ferri phos. co. in a little milk as drench and several quarts of limewater to drink.

" H. F.," Mount Barker, seeks (1) information in regard to chlorodyne for horses affected by colic, and (2) as to temperature of livestock.

Reply—(1) The various proprietary veterinary chlorodynes are prepared as cheaply as one can do so oneself. The following is frequently used :—Chloric ether, 1dr. ; spirit camphor, 1dr. ; ext. cannabis Ind., ½oz. ; sp. chloroform, ½oz. ; turpentine, ½oz. ; oil of peppermint, ½dr. Mixed makes one dose. Given in water or gruel. (2) A centigrade thermometer can be easily read because the range required is not great ; the following are equivalents in the Centigrade and Fahrenheit scales :—

C.	37	37·2	37·5	37·7	38	38·3	38·6	38·8	39	39·4
F.	98·6	99	99·5	100	100·4	101	101·5	102	102·2	103

C.	40	40·5	40·6	41	41·1	41·6	42	42·2
F.	104	104·9	105	105·8	106	107	107·6	108

Normal horse, C.38 ; normal cattle, C·39. To convert degrees Centigrade into Fahrenheit multiply by nine, divide by five, and add 32.

" G. W. W.," seeks advice concerning mare which is very much off color ; she has foal just weaned and has slipped another ; has high temperature, is stiff in her movements and the bowels are a trifle loose.

Reply—The symptons are those of laminitis after slipping foal ; the stabling and feeding on green barley are correct. Ten drops of tr. aconite in a little bran or molasses morning and evening for a few days till temperature falls, then 10 drops of tr. pulsatilla in the same way will do good. Moisture or Stockholm tar to the feet.

" T. H.," Iron Knob, has medium draught horse which is on saltbush, myall, and sandalwood feed, but gets two feeds of chaff a day, and yet craves for rubbish, bark off old rails, and so forth. He is losing condition, has a rough staring coat, grinds his teeth terribly, and is very sluggish. Water and dung seem all right, but there is a lot of both.

Reply—The symptoms point to abscesses of the stomach and liver, and probably the horse will die, in spite of treatment. It would be well to feed him on bran only for two days, and then give him a six dram aloes ball to purge him, feeding on bran and long hay for two days after ; then give him once a day a ball made of powdered nux vomica, gentian, saltpetre, ginger, of each one dram, and enough glycerine to make a paste—a ball every day for a fortnight. It is more than probable, however, that the disease has such a hold on him that treatment will not be of much use.

" A. B. F.," has some ewes in lamb which become suddenly ill, stagger and go blind ; the losses cease for a time after change of paddock, then recommence ; the ewes are on natural grasses springing in paddock ; the ewes are generally within a fortnight of lambing, and there is slime on the dung.

Reply—The symptons are of a disease common throughout Australia, like braxy, due to a special germ, the bacillus *oedematis malignae transudationis*. Prevention—Change paddocks every three days, as the germ is discharged in the slime, but is destroyed after some hours exposure to sun and air. A lick of salt and sulphate of iron is useful if the ewes will take it. Treatment—Bleed freely at the eye vein, and drench if feasible with 2ozs. of Epsom salts, or what is better, give a Cooper arsenical worm tablet. Treatment as a rule is not of much avail. Constant change of pasture is better.

" M. W.," Millicent, has three-year-old gelding with trouble akin to stringhalt when backing or turning, but not when going forward.

Reply—There is no cure for this affection, which results from degeneration of certain nerves; but sometimes the symptons may be lessened in severity by giving a purge of 5 drams of aloes, and following daily with a powder made of 1 dram nux vomica, 2 drams iodide of potassium, and ½oz. sugar; this may be given for a month or so once daily.

" R. J. R.," Edillilie, has foal, five months old, which eats very little, is very sluggish, and is always foaming at the mouth. Did excellently for three months.

Reply—Possibly teething troubles, and very probably long round worms in the small bowels. Get from the chemist 1 dram mercury and chalk, and put on the foal's tongue once a day, or if too shy on his feed, 3-5 grains, *i.e.*, as much as will lie on the point of a small penknife blade. If after a week of this there is not the desired improvement, ask the chemist for 12 powders each containing 1 grain arsenic, and give one daily.

" W. J. M.," Owen, wants advice concerning sow which is short of milk for three weeks after farrowing. She is a good, quiet, careful mother, but loses many pigs for this reason.

Reply—If possible feed milk freely to her. For a fortnight before and after farrowing let her have in a little milk before feeding each morning 10 drops of tr. belladonna, and each evening 10 drops tr. pulsatilla. She will drink both of these in say a teacup of milk.

" F. M. H." wants treatment for colt which was kicked on the inside of one of his legs between the hock and the stifle. The place swelled, and there is a yellowish discharge from the swelling.

Reply—Iodine resublimat 1dr. to one pint of methylated spirit will be a good dressing; if the discharge does not soon cease apply occasionally a pinch of chlorinated lime or soap extract. A kick in this position sometimes partially breaks the bone, and things seem to go on all right for a time, when suddenly after some weeks the animal is found with the leg hanging, the fracture having become complete. This accident must always be borne in mind.

" E. E.," Woodside, seeks treatment for mare suffering from what appears to be inversion of its vagina.

Reply—Having made sure that inversion of the vagina is the trouble, and that it is not a tumor growth, an astringent lotion, such as ½oz. of alum to a bottleful of warm water should be applied daily. The bowels should be kept loose by daily doses of 2ozs. or 3ozs. Epsom salts in drinking water, and 10 drops tr. pulsatilla might be put on the tongue morning and evening.

"J. J. F.," Coulta, lost about 100 sheep, presumably through their being turned into a paddock where there was more stinkwort than grass, the stinkwort being responsible. They fell down as in a fit and frothed at the mouth as if poisoned.

Reply—This weed at certain stages of growth will bloat sheep, and death is rapid, as described. Prevention is not to let them on to it when dew or rain has wet it, and where possible to let them have a bellyful of grass before they go on, then they can be gradually accustomed to it. Treatment is of little use, but ½oz. doses of baking soda or hyposulphite of soda dissolved in a little water may be of use on those not too far gone.

"J. J.," Forster, asks advice concerning cow which goes off feed and milk and loses flesh. This has been intermittent during six months.

Reply—Possibly hydatids on the liver. As she is not likely to do well, it would be better to kill her.

"S.," Forster, asks treatment for (1) cow which gives bloody milk when stripped, and (2) for foal which staggers and has been weak across loins for about three months.

Reply—(1) Probably diseased udder, mammitis or tuberculosis. If a lot of blood, dry off; if only a little, rub into the teat after milking an ointment made of vaseline 1oz., tr. arnica 1 dram. (2) Possibly met with injury, but more probably has an affection of kidneys due to a form of blood poison contracted in the womb. Rub back daily with warm olive oil, and give once daily for a fortnight a dessert spoon of syr. phos. Co. (Easton).

"B. B.," Koolunga, has draught filly, 2 years 8 months, with soft swelling in front of off hock, with similar ones each side of point of hock. He asks for treatment.

Reply—Bog spavin and thoroughpin, *i.e.*, bursal enlargements due to poor quality of oil secreted in the oilbags of the joint. On no account should so young a filly be worked, or the swellings will never be reduced. As blistering has failed, as it was likely to do, try a good thick plaster made as follows :—Stockholm tar, pitch, Venice turpentine, warmed together till thin enough to work. Put on a little, then some dabs of wool, more plaster and more wool, till about an inch thick, and turn out in a paddock of good feed for 12 months. The plaster will stick on for some months, and should not be removed.

GRADING LAND FOR IRRIGATION.

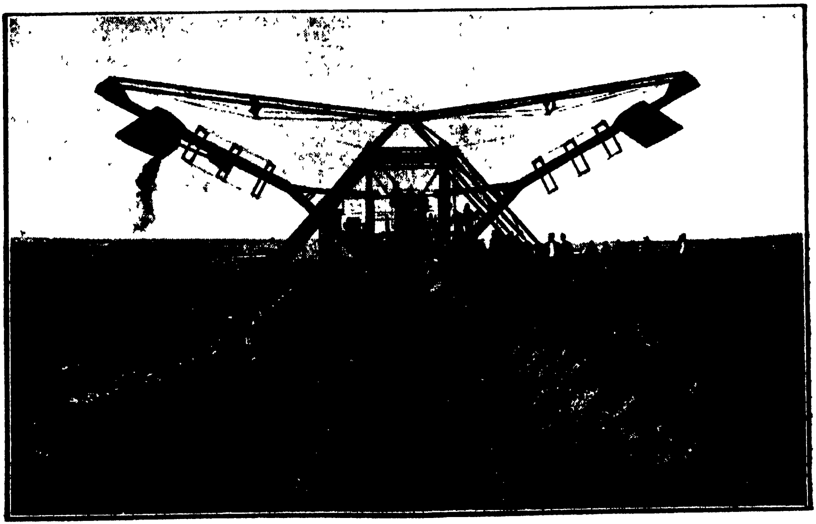
"H. F. C." seeks information as to best way of grading land for irrigation, the most suitable implements to use, and best variety of maize for feeding stock.

Reply—The Director of Irrigation (Mr. S. McIntosh) replies :—"I would suggest grading your land with a Dennis, Fewings, or other suitable grader;

if you have had no experience with this class of machinery, I would recommend the Fewings. If possible secure a surface fall of not less than 3in. to the chain. You cannot trust to the naked eye to give your levels, and would advise securing the services of some competent person to take such levels and furnish you with a sketch showing same. *Re* best variety of maize to plant for feeding stock, I would recommend American Horsetooth and Ninety Days. There are a number of other varieties on the market, but you cannot always get the seed true to name."

Killing a Pepper-Tree.

" H. B. C.," Solomontown, asks how to kill a pepper-tree without uprooting. Mr. G. Quinn, Horticultural Instructor, replies :—" The tree may be killed by injecting a solution of white arsenic into the stem. Holes may be bored with a fairly large auger into it in a downward sloping direction, and after filling these with the solution they should be plugged with clay or putty to prevent evaporation. Arsenic may be dissolved by boiling it in water with washing soda. A couple of ounces of arsenic and four ounces of washing soda would make a gallon of very strong solution. Care must be exercised in making and handling this solution, as it is extremely poisonous to all animal and vegetable life. Strong solutions of common salt or bluestone will kill the tree, but take longer to effect the purpose."



Excavator, Mypolonga Reclaimed Area.

TUBERCULOSIS IN DAIRY CATTLE.

By F. MURRAY-JONES, Assistant Government Veterinary Surgeon.

Tuberculosis is a disease of the greatest importance, not only from the fact of the economic losses to cattle owners, but also owing to its prevalence in the bovine species and the consequent serious bearing on the health of mankind through consumption of milk and meat. The world's authorities of to-day are agreed that the consumption of milk from tubercular cows is a grave menace to the health of mankind, particularly so in the cases of the very young and the aged.

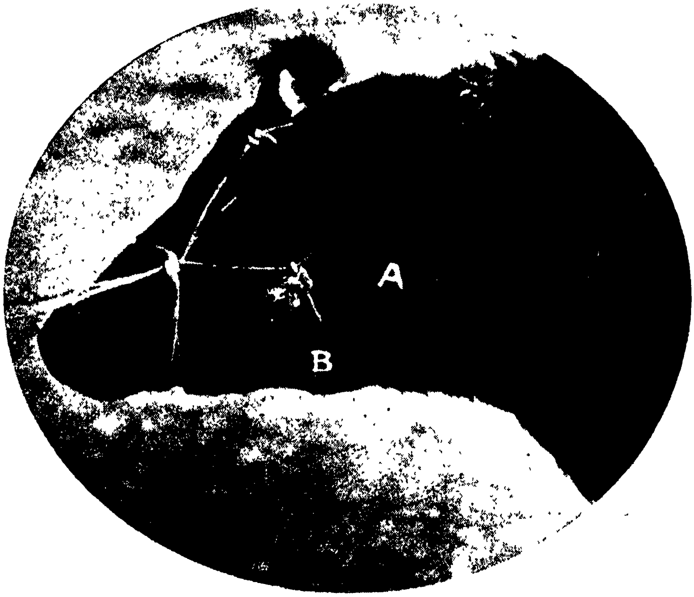


FIG. I.—A TYPICAL "LUMPY" ANIMAL.
A Tubercular subparotid lymph gland. B Tubercular submaxillary lymph gland.

The population of Adelaide and its adjacent suburbs are protected from one phase of this danger (*i.e.*, consumption of tubercular meat) by an efficient system of meat supervision. However, another aspect is the health of the animal responsible for the production of our milk supplies. This remark is not intended as an alarm note, but is made simply to direct the attention of dairy cattle owners to the need for greater vigilance, care, and attention in respect to any indication of tubercular trouble in individuals of their herds, and to suggest measures of co-operation with the officials at present responsible for their supervision, toward one end, namely, the eradication of the disease. The Stock Department is seizing this opportunity of placing before those interested the real significance of this form of the malady, and at the same time directing the attention of stock owners, by practical suggestions, to the best means of safeguarding their own, and at the same time others' interests in the detection and elimination of this disease in their herds.

The dairy cows of South Australia may be divided geographically into metropolitan and country residents, but the percentage of tubercular animals in the one area must not be quoted as the index of the other. *E.g.*, because one hears occasionally of several animals in a metropolitan herd being tubercular, it certainly must not be taken to convey that this represents the state of every metropolitan herd, or can it in any way be made to represent the state of herds existing in the country. Experience and authority agree on this point, that the closer animals are herded together, especially under doubtful hygienic conditions, and the closer they live to mankind, the higher will be the percentage of disease. On the other hand, the wider animals graze and the less frequent their contact with mankind, the smaller the number affected. The doctrine of tubercular emancipation is being preached by the authorities of the leading countries of the world. Even England, conservative as she has been in the past, has now fallen into line and has passed an Act known as the Tuberculosis Order. American cattle men are beginning to appreciate these forward movements, and have refused to admit any animals that have failed to pass the tuberculin test.

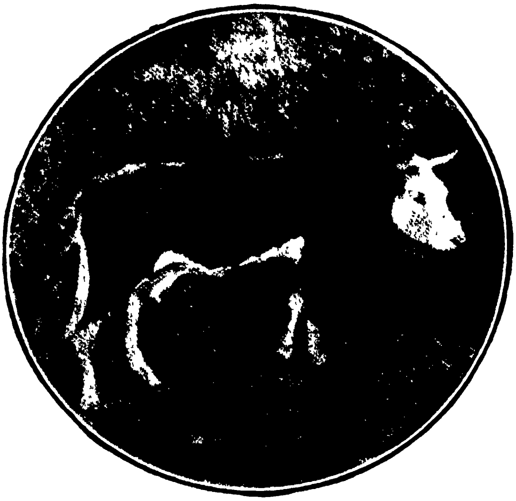

FIG. II.—A TYPICAL "WASTER" OR "PINER."

CAUSE OF TUBERCULOSIS.

The causative agent of this disease, the bacillus tuberculosis, was discovered by Koch in 1882. It is a slim, straight rod measuring 2·5mm. to 3·5mm. long, and ·3mm. to ·5mm. thick. It grows on blood serum in from 10 to 14 days, but will not grow in ordinary agar or gelatine. There are three varieties of bacillus tuberculosis, *i.e.*, human, bovine, and avian. The bovine is shorter and thicker than the human; it is more virulent for cattle than the human, *e.g.*, innoculation of this form into cattle produces generalised tubercular, but innoculation of the human only produces a local form. An important point is that outside the animal body the organism, if exposed to direct rays of sunlight, are soon killed. The dried expectorate from the cow containing the organism has been proved to remain virile for over 150 days. Sunlight, ventilation, and disinfection are the enemies of this organism.

FIG. III.—A SUSPICIOUS CASE.

PREDISPOSING CAUSES.

Sufficient for the purpose of this article the predisposing causes may be summoned up in two words—constitution and environment.

It is a recognised biological fact that the finer or higher the standard of the breed, the less resistant is the subject to an invasion of this character. Some breeds, like the Jersey, seem less resistant than others of a coarser type to the disease. The inference is not that Jerseys are in the ascendancy so far as percentage, but when subjected to condition of infection are less able to resist. As man has sought, by a system of selective breeding and domestication, to produce an animal on the lines of a milk machine, he has largely reduced that character of hardiness once possessed by the bovis under their natural condition.

Environment.—This plays a much larger part than that of so-called heredity. Cases of congenital infection are occasionally met with, but these are due to infection direct from the womb, or by portal blood stream. The retention of diseased animals in a herd has been found after a period of six to seven months to have infected their companions. Insanitary buildings, faulty drainage, filthy feed boxes, indifferent light, cowyards with several inches of dry manure upon which these animals recline, inhaling the dust, and infecting the udder by way of the teats, are, in my opinion, the factors predisposing towards the disease.

MODE OF INFECTION.

This occurs mainly by one of the three following channels :—(1) Inhalation, (2) ingestion, (3) coition.

Inhalation.—In adult animals the most common mode of infection is by that of the lungs. This frequently occurs as the result of close contact with diseased animals. In old cows examined at the abattoirs and slaughtery houses the lesions in the lung glands and lung tissue bear ample testimone to the path of infection. In this way one can easily understand how on, diseased animal introduced to a herd can, in a comparatively short time-infect a number. Cattle do not expectorate in the way that human beings do, but as the result of the explosive effort induced in coughing, a fine spray of moisture is discharged into the atmosphere in the form of small globules. These globules have been proved at times to contain the tubercle organism. These globules descend over herbage, fodder, fittings, as well as upon the companions of the diseased animal. Again, a percentage may dry, and in the form of fine dust be inhaled by other members of the herd. The chances of infection in this way can be easily understood when it is remembered how often we see three bails provided for 15 to 20 cows, and when it is the

A A Tubercular subparotid lymph glands.
B B Tubercular throat glands (retropharangeals).

exception rather than the rule to observe any precaution being taken along the line of cleansing or disinfecting the bail and adjacent fittings.

Ingestion.—In old animals infection in this way is generally in the nature of a secondary infection. By this is meant that the animal has had the infection already in the lungs, and that during the progress of the expectorate from the lungs as it reaches the mouth it becomes swallowed, and so the organism is carried along the digestive tract with all the possibilities of infecting. the stomach, bowels, &c.

In Victoria, prior to the introduction of the Dairy Supervision Act, it was found that a common cause of bowel infections in calves and pigs was feeding unsterilised separator milk that had been returned from the factory. This occurred in the following manner, *e.g.* :—Twenty farmers contributed milk to the factory. Unknowingly, one of them contributed milk from animals suffering from tuberculosis. At the factory the milk from the 20 was mixed. After the process of separating was completed the separator milk was run

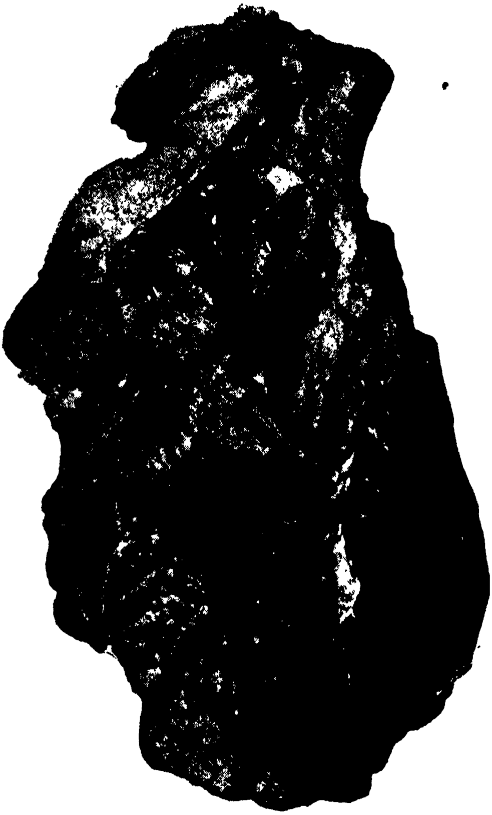

FIG. V.—TUBERCULOSIS IN LUNGS.
A A Tubercular lymph glands (anterior mediastinals).

into a common receptacle, from which each man collected his share. What did this mean ? It meant that infected milk left one farm but was distributed again to 19 others, and, being fed to calves and pigs, no doubt largely contributed to the percentage of the disease in these animals. A real menace to the health of the dairy cows of this State exists through allowing animals to feed from filthy boxes, often caked with dried discharges from earlier feeders whose health in this respect was perhaps of the most indifferent character.

Coition, or Sexual Contact.—Infection in adult animals may be spread by means of the bull during service. Occasionally one meets with a cow whose uterus on *post mortem* proves to be one mass of tubercular infection. On inquiring the history of this animal, you learn perhaps from the owner that she could never be made to carry a calf, although a frequent visitor to the bull. You may also learn that she has been discharging, sometimes scantily, at other times freely. Bearing this in mind, it is an easy matter to imagine how a bull that has served such an animal could again in turn convey infection to other animals.

Congenital.—Cases have been noted of animals being born with evidences of the disease. This has been caused probably by the direct contact with an infected womb during the fœtal life.

SYMPTOMS.

The disease is usually insidious in its development, and slow and chronic in its course. They may be in the acute or early stages, or the chronic or advanced form. In the initial stages the presence of tuberculosis may be overlooked, and not uncommonly well marked and advanced lesions may be found in slaughtered animals that appeared perfectly healthy in life. As the pulmonary or lung form of the disease is most commonly met with, the symptoms, as might be expected, are chiefly in connection with the respiratory system.

In popular language the following terms are used by cattle men to indicate certain classes of animals showing certain deviations from the normal :—(1) The waster or piner ; (2) the lumpy ; (3) the cougher ; (4) the roarer or snorer.

The Waster or Piner is an animal that may be suffering from the disease without showing any definite symptoms. It is usually unthrifty, remaining poor in spite of good feeding, tucked up in appearance, arched in back, head carried forward, eyes sunken, face muscles shrunken, coat rough and staring, legs " proppy," altogether a miserable and dejected animal. (See Fig. II.) Being moved quickly may give rise to a short, dry, intermittent cough, easily induced, especially early in the mornings if the weather be cold. This type of animal should be regarded with the greatest suspicion.

The Lumpy (see Fig. I.).—This term is meant to convey that the animal is suffering from a form of glandular tuberculosis, involving the " kernels " or lymph glands of the head or some other part of the body. The most common region is that of the head. Frequently the parotid gland below the ear, or submaxillary below and on the inside of the angle of the jaw, or the retropharangeal gland situated at the base of the tongue. When the latter are enlarged they may be distinctly felt filling the space between the lower jaws. Often the term is used to indicate an enlargement on the jawbone itself, which is frequently of an actinomycotic character. Again, these lumps may be seen in other regions of the body in the position of the lymphatic glands, *e.g.*, (1) along lower part of neck, cervical glands ; (2) at point of shoulder, prescapular glands ; (3) in flank, precrunal glands. One of the most important situations of this lumpy condition is the mammary gland, or udder. This gland is situated high up at the back of the organ, and the best method of detecting it is to examine the " bag " after milking. The person examining should stand at the side of the hind limb, one hand resting on the rump, and the free hand to be used in carefully manipulating the udder at the " back show " in the centre line high up. Should this gland appear enlarged and hard, somewhat resembling a walnut or golf ball, immediate steps should be taken to have the animal examined by a competent person. If neglected this may extend to other quarters of the organ, with serious effects on the milk, which may become infected with the tubercle organism. The term " lump " is often used to describe the swelling caused by a grass seed abscess in the region of the throat. A rough guide is as follows :—In the case of a grass seed abscess, there is heat, pain, and a tendency to point or suppurate. After breaking, the skin at that spot is found considerably thickened. The

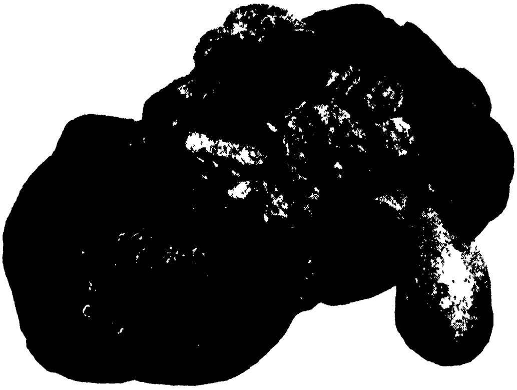

FIG. VI.—TUBERCULAR INVASION OF LIVER.
A A Tubercular glands (hepatic-portals). B Gall bladder.
C Tubercle distributed throughout liver.

more serious lumps are usually hard, "cold," and, in the case of tuberculosis, not inclined to suppurate. But in cases of actinomycosis there may be a suppurative discharge.

The Cougher.—By this term we refer to an animal whose cough is frequent, and may be short and dry or prolonged and moist in character. This is generally an advanced case, and there is usually a loss of condition. Nevertheless, we frequently meet with animals which, in spite of these symptoms, maintain condition, and yet on subsequent slaughter present extensive lesion. The appetite may be slightly impaired. Usually there is not any nasal discharge, and any expectorate is generally swallowed when it reaches the pharynx (gullet). The significance of this swallowing is that the expectorate generally contains the tubercle bacilli, and so secondary infection of bowels may take place. As this form of the disease progresses the animal becomes more emaciated, the eyes become sunken, followed by anæmia and general debility.

The Snorer or Roarer.—This symptom generally follows as the result of the glands at the base of the tongue (retropharangeals) becoming involved, and a distinct snoring sound is produced in moving the animal. When the larynx or voice box is affected by the formation of this tubercular tumor, a distinct roaring sound follows.

THE OWNER'S RESPONSIBILITY.

It must be carefully borne in mind that it matters not where the lumpy conditions may exist, they must always be regarded with the gravest suspicion, and in compliance with regulations under Stock Diseases Act are to be treated as notifiable diseases. ***Immediate notification to the local stock inspector, or to the Stock and Brands Department is necessary***

THE TUBERCULIN TEST.

This test is used for the purposes of diagnosis. The principle of the method consists in the thermal or temperature reaction which follows the introduction of a quantity of specially prepared glycerine extract of pure cultivation of tubercle bacilli. The test requires skill and knowledge in its use. In the hands of the untrained or inexperienced the results are misleading and absolutely unreliable.

PREVENTIVE MEASURES.

Hygiene.—In discussing this aspect as bearing a most important part in the spread or eradication of this disease, one cannot emphasise too strongly the necessity for a higher standard of hygienic conditions than at present exists as regards buildings, drainage, disinfection, light, and ventilation of places used for accommodation of dairy animals.

Buildings.—Many of the present day cowsheds were constructed probably from 30 to 40 years ago, without any pretence whatsoever to hygienic

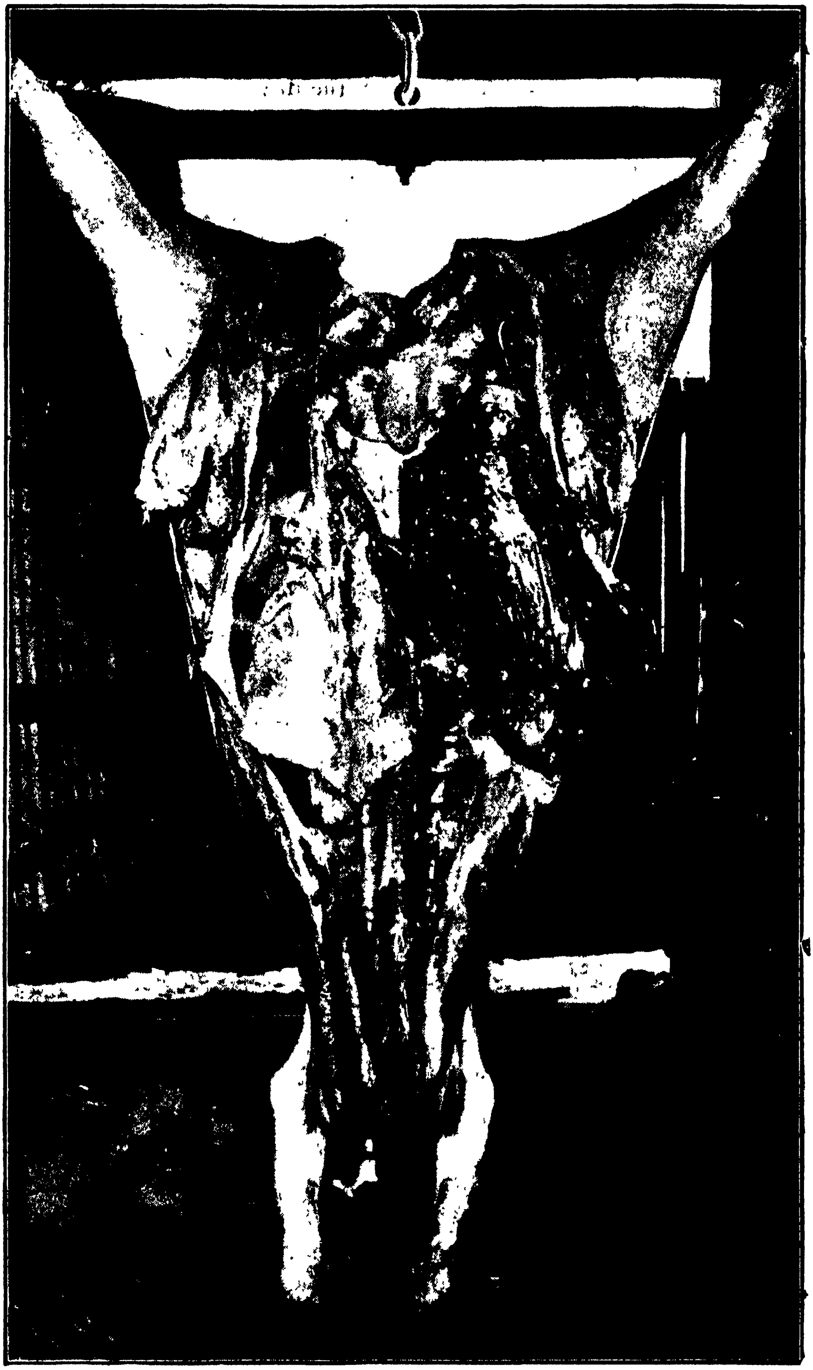

Fig. VII.—A Case Condemned for Generalised Tuberculosis.

principles. In many cases sheds accommodating from 20 to 25 cows possess roofs so low that a man of average height must stoop to enter; the stall accommodation so inadequate that it is almost an impossibility for a person to walk in and release the bail pin in order to liberate the cow; the floors are ill-drained, and the fittings corroded with the dust of ages.

Drainage and Disinfection.—These are phases that should receive the closest attention. In many obsolete sheds the floors are pervious, allowing absorption of the escaped body fluids. One effect of this is the pollution of the atmosphere breathed by the animals during detention, and another that accommodation is provided for disease organisms. A good, cheap, and effective disinfectant is the application of common lime, or the chloride of lime. The best way to use this is in the form of milk-lime, distributed with a spray pump. By this means it is an easy matter to disinfect floors, walls, and fittings.

Light.—All authorities agree that the influence of daylight has a beneficial effect on the health of the individual, whether that individual be human or animal. Sunlight has in a very short time a most destructive effect on the tubercle bacilli. There should not be any corner of a cowshed to which sunlight is unable to gain access.

Ventilation.—By this we do not mean draught, but simply the establishment of currents of pure air throughout a building by the provision of apertures provided at certain points; these being directed in such a manner as not to bear directly upon the animal within. A cowshed being open one way does not provide everything necessary. There must be a free circulation of pure air. How often does one find a cowshed cleanly in many ways but with a close and stuffy atmosphere, and the place black with flies, the latter often dropping into the milk cans waiting to receive the milk when drawn. On asking one owner why he did not have better ventilation, which would not only have sweetened the air, but also dispersed the flies, he informed me "that it remained so for the comfort of the milkers during the winter." This man was evidently quite oblivious to the real object of good ventilation.

In urging that efforts should be directed along the lines indicated by providing conditions that will make for an improvement in the general health of the dairy cow, and so ensuring a higher degree of resistance to this dreaded disease, one cannot overlook the good work that has been done in Victoria in this direction. On the introduction of the Dairy Act in 1906, dairymen in Victoria were strongly opposed to what they called newfangled ideas, but what do they say to-day ? The men whose opinions are worth the having are more than satisfied with the results. The latest statistics quoted by the Director of Agriculture (Dr. Cameron) and the Chief Veterinarian of Victoria show that in the districts where the Dairy Act is in force the percentage of tubercular cases are considerably lower than before, this being largely due to the improved conditions under which the dairy animals are being kept.

QUALITY IN SHEEP FOR MARKET.

By HENSHAW JACKSON, Wool Instructor, School of Mines and Industries.

Now that the breeding of lambs for market is receiving pretty general attention, and in view of the fact that prospects never looked brighter for mutton producers, both as regards local realisation and export, it is well to bear in mind what a big factor "quality" is in regard to cash returns. The price of mutton is affected and the difference between various lots of sheep marked by nothing so strongly as the quality of the animals, and striking instances of this can be seen at any metropolitan saleyard on a market day. It is often noticeable in various drafts of sheep or lambs how one man who produces sheep of the highest quality makes a success of the business, and always finds his drafts of fats keenly competed for, while another, who sends down to market something that he has bred, just because they can be called sheep, cannot make out why it is that none of his lot ever "go off" as prime.

In breeding either sheep or lambs for market, nothing is so essential to success as quality, maintained with the greatest possible uniformity throughout each draft. When sheep come under the hammer they are sold absolutely on their merits, being carefully drafted before offering, for mixed lots are an abomination. Any lots displaying quality, even if only medium in size, will sell as well as any others, and better than most, for should the market go up they are always in the van, and when a drop occurs still maintain a good position in the quotations. Many owners have a sprinkling of "tops" in their drafts, but rarely in big lots is every sheep prime. As the woolbuyers evince a predilection for the best clips, so do the butchers, and especially the exporters, lean in the same direction when buying sheep. This is a good thing, for when quality is in demand then it must be supplied, and in endeavoring to do this we shall raise the standards of our sheep.

Everyone who is any way interested in sheep-breeding knows what a big difference obtains between common and good sorts, and it should surely be the aim of all farmers to raise the best possible sheep, whether wool or mutton be the objective. To do this it should be an axiom to use none but the best rams, and thus sensibly increase the proportion of prime mutton at the yards and first-grade fleeces at the wool warehouses. Some sheepmen in the past have not always been so careful as they might in their breeding operations, and rams of no particular pedigree have been used, with results that, to say the least, have been disappointing. A ram may look very well in appearance, and will sire some good lambs, but perhaps his ancestors have been inferior animals, which fact, in the nature of things, debars him from proving as good a sire as is necessary for success. In the course of time all the shortcomings of his ancestors will be stamped upon his progeny, until the lamb crop degenerates into mixed mongrels, and sells accordingly. By using rams selected from known flocks with guaranteed pedigree, the reverse of this will be the case, and each season will bring a marked improvement in the flock, with correspondingly greater profits.

All over the world the improvement of sheep has been the result of careful breeding and selection, and a still greater general advance can be made in the future by doing away with low-grade sires. Anyone who thinks he can succeed with nondescript animals is bumping up against and running counter to the knowledge and experience of the greatest breeders, and his results cannot fail to disappoint him. A good many farmers still persist in using the ram that is handiest, and " blow the pedigree." So long as they continue at that kind of breeding, the general quality of farmers' sheep cannot be expected to improve. I trust that the importance of this question will be realised, and venture to say that in any district the man who pays the most attention to breeding is also the most successful farmer.

Do not be easily satisfied with any old ram, and do not buy him because you heard he has a pedigree, but go to a reliable breeder for your sires, and get a class of sheep that is true to type and of undeniable descent. When you go on these lines, and not until then, can you hope to produce lambs " like as peas in a pod." Because you breed sheep only for market is no reason for neglecting your breeding flock; and, apart from the ram question, you should cull out each year the ewes which drop the undesirable lambs, replacing them with the best of last year's lambing. In this way you will gradually get together such compactness and uniformity as at the beginning you would have thought impossible. Above all, do not rush things. Take time to achieve your object of quality. You cannot do it in one year, nor two, but get into the right groove and stick there, or rather, move along it. Get your breeding right on proper blood lines, and your sheep, with fair feeding, will do the rest.

There is a big field open to the lamb breeder, in which right principles backed up by unfaltering perseverance must inevitably bring the success due to quality.

* * *

PICKLING OLIVES.

By H. E. LAFFER, Lecturer on Viticulture and Fruit Culture, Roseworthy College.

At this season of the year there are, in a great many places, quantities of olives which ultimately go to waste, and which with a little care may be turned into an excellent article of diet by pickling.

To anyone familiar with this form of pickle probably no other is so highly esteemed, but it may safely be said that a great deal might be done to make it more generally used. To those who have been tempted by the attractive appearance of a ripe olive so far as to take a bite, the realisation has been a rude shock to the palate, due to the acrid astringent flavor imparted, and it is the object of the pickling process to remove this objectionable property.

The bulk of commercial olives such as one buys from the grocer, are pickled in the green stage, and as they are got up in glass vessels with attractive labels, look very fine. It is the less known ripe fruit, however, which forms the more readily digestible article as well as the most nutritious, owing to the greater oil development. In either case the same utensils are required, the principal one being a glazed earthenware or wood vessel, preferably with a moderate sized opening and of a suitable capacity. A tin of caustic potash, of 98 per cent. strength, such as may be obtained from any store, a supply of salt, and good water complete the outfit.

GREEN FRUIT.

The olives should be full grown and picked just before they begin to turn color. Gather carefully and grade out all small or injured fruits. Place in the pickling vessel, and if possible fill up to the mouth. To each gallon of liquid necessary to fill the vessel add 1½ozs. of the caustic potash. Completely fill and allow to stand for four days, keeping the olives submerged the whole time.

After four days draw off the potash solution and replace immediately with a salt solution or brine made by dissolving 2ozs. of salt to each gallon of fresh water. Allow this to remain two days, and then replace with brine, using 4ozs. salt per gallon. After four days replace with brine, 6ozs. per gallon. Repeat in four days with brine, 8ozs. per gallon. Finally after five days at this strength, replace with a brine of 12ozs. salt per gallon, and allow to stand three weeks. Keep the fruit submerged, and if signs of mould appear change the brine.

After a period of three weeks has elapsed the fruit may be bottled for convenience of keeping. Make a brine with from 12-16ozs. salt per gallon and boil well. Place the fruit in bottles, jars, or other vessels as may be expedient, and pour on the brine at about 80 degrees C. or 176 degrees F. Roughly this may be taken as just off the boil, and in fact boiling water will do the fruit no harm. The olives are shortly ready for use, but improve on keeping say from three to six months before using. Sterilised in proper jars they keep indefinitely.

RIPE FRUIT.

The greatest difficulty experienced in pickling ripe olives is that they tend to go soft, and it is found that the first or " lye " solution if composed of part potash and part salt will help to prevent this defect. Only sound ripe fruit should be used, and the larger the better.

Make a solution of 1½ozs. caustic potash and 3ozs. salt to each gallon of water, and allow the olives to remain in this from one to two days. Next rinse and stand in clean water for some four hours, and then place in brine made with 3ozs. of salt per gallon for one day. Gradually increase the strength of brine, as in the case of green fruit, finally bottling in the same manner.

In both processes care must be taken to prevent the formation of mould on the surface, but provided the treatment is carried out carefully there is little danger of this arising.

Bottling with a brine of 12-16ozs. salt to the gallon gives a finished article highly charged with salt—too much so for most palates—and to reduce this the following plan may be recommended. A day or so before use pour out the brine from a jar and fill up with hot water. This reduces the percentage of salt in the fruit, and it may be reduced still further to suit the palate of the consumer.

In the treatment of green fruit one of the main difficulties to contend with is discoloration of the skin by oxidation processes. Not only does this occur in the fruit exposed on the surface, but also to a certain extent to the whole by reason of air dissolved in the water. A plan to overcome this is to boil all solutions and allow these to cool before use. The result is a much more evenly colored and attractive pickle. It is more trouble to carry out, but is worth the extra bother when results are compared.

Now a final word as to bottling. If the olives are to be kept any considerable length of time, they should be sterile to prevent the growth of moulds, and for most purposes good hot brine is sufficient, provided the bottles are airtight. The best result obtained by the writer was to bottle the fruit in Mason one pint jars with rubber rings, and fill up with fresh water. These bottles were then placed in a preserving pan and immersed in water which was heated until the water in the jars was boiling. The jars were then screwed down while hot. The fruit kept in excellent condition, being firm, with a fine nutty flavor

INTER-STATE FRUIT EXHIBITION, HOBART.

SOUTH AUSTRALIAN SUCCESSES.

MEETING OF POMOLOGICAL COMMITTEE.

By GEO. QUINN, Horticultural Instructor.

Mr. Geo. Quinn, Horticultural Instructor, who, with Messrs. G. Laffer, M.P., and H. Wicks, representing the South Australian Fruitgrowers' and Market Gardeners' Association, attended the recent Interstate Fruit Exhibition and meeting of the Pomological Committee at Hobart, has submitted a report to the Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.). After acknowledging the great assistance rendered him by Messrs. Laffer and Wicks, both in connection with this State's display at the show and the meetings of the committee, Mr. Quinn proceeds :—

THE EXHIBITION.

The exhibition was organised by the Tasmanian Fruitgrowers' Association and its success was largely attributable to the energetic action of the President of that body, Mr. L. M. Shoobridge. It was claimed to be the finest display of apples yet brought together in Australia. The show, which was opened to the public on May 6th, 7th, and 8th, was held in a large wool store lent by Messrs. A. G. Webster & Son, and, as it possesses an unbroken floor space of upwards of one acre in extent, the magnitude of the display can be pretty well imagined. The prize schedule comprised 60 sections, for which prize-money to the extent of £400 was offered. Most of the classes were confined to Tasmanian-grown fruits. In the open collections the exhibit entered by the South Australian Horticultural Branch was the only instance of a State department competing. The Victorian Department of Agriculture sent collections of apples and pears, which were not entered for competition, whilst the New South Wales and Queensland departments only forwarded such fruits whose identity was in doubt, and on which the opinions of the Nomenclature Committee were sought.

There were good entries in almost every line, and consequently the competition was keen. The outstanding feature of the show was undoubtedly the cased fruit, most of which was displayed unwrapped, the hundreds of cases displayed in the various sections making a fine spectacle. A big percentage of this fruit would have been hard to beat in any part of the world, as it obviously had been selected with great care and marked regard for evenness of size, shape, and color. In this section the varieties which could be exhibited were specifically stipulated, with the result that the artistic efforts of some of the exhibitors produced particularly fine color effects.

METHODS OF PACKING.

Of noteworthy interest in the sections for cased fruit was the almost general abandonment of what is known as the square or straight pack, which is generally adopted by South Australian packers, in favor of the numerical or diagonal packs universally practised by the American apple growers who put their fruit up in cases. This alteration doubtlessly can be largely attributed to the demonstrations given by Mr. A. Sampson, of Oregon, U.S.A., whose services were secured by the Tasmanian Department of Agriculture for a month in two successive seasons for the purpose of giving lessons in the fruit-packing sheds of the State. It is to be regretted that South Australia missed the opportunity of securing the services of this expert packer. There is no doubt in my mind that the diagonal system will prove to be of considerable benefit to those engaged in the apple-exporting business, because it ensures more even grades and better carrying powers to the fruit ; in fact, to successfully pack by this system accurate grading becomes essential, and the Tasmanians consequently have resorted extensively to the use of mechanical grading machines, several of which I took the opportunity of closely inspecting at work, both at the exhibition and in private packing-sheds in the orchard districts. Those which attracted my attention most were the "Lomas" grader and the "Shields" grader, the former sorting its fruit through the medium of a perforated leather belt working on an inclined plane. The Shields consisted of an inclined surface, down which the fruit is passed between sloping longitudinal rollers—which are fixed in a gradually-widening position as they descend—their revolving movements causing the fruit to roll and turn as it passes down the slope, and thus dropping through the holes as soon as space between the rollers is sufficiently wide. By means of these graders the fruit is divided into sizes of no greater difference than ⅛in. or ¼in. in diameter, and, where properly padded on the outlets, bruising seemed to be practically avoided. These machines cost from £30 to £35, and are in general use throughout the larger orchards of the State. The manager for Peacock & Co., on the Huon River, informed me that he had graded upwards of 30,000 cases during the past season, and no apparent injury was known. Owing to the period over which the packing operations extend there would appear to be some difficulty about properly utilising the machines in the small packing centres, but wherever district packing sheds are formed I am confident that some similar mechanical grader must necessarily be adopted here if we are to maintain our position in the competition with other apple-exporting States.

SOUTH AUSTRALIAN SUCCESSES.

In respect to the position taken by our South Australian collections of apples and pears, I am pleased to report that the first prizes were granted to them in the competitive sections. The collection of pears consisted of 78 varieties, and, on the whole, the quality was unapproached. In the apple collection the South Australian exhibit was placed third in the initial decisions of the judges, but as this was so palpably incorrect, viewed in the terms set out in the section of the schedule, I, at the request of my colleagues, Messrs. Laffer and Wicks, lodged a protest, which the committee upheld, and appointed the President and Mr. James Lang, of Harcourt, Victoria, to review the decisions. These gentlemen, after a very protracted scrutiny, reversed the positions, placing the South Australian fruit first. It was in consequence of this dispute that I took the liberty of seeking the Hon. Minister's permission to donate the prize money awarded for the collection of apples to the local charities in Hobart, and on receipt of a wire conferring the Hon. Minister's permission I wrote the President of the Show, intimating the Minister's wish to give, not only the prize money, but the whole of the fruit sent by our State, to the local charities.

The collection of apples we staged consisted of 270 varieties, most of which were drawn from the collection growing in the Typical Orchard at Mylor, though Messrs. Wicks (of Balhannah), Woodlands (of Wirrabara), and Collins (of Summertown), generously contributed some excellent samples. Amongst the pears, the fruit contributed by Messrs. Wicks, Laffer, and Robin helped most materially the remainder, which also originated from the collection gathered together by the Director of Botanic Gardens at Mylor.

CARRIAGE OF FRUIT.

In regard to the method of transporting the fruit for exhibition purposes, more particularly where, as was the case in this instance, it is subjected to many handlings after having been held in cool store for some weeks, we had in this experience a striking illustration of the advantages possessed by the tray system over the ordinary export or dump case. Our consignment consisted of over 30 crates, made up of three trays cleated together at the ends, and seven or eight export cases. In the former it was quite the exception to find a damaged fruit, but in the export cases—some of which were made of pine and others of hardwood—many of the apples were badly bruised and damaged thereby. The fruit from the Mylor orchard was selected by and packed under the supervision of Mr. Savage, the orchardist at the Blackwood Experiment Orchard, and the care exercised by him contributed in no small degree to the results achieved.

MEETING OF POMOLOGICAL COMMITTEE.

This committee was composed of representatives of the Departments of Agriculture and the Fruitgrowers' Associations of all of the States excepting Western Australia. The sittings were held simultaneously with the progress of the show, and in a room adjoining it, so that the scrutiny of the fruits in any of the collections was facilitated. The principal work of the committee at this meeting consisted of the verification of the identity of a great many of the varieties of apples and pears commonly grown in each of the States. The sample dishes on exhibition were minutely compared, and in some instances it was found that totally distinct fruits were being grown under identically the same name in different States of the Commonwealth, and even in different parts of one State. Although I took a minute record of all the resolutions arrived at in regard to these matters, it is not proposed at this juncture to trench on the official report, which will be issued shortly, and placed before the different State authorities. In regard to this matter of uniform nomenclature there is, besides the verification of the identity of varieties which have been fully described by pomological authorities in other parts of the world, a number of Australian seedlings of which no standard description exists; and it was decided in reference to these that the Government Horticulturist in each State should, after minute dissection of typical samples, compile a description of the seedlings deemed of value which have originated in his State, and that these descriptions be submitted for verification at the next meeting of the committee, which it is proposed should take place in Adelaide next year. This, doubtless, is a step in the right direction towards securing uniformity, and establishing the identity and origin of Australian varieties; but it will be only half fulfilling its object unless it be possible to supplement the written description with sectional and colored illustrations, as well as durable and properly-colored models. As this appears to me to be a matter of national interest, I would respectfully suggest for the Hon. Minister's consideration the advisableness of each State department placing a small amount annually on its Estimates, say £20, for the purpose of furthering this idea. Without some such permanent record of the deliberations and decisions of the committee can be established the value attachable thereto will be largely lost to the fruitgrowing community.

TASMANIAN FRUIT CULTURE.

Advantage was taken of the opportunity to visit orchard country along the Huon and Derwent Rivers in the south, and along the Tamar River in the north of the island, and much evidence of progress was noticeable during the period which had elapsed since a previous visit paid some years ago. Although the main bulk of Tasmania's apple production still consists of Sturmer Pippin, Scarlet Nonpareil, Cleopatra, and French Crab, new varieties are gradually creeping in; principal amongst these are the Delicious, and Stayman Winesap, of American origin, and Crofton Pearmain, a locally-raised Tasmanian apple. These are all highly-colored apples of valuable qualities, and the two last-named appealed to me as being worthy of consideration from our planters in this State.

FRUIT CASES.

I was particularly struck with the cheapness of the Tasmanian cases of the better type, which are made from the stringybark timber growing in the vicinity of most of the orchards. I was assured by growers in the Huon Valley that the best case cost them 6½d., as against 10¾d. to 1s. paid by our growers for pinewood cases possessing little or no superiority over these better types of Tasmanian cases. The timber available for case-making in Tasmania is undoubtedly superior to anything indigenous now growing in this State. This difference in the cost enables the Huon apple grower to purchase his case, pack it, and pay 2½d. required for the water carriage to the ocean steamer at Hobart, at no greater cost than the bare cost of the case in South Australia. I am assured that this timber, if cut to sizes for box-making, and carefully stacked for some months before being used, lends itself to making an excellent package, and it would be, in my opinion, worth while our local fruitgrowers attempting to secure a trial shipment.

I took the opportunity of inspecting drying plants, and sampling the products of the Tasmanian Cider Company's operations, where a most excellent sparkling cider is being produced under the managership of an ex-South Australian, Mr. Foureur, formerly of Mitcham, in this State. These efforts to utilise the rejects from the packing sheds are undoubtedly proving a boon to the fruitgrowers, and there is no reason why our own State should lag behind in these respects. In the valley of the Tamar much substantial progress has been made in the planting of apple and pear orchards, and the results so far are extremely encouraging; so much so that they offer much support to the belief of the residents of the North that they are likely to seriously challenge the South in the extent of their fruitgrowing. The Marine Board at Launceston have undertaken to accommodate deep-sea vessels a few miles below that town. This will facilitate the handling of the fruit and encourage the extensions of the orchards.

POULTRY NOTES.

By D. F. LAURIE, Poultry Expert and Lecturer.

YOUNG STOCK.

All utility poultry breeders are now hatching and rearing chickens. The future of the fowl, for whatever purpose it is bred, depends upon the early treatment meted out. There are various modes of treating young chickens, both in regard to brooding and also as to feeding, and the kinds of food used. The objects of feeding are many; the first and main object is to supply warmth. Food values are often considered in the light of heat producers; the accepted rule is to calculate food values on their heat production—combustion. The processes of life may be likened to combustion. But if you provide merely sufficient food to supply the necessary animal warmth and no more, there will be stagnation, and stunted chickens. You must go farther and supply sufficient to repair losses due to the action of living, and, naturally, you must provide food which will promote growth—*i.e.*, increase of the tissues. More than this is required; for you must enable the bird to build up a reserve. Eggs can only result when a pullet has been so fed that she has stored up reserves from which egg-forming materials can be elaborated. Birds intended for egg and stock production need special treatment, and in the matter of food there should be a difference in the treatment of chickens intended for early market.

KINDS OF FOOD.

In this State many poultry keepers do not recognise that variety in food for all stock, and poultry in particular, is highly advisable and necessary. Not any one grain, nor even a combination of grains and seeds is a perfect food, because all the constituents necessary for the welfare of the bird are not contained therein. A general combination of grains and their by-products, with plenty of vegetable food and a due proportion of animal food is what is required, and within the reach of every breeder. The value of change is well known to careful stockmen, and the recognition of properly nutritious feeding has led to the crude generalisation "Half the breeding goes in at the mouth." We grow, and breeders can obtain, wheat, oats, barley, rye, and peas, and at times maize is obtainable and can be well used, because the small quantity required does not materially add to the average cost per hen, and yet is very satisfactory. The ordinary mill products of wheat—bran and pollard—can be obtained anywhere, and in the South-East oat bran and pollard are to be had. Every breeder, farmer, or otherwise, should grow green food. Animal food—rabbits, plucks, livers, &c.—and meat meal are also obtainable. Space does not admit of a general dissertation on the feeding value of different grains, vegetation, &c. I have dealt with that elsewhere. Wheat is a good staple grain, but in cold weather feed also stout oats, a few peas, and a little maize. Rye need only be used when there is surplus on the farm. Barley is serviceable for growing and fattening table poultry. Bran and pollard fed as mash, wet or dry, are not absolutely essential, but the results when these are intelligently used are most satisfactory. Where wet mash is fed meat meal, &c., can be most conveniently and economically combined. Green and cured vegetable foods are of the utmost importance, because they contain the valuable mineral salts which are lacking in grain and mill products. Moreover, green food should be cheap, and as a large amount may and should be fed, the food bill can be very materially reduced.

Chickens are better managed when fed for the first month on cracked grain mixtures, after that period they may have a little mash daily. Hulled oats, flaked oats, and coarse oatmeal look expensive, but the actual cost per bird is so little that it is the best policy to use these ; also canary, millet, and hemp, in addition to cracked wheat, oats, and maize, so as to give the chick a good start. Dry mash is favored in many parts of the world, and growing stock, especially chickens for sale as market birds, are greatly benefited if a little hopper of dry mash is provided. The dry mash may consist of ground wheat, oats, barley, adding a little peas and maize, and finally 5 per cent. of meat meal and the same amount of screened charcoal grit. Keep hoppers of sharp sand and grits of all kinds. See that fresh clean water is always at hand.

SEPARATE THE SEXES.

Autumn-hatched chickens make good growth, and they do better if the sexes are separated as soon as the cockerels begin to make themselves prominent. This point is not always observed.

MARKET EARLY.

Feed well and get your chickens to market as soon as possible. If properly fed they will always be plump, and you can send them in as soon as they reach 3lbs. If plump, this is a satisfactory weight for our market. Larger birds are not always so profitable. The prices have been excellent, and will continue so. Good chickens are now becoming scarce, and this will be the case for many months. Fattening properly is of vital importance. Very few really well fed fowls are obtainable in Adelaide markets. The usual flaky mash fed to fowls for egg production is not sufficient; you require less bran and should add ground oats, maize, and a little peas.

PULLETS NOT LAYING.

In many cases where pullets have not been laying well the trouble has been due to shifting them from pen to pen, and thus throwing the birds into a moult. Wherever possible the young pullets should have a big run to develop them, and then, before they show signs of laying, should be drafted into permanent quarters and not disturbed. It is both annoying and unprofitable to find flocks of pullets moulting when eggs are at their highest price.

TABLE POULTRY.

Those who are undecided should obtain specimens of the all-round or general purpose breeds, and produce market chickens. The high price of butchers' meat, we are informed, is likely to prevail in the future. This is the breeders' opportunity; breed and sell at the excellent prices obtainable. In breeding for table you have a quick crop, and when you sell the last, in February or March, you have time to clean up and do many things that cannot be done while the yards are stocked. There is a big and growing demand for chickens and ducklings, and prices are high and profits good.

PROPER HOUSES AND YARDS.

Many breeders have not yet recognised that proper houses and yards are essential to success. Design is everything. The covering material should be iron. The framework can be put up much cheaper than is thought. It is satisfactory to note that during the last few months hundreds of applications for advice on this matter have been received. Letters are always welcomed and answered promptly. Occasionally a letter is received in which the writer asks me to tell him "everything" about poultry—breeding, housing, feeding, diseases, marketing, &c. This is unreasonable, and is not practicable. It is advised that all who contemplate breeding should first obtain from the Government Printer, Adelaide, a copy of my Poultry Manual (7d. posted). They should also subscribe to this *Journal*; it is only 1s. a year posted. Then if they write for definite information, and say what capital they have to invest, and a few details of locality, land, &c., much time can be saved.

FARMERS TAKE NOTE.

I have heard many harrowing accounts of those who have taken up farming and through bad seasons have met disaster. I would say decidedly there is no part of the State where farming is possible which is not also suited to poultry culture. I say definitely that if each beginner on the land had regarded as essential a good flock of poultry of the right sort, and with adequate accommodation, there would have been returns sufficient to have fed and clothed him and perhaps his family, and so enabled him to tide over bad seasons. Hundreds lived upon their poultry products in days gone by, when the market for eggs and table birds was about half what is now obtainable. Information as to requirements can always be obtained on application.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1914-15.

[Started April 1st, 1914, to terminate March 31st, 1915.]

Competitor.	Eggs Laid for Month ended May 31st.	Total Eggs Laid from April 1st, 1914, to May 31st, 1914.

PARAFIELD EGG-LAYING COMPETITION.

REPORT FOR MAY.

The general moult which is affecting the majority of the birds is resulting in a low egg yield. Last year the birds were enclosed during the cold weather in comfortable, roomy scratching sheds. The cold weather records were excellent. The feeding is as usual. No undue stimulants are used at Parafield, as is apparently the case elsewhere. Animal food in moderation only is the rule. To give each hen daily an ounce of boiled liver is the adoption of forcing methods which must seriously affect the constitution of the birds which will probably be used as breeders next year; besides the use of such quantities of animal feed is expensive, and not practical from the general breeder's standpoint. Doubtless the abnormal season has affected the laying competition fowls, as well as in numerous other cases. As the season advances no doubt egg production will improve.

Health.—The general health of the birds has been good. Two have been in poor condition, three were pecked by other birds in their respective pens, one has been treated for diphtheria, one for roup, and one for a blackened comb. Four of these have now been returned to their right pens.

Moult.—The moult, which is of a very protracted nature this season, is still the cause of either a very low score in some pens, or of none at all in others. The moult has played havoc with the laying among all fowls of various ages this season, and in many cases is likely to do so for some time.

Green Feed.—Green feed is luxuriant in its growth, owing to seasonable rain and genial sunshine. The birds get an abundance of lucerne, and will shortly get a liberal supply of green barley.

Broodiness has made its usual early appearance among the competition birds. Cases have been recorded from both pens of heavy breeds in the open section.

Visitors.—Forty-five visitors have inspected the station during the month. It is surprising the number who mistake the Saturday visiting day, as many think it is the last Saturday in the month, whereas it is the fourth. Others again think it is the fourth Wednesday. However, a total of 1,098 have inspected the station to date.

Weather.—The weather has been mild. On two mornings only frost was recorded. There were some very nice warm days during the month, and the birds have kept going.

Rainfall.—Rain fell on eight days, with a total of precipitation of 149 points.

D. F. LAURIE, Poultry Expert and Lecturer.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board was held on Wednesday, May 13th. The Vice-Chairman (Mr. F. Coleman) presided, and there were also present Professor Perkins, Col. Rowell, Messrs. A. M. Dawkins, T. H. Williams, C. J. Tuckwell, J. Miller, and G. G. Nicholls (Secretary).

Saline Water for Stock.—The Secretary intimated that arrangements had been made in connection with the testing of saline stock water by the chemist at Roseworthy College, for samples of water to be forwarded at regular intervals from Salt Creek (running into the North Para), Coorabie (far West Coast), Appila-Yarrowie, and Monarto South.

Gratwick's "Beats-all Fertiliser."—In reply to the Board's request for a report on this subject, the Minister of Agriculture wrote—"The Government is unable to experiment with proprietary compounds." The Chairman regretted that apparently it was not possible to have the stuff properly tested. The purpose of the Fertiliser Act, he pointed out, was to protect the users, and ensure them receiving exactly what they paid for. The question was—were the people in this particular instance getting what they wanted. He felt that it was highly desirable, in the interests of the farming community, that an official report on the compound should be obtained and circulated. Professor Perkins suggested that if the position were placed before the Minister in that light he might be prepared to instruct the Inspector of Fertilisers to go into the question, and furnish the information desired. Ultimately it was resolved that the Chairman should personally interview the Minister.

Combined Implement.—A letter from the Willowie Branch requested that the Government should bs approached with a view to induce it to encourage the manufacturing of a compound cultivator and seed drill by offering prizes at the Royal Agricultural Society's show, or by other means. The opinion was advanced that under present conditions such an implement would prove to be very convenient and labor saving. Professor Perkins said that the more people were encouraged to use labor on the farm the better. In regard to this matter the use of separate implements would be preferable to the employment of only one because of the double stirring of the ground. Mr. Dawkins held that the combination implements of the kind indicated were inclined to bury the seed too deeply. It was desirable that the cultivator should precede the drill. At the instance of Col. Rowell it was decided to send the communication without comment to the Agricultural Committee of the Royal Agricultural Society for an expression of its views respecting the wisdom or otherwise of adopting the course suggested.

Feeding Value of Maize.—A letter from the Longwood Branch stated that a member who had perused the published results of experiments undertaken with a view to ascertain the feeding value of hay cut at different stages, wished to know whether particulars of the feeding value of maize cut at different stages could be supplied. Professor Perkins said experiments to that end would take a long time. Investigations had already been made in other parts of the world, and it had been found that maize cut green showed the highest feeding value when the cobs were in the milky stage. Except where it was properly irrigated, however, it seldom reached that stage in South Australia. Professor Perkins, at the request of the Board, undertook to write his comments for the benefit of the Branch.

Lectures on Forestry.—Mr. Dawkins asked whether it would be possible to make arrangements for Mr. Corbin (Lecturer in Forestry) to give addresses before the different Branches of the Bureau. If they could be, he submitted, the lectures would undoubtedly do a lot of good. The State was constantly distributing young trees among the farmers, and these were planted in all sorts of ways. Through improper treatment many of them were annually sacrificed. He moved that the Minister of Agriculture should be approached on the matter, and this was agreed to.

Prizes for Sows.—The Chairman reported that the Royal Agricultural and Horticultural Society had agreed to include first, second, and third prizes for young sows at the next livestock show.

Spontaneous Combustion of Oily Rag.—Mr. Tuckwell uttered a warning in respect to the danger of leaving oily rags where damage could be caused by fire. He said—"Recently we had the front of our premises at Willowie rubbed down with linseed oil, and afterwards the rags were thrown in a heap in the gas generator house. Some hours later we found that they had ignited spontaneously, and when discovered the fire was rapidly spreading. At first we could not believe that it was a case of spontaneous combustion, but an experiment demonstrated conclusively that that was the explanation of the outbreak. To make assurance doubly sure we wrote to the Superintendent of the Metropolitan Fire Brigade, and his reply was absolutely confirmatory."

New Branches and Members.—Approval was given to the formation of new Branches as follows :—Halidon—Messrs. M. O. Weste, W. F. D. Clarke, J. M. Braithwaite, D. C. Chambers, C. H. Coventry, J. C. Gallasch, E. Grace, H. T. Harris, J. A. Hehir, J. L. Opie, L. Rosser, D. Thomson, L. A. von Doussa, D. Westover. Mount Compass—Messrs. A. J. Hancock, W. Cocks, R. Peters, F. E. Slater, M. Wherman, C. C. Kieswetter, G. H. Waye, J. Norman, C. Skews, E. A. Jacobs, T. Trevena, D. J. Hutton, A. Perry, O. Wherman. Albert—Messrs. J. Lee, C. A. Evans, J. T. Colbert, W. H. Cope, A. B. C. Dohse, C. W. Cope, A. Dohse, R. Copp, M. J. Walsh, H. S. Cope, J. Lambert, R. Manning, H. F. Beckman.

New Members.—The following gentlemen were approved as members of the Branches shown :—Berri—W. C. Stidiford ; Morgan—G. Hoffman ; Quorn, G. D. Watt ; Strathalbyn—C. Verco ; Monarto South—R. Hein ; Crystal Brook—W. J. Deer, J. L. Washington, H. H. Nicholls ; Wilkawatt—G. Oram ; Maitland—A. Oakley, W. Quallmann, G. Gapp ; Roberts and Verran—W. E. Bowers, H. J. Crutchett ; Mitchell—W. Dorward ; Bute—H. N. Paterson ; Lameroo—F. Bull ; Borrika—D. J. Leadbeater ; Hartley—W. Jaensch ; Mitchell—W. J. Trimble, R. J. Tehan, T. Bishop ; Claypan Bore—G. R. Small, G. W. Small ; Mount Barker—R. G. Birt ; Glencoe—H. E. McRostie ; Mundoora—S. Carman, H. H. Stephenson, F. W. Button ; Naracoorte—J. A. Kluge, A. B. Feuerheerdt ; North Bundaleer—A. Pitt, J. Pollard, E. O'Halloran, D. J. Shepherd ; Yorketown—F. Emmell ; Port Germein—W. Nevin ; Carrieton—W. G. Brown ; Parilla—P. B. Clegg, A. J. Wilson, W. J. Mitchell, A. Carmen ; Clarendon—W. Biddle ; Leighton—W. Lloyd ; Morphett Vale—C. Renihan ; Monteith—R. M. South, J. L. McAuliffe ; Belalie North—W. R. Bradtke ; Woodside—J. Lauterbach, J. Caldwell ; Mount Bryan—S. Robinson, W. H. Quinn ; Coomooroo—L. G. D. Palmer ; Gladstone—E. P. Rowe ; Meadows—W. L. Schroeder ; Kalangadoo—A. P. Gardiner, E. V. Barlow ; Strathalbyn—J. F. Dodd, G. Tucker, A. Tucker, H. Meyers ; Riverton—W. S. Kelly, H. C. Thomas, A. Bailey, W. Knaeurhase, W. R. Fisher ; Saddleworth—J. M. Fraser, E. Stilling.

Shipping Wheat.

AGRICULTURAL STATISTICS.

RESULTS FOR SEASON 1913-14.

WHEAT PRODUCTION, 16,936,988 BUSHELS; AVERAGE, 7·47 BUSHELS.

The Government Statist (Mr. L. H. Sholl, C.M.G.) has issued the final results of the last harvest of cereal, hay, and fodder crops. The year 1913 was an exceptionally dry one, the rainfall being even lower than in the previous two dry years, 1911 and 1912. In view of this fact the returns of the harvest which were compiled by the Assistant Government Statist (Mr. W. L. Johnston) must be taken as affording indisputable evidence of the improvement in the practice of agriculture generally in the State. The total yield of wheat was 16,936,988bush. off 2,267,851 acres, or an average of 7·47bush., which, considering that the crops sown for grain on at least 190,000 acres were an absolute failure, and the low average in some divisions of the State, must be considered very satisfactory. The yield of hay was 571,616 tons, a decrease of 143,150 tons on the return of the previous year. One significant feature disclosed by the statistics is the large increase in barley production, the yield of 1,332,714 bushels being 13,980bush. more than the previous best yield, and the acreage sown, 94,039 acres, being 22,170 acres in excess of the area sown to barley last year. The total acreage under all kinds of cereals for grain, hay, fodder, or fed off, was 3,104,366 acres, an increase of 102,643 acres.

Commenting on the season Mr. Johnston states that prospects at the end of August were distinctly unpromising. Except in the Far Northern and Far Western Divisions, however, good rains fell in the greater part of the agricultural areas in September, October, and November, but early in December hot winds prevailed in the wheat districts, and this resulted in a considerable decrease in the anticipated yield.

Below will be found further details taken from the report:—

WEATHER CONDITIONS.

As will be observed from the following details of rainfall for the six months—April to September—only 9·00in. were recorded as the average over the agricultural areas, being 5·83in. below the average for 53 years, and the lowest ever recorded in the history of the State, with the exception of 1902, when only 6·20in. fell for the six months.

Average Monthly Rainfall over Agricultural Areas.

Acreage under Cultivation.

(Figures in parentheses are those for the previous season.)

The total acreage under all kinds of cereals for grain, hay, and fodder, or fed off was 3,104,366 (3,001,723) acres, an increase of 102,643 acres. The acreage under wheat and barley shows an increase respectively of 120,072 and 22,170 acres. The area under oats decreased to the extent of 42,802 acres.

All other crops accounted for 36,977 acres, an increase of 3,203 acres. The crops included are maize 1,562 (1,055), rye, 2,660 (2,371), lucerne, 17,554 (16,181), peas and beans, 9,031 (9,308), and other 6,170 (4,859).

The following table shows the distribution of the area in comparison with the previous season:—

Division of State.	Total Area under Cereal Cultivation.	Total area sown for all purposes with—			
		Wheat.	Barley.	Oats.	All other.
	Acres.	Acres.	Acres.	Acres.	Acres.

Increase or Decrease	+102,643	+120,072	+22,170	—42,802	+3,203

Fallow.

The total acreage of land placed in fallow during the season was 1,569,623 (1,537,789) acres, an increase of 31,834 acres. The fallowed area in the Upper North Division shows a big decrease and the area in the Lower North and South-Eastern Divisions a substantial increase, the area in the other divisions being practically the same as the previous year,

PRODUCTION.

In the following summary of the various crops a comparison is made of the total yields and averages with those of the previous season :—

Kind of Crop.	Seasons.				Increase or Decrease.	
	1912-13.		1913-14.			
	Bush.	Avge.	Bush.	Avge.	Bush.	Avge.

The production of wheat, barley, oats, and hay in the several divisions of the State was as follows :—

Divisions.	Wheat.	Barley (all kinds).	Oats.	Hay (all kinds).
	Bush.	Bush.	Bush.	Tons.
I. Central	5,035,986 (6,161,030)	783,873 (763,041)	414,409 (637,004)	291,435 (355,964)
II. Lower North	6,833,870 (7,836,007)	61,453 (65,922)	135,274 (260,797)	144,006 (191,332)
III. Upper North	1,038,072 (2,035,124)	826 (3,895)	7,618 (27,056)	20,358 (44,009)
IV. South-Eastern	2,011,703 (2,618,292)	405,991 (444,867)	414,449 (480,802)	74,142 (81,458)
V. Western	2,015,357 (2,841,263)	80,101 (40,809)	228,920 (267,149)	41,612 (41,884)
Outside of Counties	2,000 (4,500)	470 (200)	70 (700)	63 (119)
Total 1913-14	16,936,988	1,332,714	1,200,740	571,616
Total 1912-13	21,496,216	1,318,734	1,673,508	714,766
Increase	—	13,980	—	—
or				
Decrease	4,559,228	—	472,768	143,150

Hay.—The cut of hay yielded a tonnage of 571,616 (714,766), a decrease of 143,150 tons. The principal kinds were wheaten, 418,972 (556,444), decrease 137,472, and oaten, 143,380 (149,195), decrease, 5,815. The average was just 1 ton per acre.

Barley.—The yield of 1,332,714bush. of barley shows an increase of 13,980bush. over the previous best yield of 1,318,734bush. in 1912-13. The average of 14·72bush. per acre is the lowest since 1904-5. The South-Eastern division produced 405,991bush., averaging 22·25bush. per acre.

Oats.—This crop shows a decreased yield of 472,768bush., the total being 1,200,740bush., averaging 10·27 (10·76) bushels per acre.

Straw.—The quantity of straw gathered reached a tonnage of 17,134, being 7,853 tons less than the previous season.

Green Fodder and Fed Off.—49,948 (39,806) acres were either fed off or cut for green fodder. At least 20,680 acres of wheat and 5,092 acres of oats were fed off owing to the dryness of the season. The cut for green feed is reported to have been 48,930 tons, of which lucerne yielded 34,279 tons.

Wheat.—On February 3rd last advices were received from every wheat hundred in the State, and on the basis of these a revised forecast was issued, which placed the wheat yield at 16,805,945bush., with an average of 8·18bush. per acre. The final results show the yield to have been 16,936,988bush., averaging 7·47bush. per acre. A much larger acreage was sown than anticipated, but owing to the absolute failure of at least 190,000 acres for grain the average per acre was much reduced. Fully 19,000 acres of the hay area were also an absolute failure. Excluding the failures of the grain area the average yield for the 2,077,570 acres actually reaped was 8·15bush. per acre.

The following tables show particulars of wheat culture in each division of the State for the season 1913-14, contrasted with the mean of the last five seasons:—

ACREAGE UNDER WHEAT FOR GRAIN ONLY.

Season.	Total for State.	Divisions of State.					
		I. Central.	II. Lower North.	III. Upper North.	IV. South-Eastern.	V. Western.	Outside Counties'
	Acres.	Acres.	Acres.	Acres.	Acres.	Acres.	Acres.

AVERAGE YIELD PER ACRE.							
	Bush.	Bush.	Bush.	Bush.	Bush.	Bush.	Bush.
1913-14 ..	7·47	8·02	10·89	4·00	6·63	4·49	2·86
Mean last five seasons ...	10·27	10·98	13·42	8·49	8·25	7·12	5·30

In view of the low average rainfall of 17·20in. over the agricultural area of the State for the year 1913 the production of cereals and hay for the season under review is most satisfactory. It should be specially noted that the wheat crop has averaged 21,652,903bush., or 10·27bush. per acre for each of the last five seasons, the Lower North Division alone having averaged each season in the same period 7,765,053bush., or 13·42bush. per acre.

VALUE OF WHEAT CULTIVATION.

To show the importance of the wheat harvest to the State it may be mentioned that the production of grain for each of the last five years has averaged 21,652,903bush., and inclusive of the wheaten hay crop, the mean annual value for the five seasons was £5,296,789, the value of the 1913-14 wheaten grain and hay crop on the average prices to date being £4,190,579.

As intimately associated with wheat culture the fact should be remembered that the capital invested in machinery and implements owned by agriculturists was in 1912 assessed at £2,698,231, and, further, that the prosperous condition of the farming industry is directly reflected in the flourishing condition of many of the secondary industries of the State, notably the agricultural implement and machine works, which for 1912 numbered 57, all employing four or more hands, the total hands being 1,229, who received in wages £124,705, and turned out work to the value of approximately £297,105.

KYBYBOLITE AND GREEN PATCH.

COMPARISON OF CLIMATIC AND SOIL CONDITIONS.

(Address by W. J. COLEBATCH, Superintendent of Agriculture in South-East.)

As a result of a visit to Green Patch, near Port Lincoln, Mr. W. J. Colebatch (Superintendent of Agriculture in the South-East) has forwarded to the Minister of Agriculture an interesting comparison between the climatic and soil conditions in the district mentioned and at Kybybolite. In a covering letter Mr. Colebatch states that he spent a week driving round the Green Patch district, and came to the conclusion that the similarities with conditions at Kybybolite were much greater than the differences, and that therefore the Government farm in the South-East should be regarded as of equal importance to the men on the West Coast ironstone gravel country under good rainfall as to the settlers on the Binnum, Kybybolite, Hynam, and Struan estates. The conclusions arrived at by Mr. Colebatch were embodied in an address delivered by him at Charlton, a synopsis of which is as follows :—

CLIMATIC CONDITIONS.

The rainfall charts of the two districts show that in both cases the annual precipitation ranges from 18in. to 36in., with a mean annual fall of from 25in. to 26in. Further it is to be noted that although the average fall is relatively heavy, yet both districts are subject to the same difficulties in the autumn and spring as the drier wheat areas. The bulk of the rain falls in the months of June, July, and August, leading to waterlogging and a consequent drowning out of the young crops, whilst the spring and autumn months are often marked by protracted spells of drought. It would appear that the Green Patch suffers less from hard frosts than Kybybolite, but otherwise the climatic conditions do not differ in any material manner from those experienced between Frances and Hynam.

THE SOIL.

As to the soil, an examination of the various cuttings and sections revealed in some places a very striking similarity with those predominating on the Government Farm in the South-East. The depth of loam overlying the ironstone rubble was greater, and in some instances the rubble was coarser and more angular. From the absence of "crab-hole" areas and "runaway" holes it would appear that the limestone layer underlying much of the Kybybolite and Binnum country is either wanting or more deeply situated at Green Patch; but in any case the depth of yellow clay beneath the rubble is sufficient in both districts to bring about a soggy condition of the soil in the winter and spring. And this is the main cause of unsuccessful cropping in these districts. In general it may be said that the structure and physical character of the soils in question present strong resemblances, and I am much inclined to think that the results obtained at Kybybolite may be taken as applicable to the country I have inspected. The settlers' experiences in both places have been similar.

1. It was quickly observed that the land became boggy, spuey, and even treacherous in seasons of heavy rainfall.

2. Crops, even when put in well, were noticed to make good growth in the autumn and early winter, but about July and August they changed color, became red and then black in the foliage, and developed a sickly, stunted appearance, from which they never recovered.

3. The failure of crops on fallowed land led to a diversity of opinion as to the applicability of the usual methods of wheat growing, and many were prepared to denounce fallowing as useless.

4. Spring-sown wheat and oats sometimes were found to yield as good returns as those seeded in May, and it was concluded that there was no "proper" time to sow cereals. It was merely a gamble with the seasons.

5. In both places it was seen that the crops sown on sloping banks generally yielded better than those on lower levels, and dry seasons were found to suit crops better than wet ones.

DIFFERENCES BETWEEN THE AREAS.

1. The Green Patch country is more undulating, and the slopes are steeper than in the South-East. From the point of view of drainage this is an important difference.

2. The rubble country in the South-East carries heavier timber as a rule. Redgum predominates there, whilst on the West Coast land of similar character carries mostly sugar gum.

TREATMENT.

From the practical standpoint the more important features of these laterite soils are:—

1. The tender character of the land. Soils of this description cannot be handled roughly with advantage, as in the case of a stiff, fat clay. They break down very readily into tilth even with a stroke of the light harrows if worked dry, and this is a serious matter when heavy rains follow within a week of seeding, as such fine-grained soils melt down and dry out again, leaving the paddocks in a worse state than before. Early fallows are often

injured in this way, and re-ploughing is usually the only remedy. For this reason it is to be hoped that spring fallowing with little if any summer working will be found to suit these districts best.

2. The sourness of the land due to the soddening effect of ages of heavy rainfall, the consequent leaching out of the lime from the upper layers of the soil, and the steady accumulation of organic matter. The evidence in favor of the view that the soils in question are acid is abundant and convincing.

(*a*) The appearance of water grasses and sedges in the natural pastures.

(*b*) The moistened soil gives an acid reaction when tested with litmus paper;

(*c*) Repeated trials have shown that there is a limit to the amount of acid fertiliser that may be applied advantageously to these soils. Up to 1cwt. per acre will give payable returns, but over that amount results in diminished yields;

(*d*) The apparent superiority of soil so situated as to be able to shed a good proportion of the surplus moisture it receives is evidence that too much of the winter rains is retained, and land that is long subjected to water logging is bound to be sour.

To remedy this natural defect we must resort to draining and liming. I place draining first, as in my opinion it is useless to discuss the cultivation of these soils unless we are first of all prepared to assist them to quit the surplus winter rains. Unless farmers on land of this character are prepared to face the position, and to set to work in real earnest to accomplish this purpose, I am unable to hold out much hope of success in wet seasons. The whole system of farming adopted on the Kybybolite Experimental Farm is based on a cheap and efficient surface drainage scheme. Underground drainage, even if effective, is not an economical proposition, and mole draining proved unsatisfactory owing to the irregularity of the subsoil.

The system in vogue at Kybybolite is the " plough and crowder " surface channelling, with contributory water furrows. A "crowder" or "delver" is readily made with a couple of sleepers and iron plates, and even if purchased the initial cost would be very light, particularly when shared by two or three neighbors. The main channels should be run across the slope and should be distant from one another a distance of five to 10 chains. The water furrows are traced through immediately after seeding, and the distance between them will vary with the fall, but usually every six or seven chains will be found sufficient. This method can be carried out at a cost of not more than 6d. a chain for the main channels, so that it is within the reach of all enterprising settlers. It will necessitate working the land in strips, and obviously round and round ploughing must give place to the older system. Farmers must remember that the full effects of any drainage scheme will not become apparent at once, and it will be for each man to watch the results in order that he may be in a position to judge the requirements of his own holding as to the frequency and capacity of the channels. The liming of the land must follow, and not precede, drainage. In ironstone soils a sufficiency of lime is demanded in order to guard against the locking up of the soluble phosphates by conversion into iron phosphate. Lime is further needed to sweeten the soil and promote the growth of clovers and trefoils. Without legumes the fattening capacity of the grass and stubble feed is low, and the most satisfactory way of inducing their development is to drain and lime the soil. From 1 ton to 2 tons of ground limestone will be needed as an initial application, and after that from 5cwts. to 8cwts. at intervals of three to five years.

MANURES.

Except in so far as they might prove useful for top-dressing backward crops in September, nitrogenous manures are without effect on cereals in our soils ; nor has potash yet given payable returns at Kybybolite. All forms of phosphatic fertilisers on the local market have been tried, but none have been responded to so well as the 36-38 grade of mineral superphosphate. The acid-soluble and citrate-soluble forms have not succeeded so well as the water-soluble even in wet years. The best results at Kybybolite have been secured from 1cwt. of mineral super. per acre, and this dressing has been adopted as the standard. No doubt as the sweetening of the land proceeds through drainage, liming, and cultivation, the heavier quantities will prove more remunerative, both directly and by reason of important secondary effects.

CULTIVATION.

Ploughing should be done to a depth of 4½in. to 5in., even though this results in the turning up of the rubble. My experience leads me to think that the rubble is better interspersed through the fine-grained loam than left as a layer 3in. to 6in. deep. We have not found that the soil suffered from deep ploughing ; on the contrary, high yields have been obtained the last two years on land that has been treated in this way since 1906. It is therefore a mistake to think that deep ploughing results in impaired fertility. The natural tendency for lime to sink through the soil makes it less likely that the lower layers will be found more acid than the upper ones. With reference to the advisability or otherwise of fallowing, I may say at once that I believe in spring ploughing with one, or at the most two, subsequent working in preparation for wheat. Fallowing is not so essential for other cereals or pulse crops, but, inasmuch as the object of fallowing in our district is to aerate and mellow the soil, there is no doubt that all autumn-sown crops would thrive better on land prepared the previous year. Still, on all farms it is generally necessary to sow an area on autumn ploughing, and the point arises as to whether one is justified in ploughing dry instead of waiting for a useful rain. Our plan is to expend from 1s. 6d. to 2s. per acre on new shares and plough up dry, to secure aeration of the land and an early seeding. Land ploughed dry should be used for oaten hay or oats, and if the rains hold off the seed bed may be got ready and sown during April without fear of disaster.

Experience at Kybybolite showed — (1) Autumn ploughing is about equal in value to "green" ploughing, even in a dry year; (2) summer fallowing proved superior to autumn fallowing, probably because better aeration was obtained; (3) winter fallows yielded better than the autumn, and the spring better than the winter; (4) the unworked ploughing came out best on the late-lifted plots; (5) the spring working was best on the late fallows; (6) an additional summer working was more effective on the early than on the late ploughed fallows; (7) spring ploughed fallow receiving one spring cultivation gave the highest yield.

CULTIVATION.
Spring, October 18th.
Summer, November 21st.

SEEDING.

Algerian oats, graded, 1½bush. per acre: 36-38 min. super., 1cwt. per acre.

Seed bed prepared between May 2nd and May 6th. Drilled May 7th-8th. Plots harrowed September 2nd.

(To be continued.)

THE WHEAT MARKET.

Commenting on the wheat position *Beerbohm's Corn Trade List* under date London, May 8th, states :—There has been a further improvement in the demand, both for the United Kingdom and the Continent ; some 30 cargoes have changed hands, prices at the close being about 6d. higher than a week ago for Australian and Plate, and 3d. for other descriptions. The demand is almost entirely for cargoes afloat, there being very little disposition on the part of buyers to operate in distant positions, in view of the favorable crop outlook in most countries. France has bought pretty freely, and is expected to continue doing so. It is still believed that farmers hold fair reserves of wheat, but much of it is of inferior quality, which necessitates a free admixture of good foreign descriptions. Germany also, having exported such a large quantity of native wheat, will continue to be a large importer for some time to come.

Shipments last week were the smallest of any week since the commencement of the season, amounting to 930,000 quarters, of which only 260,000 quarters were for direct ports United Kingdom. This week's total promises to be about 1,250,000 quarters. The net imports into the United Kingdom for the nine months ending 30th April have amounted to 19,476,410 quarters, against 21,497,890 quarters in the corresponding nine months last season. Farmers' deliveries, reckoned on the old basis, have been about 750,000 quarters in excess of those of the previous season, so that the total supplies for the nine months are about 1,250,000 quarters less than last year. Stocks, however, at the ports are 400,000 quarters larger than in 1913, instead of being considerably smaller, and it would appear pretty evident that not only has English wheat been delivered more freely than represented by the quantity mentioned above, but that invisible reserves must have also been drawn upon, and the consumption also smaller than usual.

The Washington Agricultural Bureau report for May gives the condition of winter wheat on the 1st of the month at 95·9, against 95·6 last month, and 91·9 on the 1st of May last year, and 85·5 the average condition of the 10 previous years. At harvest time last year the condition was 81·6. The area abandoned amounts to 1,123,000 acres, leaving 35,387,000 acres to be harvested, against 31,699,000 acres last year. On the basis of this report, and allowing for a normal deterioration of 5½ points between now and harvest, the indicated yield is 630,000,000bush., against 523,561,000bush. last year. It is more than probable, in view of the fact that climatic conditions hitherto have been so exceptionally favorable, that the deterioration in the next two months will exceed the normal. The present outlook, however, is a very promising one, and, with quite an ordinary yield of spring wheat, the total yield would be a record one by many million bushels.

THE WORLD'S VISIBLE WHEAT SUPPLY ON MAY 1.

Steamer Freights.—(June 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 21s. per ton (6$\frac{7}{10}$d. per bushel) ; to South Africa, 20s. per ton (6⅖d. per bushel). Parcels, Port Adelaide to London-Liverpool, or Continent, 20s. per ton (6⅖d. per bushel) ; Port Adelaide to Melbourne, 12s. per ton (3⅘d. per bushel) ; to Sydney, 14s. 6d. per ton (4⅗d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 20s. to 21s. 3d. per ton (6⅖d. to 6⅘d. per bushel) ; South Africa, 18s. 9d. per ton (6d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Government Produce Department reports on June 1st :—

Butter Factory.—There was a slight increase in the quantity of the cream received at the factory during last month, and the quality generally was better. The price of butter eased slightly, and present prices are—Superfine, 1s. 3½d. per lb.; pure creamery, 1s. 2½d. per lb.

A. W. Sandford & Co., Limited, report on June 1st—

Butter.—Local supplies have shown a fair increase, but are still far short of requirements, heavy consignments being brought along from Victoria, New South Wales, and Queensland to fill up the shortage. Values have only shown slight fluctuations—"Alfa" is selling at 1s. 3½d.; "Primus," 1s. 2½d.; choice separators and dairies, 1s. to 1s. 1d.; store and collectors', 10d. to 11d. per pound.

Eggs.—Rates ruling throughout the month have been very stationary, with the exception of the last market, when values firmed 2d. per dozen. Holders of refrigerated and pickled sorts are now anxious to quit, as it is getting late in the season. Hen eggs, 1s. 8d.; duck, 1s. 9d.; refrigerated, 1s. 4d.; well preserved, 1s. to 1s. 0½d. per dozen.

Cheese.—Very extensive business has been put through both for local and Broken Hill orders, so that stocks held at the moment by factories are light, and prices record an improvement of ½d. Present quotations are from 8d. to 8½d. per pound for large to loaf.

Honey.—Sales have not been quite so active, owing to purchasers having stocked up fairly heavy quantities. However, there is no quotable alteration in price, prime clear extracted selling at 3d. per pound; beeswax, 1s. 2½d. per pound.

Almonds.—The forwardings have not been equal to export orders, and rates have firmed accordingly. Brandis are 7½d.; mixed softshells, 6½d.; hardshells, 3½d.; kernels, 1s. 7d. per pound.

Bacon.—Bacon pigs have been scarce, and supplies are not equal to demand, heavy parcels have therefore been received from the East, and values show an easing tendency. Best factory-cured sides sell at 9d. to 10½d. per pound; hams, 9d. to 11d.; lard in skins, 8d.; bulk, 6½d. to 7d. per pound.

Live Poultry.—The catalogues submitted during the month have been very large, but owing to the high figures ruling for fresh meat values have shown a good improvement, with the result that consignors are taking advantage of the nice prices and forwarding each week. Good table roosters brought 3s. 3d. to 4s. each; hens and nice-conditioned cockerels, 2s. to 2s. 9d; light sorts lower; ducks, 2s. 6d. to 3s. 4d.; geese, 4s. 3d. to 5s.; pigeons, 7d.; turkeys, from 7d. to 10d. per pound live weight for medium to good table birds.

Potatoes and Onions.—Substantial supplies of potatoes have arrived, chiefly from the South-East, and in sympathy with the markets of the other States prices have eased. Onions—The onion market has been very quiet, and a tendency to lower rates was only checked by a few export orders. Present quotations—Potatoes, £4 12s. 6d. to £6 per ton of 2,240lbs. on truck Mile End or Port Adelaide; 5s. to 7s. per cwt. in the market. Onions—£7 per ton of 2,240lbs. on truck Mile End or Port Adelaide; 7s. to 8s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of May, 1914, also the average precipitation to the end of May, and the average annual rainfall.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

June 10th and July 8th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

ARDEN VALE AND WYACCA (Average annual rainfall, 16·65in.).

May 12th.—Present: six members and two visitors.

Conservation of Water and Fodder.—The Chairman (Mr. J. H. Willis) read a paper. He advised the excavation of large dams in the dry northern areas. Water conserved by this means was not only available for stock, but in some seasons a small plot of vegetables could be irrigated. Last year, by this means, he had secured 7cwts. of trombones, tomatoes, cucumbers, beans, turnips, carrots, parsnips, cabbages, cauliflowers, and melons of all descriptions, all of which had been watered from one dam. This dam had only been empty for one week during the past 11 years. A windmill alongside pumped the water into a large tank near the homestead, for convenience in watering the garden, fowls, pigs, &c. Dealing with the conservation of fodder, the paper continued—"I would strongly advise farmers to use the binder much more in the future and to use the harvester less. Farmers who used the harvester in this district during the good seasons—1909 and 1910—and did not use the chaff carrier, lost all the cocky chaff, which, in my opinion, is a valuable fodder in the time of drought. When the crop is long enough I recommend the binder, not only for hay, but also for the wheat crop, which can be cut eight or 10 days before the crop is ready for the harvester. The crop should be stooked in large stooks, of say not less than 50 sheaves, and can be left in the paddock until the stripping is finished; then it can be carted, headed, and stacked. For heading I prefer the double disc header, which is a strong and light running machine. Four men can work it and stack the straw. I am now using a stack of headed straw that was put up seven years ago, and is as good as when put in. The cocky chaff and also the hay I am using was stacked four or five years ago. If it were not for these reserve stacks my stock would be in a bad way to-day. The wheat from the straw in question realised top price and averaged from 5bush. to 7bush. to the acre more than that which was left for the stripper, which was bleached by heavy winds and rain, and for which I received 4d. per bushel less. Cutting the crop with the binder lessens the risk of losses through storm or hailstones, and the value of the straw fully repays the extra labor. In conclusion, I would strongly advise farmers to keep two years' hay on hand in the good seasons, and stack all the cocky chaff and straw possible. It will be very acceptable in the dry years."

COOMOOROO (Average annual rainfall, 11in. to 12in.).

May 9th.—Present: six members and three visitors.

Hay and Straw Stacks.—The Hon. Secretary (Mr. W. M. Robertson) in a paper emphasised the need for farmers to provide against possible dry seasons by storing hay and straw. Another drastic mistake made by some was to overstock their holdings during good seasons. Had farmers made some provision by conserving some of the straw and wheaten chaff during the past few years, thousands of pounds worth of stock would have been saved. Mr. W. Robertson had been troubled with mice in his haystacks. Mr. R. G. Polden advised fencing the stacks with 2ft. 6in. sheet iron, put 2ft. in the ground.

Supports should be on the inside; the fence should be a few feet away from the stack. Another preventive was to cut the hay before the grain developed; the mice would then not trouble it. Mr. E. Brice advised building stacks on chaff or straw, and covering them with straw. Mr. Berriman preferred straw to wheaten chaff for stock feed. He would cut a crop intended for hay on the green side, there was then no danger of horses being affected through eating too much grain. Oats and wheat should not be sown together for hay, as it was difficult to ensure their fitness to cut at the same time.

MOUNT REMARKABLE (Average annual rainfall, 14·48in.).

May 6th.—Present: 11 members.

Experimental Plots.—The Chairman (Mr. N. S. Giles, B.Sc.) was appointed to conduct wheat variety tests. Three-acre plots were to be sown with 1cwt. super. and 1bush. per acre of the following wheats:—Federation, American No. 8, Marshall's No. 3, Yandilla King, Thew, and Bayah.

Co-operation.—Mr. G. Casley read a paper under this heading. He urged on farmers the need for co-operating in their purchases and in the sale of their produce. Members of the Agricultural Bureau especially should adopt this system, he said. The paper was discussed at length.

ORROROO (Average annual rainfall, 13·42in.).

May 9th.—Present: 17 members and two visitors.

Fattening Pigs.—The following paper was read by Mr. H. Chapman:—"Pigs require a comfortable sty, not too small, *i.e.*, about 25ft. by 40ft. for about six or eight pigs. It is not advisable to overcrowd, as the animals will then struggle and fight to obtain their food, the weaker ones having a bad time. Always keep the sties clean and dry, and in winter time as warm as possible. This is a big help when fattening. In the summer, an open shed with a straw roof is necessary to keep them cool. If convenient, a small waterhole in the sty will help to keep them in a better state. If they are running out, they frequently make to the nearest water for a roll, and if not protected, the heat will discourage them to eat, whereas, if kept cool, they are able to eat as usual. Give them plenty of milk with a little pollard or grain; the milk alone is not sufficient to fatten growing pigs. When commencing to feed with pollard, do not give them too much, as it will probably sicken them. Do not change their food suddenly, as this will cause them to scour; bring them to it gradually. When fattening pigs it is best to give them a small quantity of light food, and increase the amount and the quality as they become accustomed to it. If they are allowed to have too much it will sometimes kill them. Feed them four or five times a day, and give them a quantity that they can manage comfortably, instead a giving them two big feeds a day. Some owners leave food in the troughs, but it then becomes stale and sour, and the pigs will not eat it unless they are forced. Allow the milk to stand some time rather than give it to the pigs direct from the separator; the pollard I like to soak, or scald, as it goes farther, and is better for the pigs. The Berkshire gives as good results as any; the half-bred Tamworth also gives splendid results." Mr. Tapscott had found the Poland-China and Berkshire cross very satisfactory. Mr. Cadzow mentioned that hay chaff, if soaked, proved an economical ration. Mr. Bennett had secured good results with milk and bran. Members considered that milk and wheat made perhaps the best and firmest bacon. Lucerne chaff, soaked and mixed with a little pollard, kept pigs in good condition.

Beautifying Farm Homesteads.—At the previous meeting (April 11th) the following paper was contributed by Miss Tapscott:—"One of the first things a settler should do, after erecting sheds and other necessary buildings, is to beautify his home. A few rows of gum trees make a nice plantation, as also English elm, carob trees, and Norfolk Island pines. I prefer evergreen trees to deciduous, as the latter create too much rubbish when losing their foliage. When planting, put them in systematically, as they will look better than those planted at irregular distances. The best system is in rows, about 8ft. between each tree in the row, and 8ft. between the rows. Ornamental grasses or lucerne could be grown between the rows, if necessary. A flower garden also helps to make a home attractive. In years similar to this pot plants are about as much as anyone can manage. A vegetable patch looks nice, besides being so useful. Trees often make a poor house look comfortable, while a good house without trees looks deserted. The carob always looks fresh, and the beans produced make good food for cattle. Pepper trees look well for a few years, but then begin to look shabby and after a while die, whereas a gum does not go off in this way. A fruit garden is attractive and useful. For the first few years pruning should be done with the object of shaping the trees."

TARCOWIE (Average annual rainfall, about 15in.).

May 5th.—Present: five members and 21 visitors.

Seeding.—Mr. John Symons read a paper. He said—"Wheat intended for seed should be left standing until thoroughly ripe before being reaped. Green grains produce weak, delicate plants, which are liable to develop disease. Clean the wheat thoroughly and see that all broken grains, as well as other seeds, are taken out. It will pay better to give this to fowls or pigs. Have the seed bed in good order. Cultivate the fallow not more than 3in. deep, rather less if anything. If the soil comes up rough, use a rib roller made of tee iron with a 2in. flange. This will make a nice smooth surface for the drill. If the land is fine, hang a light harrow behind the cultivator in lieu of rolling. If possible, sow after a good rain, of say 1½in., but should the season be late be careful not to cover the wheat with more than 1in. of soil; rather leave some of the grain on top than drill any deeper. Then go over it with a set of light harrows to level the ground and cover any grains that may be showing. In this way there will be less malting of seed. For dry sowing I prefer unpickled wheat. I would not advise sowing wheat too thickly, as where the wheat stools well the heads are bigger and fill better than in a crop where it is too thick to stool. I recommend seed from another district every second year. Where wheat is sown on the same class of land year after year it has a tendency to produce weak, puny plants. Fifty pounds of good clean seed sown with 60lbs. of super. to the acre is quite sufficient. Late varieties, such as Dart's Imperial, Marshall's No. 3, or Unity, stool well, and are suitable for this district. In my experience late varieties do better than early in late districts, either for wheat or hay. I would advise sowing early wheat a little thicker; about 1bush. per acre. Leave the early varieties till last when seeding, as they usually run up to ear quickly, and are not improved by being fed off. Sufficient early wheat to enable one to get on with the harvesting only should be sown in this district." Mr. Burgess agreed that shallow drilling was best. Mr. W. Ninnes concurred in respect to "white" land, but in other soils would drill to a depth of 4in. He thought it preferable to sow 70lbs. of seed to the acre. Mr. Breuer would sow 50lbs. of wheat for grain, but 80lbs. for hay.

WEPOWIE (Average annual rainfall, 13in. to 14in.).

May 12th.—Present: nine members and five visitors.

Feeding Stock.—Mr. C. W. Knauerhase read a short paper. One bag wheaten chaff, one bag hay chaff, 8lbs. pollard mixed and damped with three parts water and one part molasses, constituted feed suitable for mornings, mid-day, or the first feed at night. After the first feed at night, equal parts of wheaten hay and chaff should be used; and for a change, hay, which could be mixed with sheaved straw, when the horses were not working. The morning feed should be given at least one and a half hours before the horses began work, and the same time was necessary for the mid-day meal. Cows fed on straw chaff and bran gave good results. Pigs should receive boiled wheat and pollard three times per day.

WILMINGTON (Average annual rainfall, 18·26in.).

May 6th.—Present: 12 members.

Seed Wheat.—The Hon. Secretary (Mr. B. Jericho) read a paper. He said—"If experimental farms count for anything, and if the work done on those places should be a guide to outsiders, there can be one class of wheat for seed only, namely, the best and cleanest sample. Many practical farmers will argue otherwise, and maintain that in certain seasons good average yields have been got from decidedly shrivelled and inferior seed. However, the germinating power is not as strong in an inferior grain as in the plump, healthy, and well-filled out one. In the selection of seed for experimenting purposes as to rust and drought resistant wheats the late William Farrer has done an immense amount of good for Australia. He maintained that the better the seed the better the roots—the more parental nourishment the roots get apart from soil stimulants the better able are they to resist dry periods, rust, &c. Careful selection of seed has been one of the most powerful influences in developing wheat, and at the present time the most experienced affirm that the experimenting stage is only in its infancy. On one of the many trial farms in America—by careful selection of seed only—in four years six heads were doubled in length, the number of grains in each head nearly trebled, and the stooling out power of the plants increased more than five fold. Ninety-six tests with seed of numerous descriptions and quality gave an average of 15 per cent. in favor of selecting the best seed. The total output of wheat-producing countries would be increased by many millions of bushels were a sample of wheat sown that produced only one grain more in each head.

By the aid of graders and the use twice or three times of the ordinary winnower, seed wheat can be secured without resorting to the slow work of land selection." Members differed in opinion as to the germinating power of plump and shrivelled wheat. The plump grain supported the plant better from the start, but it was more subject to malting.

WIRRABARA (Average annual rainfall, 18·91in.).

May 9th.—Present: 16 members and two visitors.

Fertilisers.—A short paper on this subject was contributed by Mr. E. H. Piper. He considered 80lbs. per acre a sufficient dressing of super. for fallow land. For a hay crop, on stubble land, 100lbs. per acre should be applied. A light dressing of decayed stable manure, applied annually, was of distinct advantage to the garden. It was unwise to apply stable manure to land to be sown for hay, as in dry seasons this might result in a tendency to blight. Mr. P. J. Curnow favored bone super. for fruit trees, and members generally agreed that it would be an advantage to apply heavier dressings of super. to wheat crops.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

APPILA-YARROWIE (Average annual rainfall, 15·08in.).

May 8th.—Present: eight members.

Experimental Plots.—Mr. Wurst and Mr. J. W. Lines intimated that they intended to conduct tests with different quantities of seed and super. The following committee was appointed to inspect the plots:—Messrs. J. Daly, J. W. Lines, and W. Francis.

Feeding Sheep on Chaff.—Mr. Daly mentioned that several farmers in the district were endeavoring to ascertain, by enclosing five or six sheep in a small yard, whether these animals could be fattened on chaff. The condition put on in three or four weeks by station-bred sheep was remarkable.

BEETALOO VALLEY (Average annual rainfall, 18in. to 19in.).

May 4th.—Present: eight members and two visitors.

Seeding.—Mr. Murphy read a paper dealing with this subject. It was important, he said, to have the soil in good condition to receive the grain. According to its nature it should be worked to a depth of from 4in. to 8in.; rich, heavy soils would stand deeper working than those of a light, shallow nature. The seed bed should be worked fine and loose, but not deep. Fallowing cleaned the land of weeds, and conserved moisture, and for these reasons was preferable to "green" land. Seeding should be commenced about the second or third week in April, and finished in June. Early sowing was best for hay, as the wheat grew taller and thicker than when late sown. For grain, late varieties should be sown early, and early varieties late. When an early variety was sown early, it was liable to damage by frosts and storms during a critical period of its growth. With the late wheat sown late the weeds were likely to make as much growth as the wheat, and the grain ripened at a period when hot winds were prevalent, probably resulting in pinched grain. In this locality, at present, the soil was in a damp condition, on account of the frequent light showers. However, there was insufficient moisture in it to bring the plant through the ground; hence, unless rain fell within a fortnight or three weeks, grain sown now would probably malt. If the farmer waited for rain, however, and another week elapsed during which the weeds were given an opportunity of growing, seeding would be delayed, so that difficulty would be experienced with the weeds. The farmer, whose seeding operations involved two months' work, should not delay starting after May 1st, and he was well advised to spend a few pounds in hurrying the seed in whilst conditions were favorable. Unpickled seed should be sown in dry soil. Pickled grain was more likely to malt. Grain free from smut sown in dry soil stood less chance of producing a smutty crop than that sown in damp ground. Smut-infected grain should on no account be sown. When damp soil was being sown the wheat should be immersed for two or three minutes in a cask containing a solution of 1lb. bluestone to 10galls. of water. White oats and barley should be pickled in the same manner. Cereals should not be sown to a greater depth than 1in. Wheat on land previously under oats was not liable to be affected with takeall. Cape barley was recommended for feeding off as greenfeed, but rye was preferable when the crop was to be cut. The latter was a faster grower, and cutting did not check its growth, but it did not stand grazing. Crossdrilling, especially for hay or greenfeed, would well repay the extra labor. If this were practised, from

90lbs. to 100lbs. of grain and from 70lbs. to 120lbs. of super. could be used. If drilling one way, from 70lbs. to 80lbs. of seed was sufficient. For hay he preferred Algerian oats cross-drilled with a fairly late variety of wheat, such as Majestic, Marshall's No. 3, Silver King, and Yandilla King. Oats and barley should be sown at the rate of 2bush. per acre if drilled one way, and from 2¼bush. to 3bush. if cross-drilled. Oats were not suitable for greenfeed, as they were inclined to be bitter, were rather slow growing, and did not stand feeding off. Members generally agreed with the ideas of the writer of the paper. Mr. A. Bartrum would pickle all seed, and favored heavier dressings of super. Mr. Ryan would sow 2bush. of seed if cross-drilling. Mr. F. Bartrum favored shallow ploughing, and sowing carefully graded seed.

CANOWIE BELT (Average annual rainfall, 20·04in.).

May 7th.—Present: 12 members and one visitor.

Roseworthy Harvest Report.—A paper was read by Mr. E. W. Noll. He contrasted the weather conditions prevailing at Roseworthy with those of this district, and discussed the methods of cultivation and seeding adopted there, in comparison with the local practice. One hundred pounds of super. and 75lbs. of seed per acre he thought sufficient for hay crops. Mr. Dale thought that, taking into consideration the nature of the season, it was advisable to bury the seed to a considerable depth. He advised the use of the 15 by 7in. drill. The Hon. Secretary (Mr. H. A. Wedding) favored a 15 hoe drill with a harrows attached. Sixty pounds of manure per acre was sufficient for this district.

GEORGETOWN (Average annual rainfall, 18·32in.).

May 16th.—Present: 11 members.

Poultry on the Farm.—Mr. J. C. Myatt read a paper on this subject. The prevailing practice among farmers, he said, was to purchase a few fowls and give these the run of the holding. For the first year or two, although they received practically no attention, they did well, on account of the quantity of feed, grit, &c., they could pick up. However, the flock inbred, tick and foxes became troublesome, and as a result the egg production fell off. He recommended the erection of a galvanized iron house, 18ft. by 7ft. and 6ft. high at the back and 7ft. in the front, which should be open toward the east. Perches should be movable, and scalded occasionally. A netted yard, with a fox-proof gate, should surround the house, and the birds should be let out each morning at sunrise. Young, healthy birds only should be kept, the males being changed every second year. If the fowls had the run of the stables less trouble would be experienced with the bot fly. Table fowls, also, should be reared. The chicks from Wyandottes, Orpingtons, Plymouth Rocks, or Langshan hens, and modern game or Indian game cockerels at 6 months old would net 3s. each. An incubator should be used for hatching. Several members thought farmers could more profitably give their attention to other stock on the farm.

LAURA (Average annual rainfall, 18·22in.)

May 8th.

Pigs—Mr. P. T. Bowker read the following paper :—"Pigs at times certainly are very profitable animals, kept as an adjunct to farming, dairying, or gardening. At times, however, they are subject to a rapid decline in value, and profits disappear. This helps to keep breeders on the alert, for whether to sell or hold the stock is often a knotty problem. It is not our intention to go into the matter of breeds and their history, but sufficient to say that the Berkshire holds the first place in Australia, with the Yorkshire as second. Other tested and good breeds are the Essex and Tamworth, and that famous American breed, the Poland-China, which all do well in our climate, and are all so well known as to need no description here. In planning to add pigs to the farm the question of locality comes first. A piece of land with a northern or eastern slope is this thing for this district, arranged with a view to good draining, and so that the drainings can run on to a lucerne or fodder paddock. Sties facing the north, to admit plenty of sunlight in winter, are best. A handy sty can be made, say 12ft. long by 8ft. wide, with four sheets of 8ft. iron for a roof, with cement concrete floor, costing about £3. This will accommodate six to eight fattening pigs or a sow with litter. It should not be so low as to be too hot in summer. Several small paddocks should be provided, planted with lucerne or any suitable pasture, to give the pigs a change from the sties and as a run for the breeding sows. *The Sow.*—A good deal of care needs to be exercised in choosing a breeding sow; a cross-bred makes a better mother than the pure bred. The Berkshire-Yorkshire cross is a very good one, or Berkshires crossed with Essex, Tamworth, or Poland-China make good sows, and as a rule are hardy and prolific. A long, deep, vigorous animal, with a good appetite, 12 or 14 evenly-placed teats, of a kindly disposition, makes a good type of breeding sow. *The Boar.*—Should be pure bred, of good length and depth, wide, compact, and firmly set on short straight legs of fine bone; should be selected from a large and uniform litter, and should be active and robust. He should have a sty for himself, and should be well fed on good food, but not allowed to become too fat and lazy. Sows after being served do very well in a lucerne or grass paddock and will get most of their own living. A little skim milk, pollard, and grain should be given to keep them in good condition, but do not allow them to become too fat. A week or two before farrowing they should be put in their sty, made comfortable, and fed on moderate food. Successful rearing of young pigs is a difficult task for the farmer, and if he pulls the litter through the first 24 hours he has gone a long way to successful rearing. Half the losses occur soon after birth, unless vigilance is exercised, by the sows lying on the little ones. A sow should not be too fat, and she should not have too much straw or bedding in the sty at farrowing time. A rail around the inside of her stye about 8in. from the walls and 8in. from the floor is a great help in preventing the little ones being crushed against the walls. A week before farrowing some Epsom salts in the food is good, also a little bran and oilcake daily before and after farrowing, often saves a lot of trouble. Do not feed the sow too much after farrowing, but gradually increase the amount as the little pigs grow, give sloppy food and no grain unless well soaked. From 3galls. to 4galls. of skim milk thickened with pollard, with a little oilcake and a pinch of salt, varied with kitchen slops and plenty of green feed such as lucerne, maize, wheat, oats, and grasses make a good ration. At four weeks the suckers began to drink for themselves and should have a trough of their own, and be fed on skim milk, with just a little pollard, increasing the amount as they grow. Soaked wheat or barley should be sprinkled about for them to pick up, also plenty of green feed. With a start like this weaning time at from six to eight weeks old will be no hardship. *Feeding for Bacon.*—After weaning the pigs should be fed right along. With the object of turning them into prime porkers or baconers as soon as possible they should be kept in a clean warm sty and fed with a ration made up of skim milk, also any roots available, pollard, crushed wheat and barley, with a little dry wheat and peas and barley occasionally, and plenty of green feed. If thrifty young pigs, they should at, say four months old, dress at from 100lbs, to 120lbs. and at the present price of pigs, be worth from £2 10s. to £3 each, which should leave a handsome profit over feeding. Although contrary to a lot of practice, cleanliness is important. The sties need cleaning frequently. A good hoseing out, if there is water pressure enough, cannot be beaten. Clean wheaten straw makes good bedding, and is very necessary in the cold weather A shovel of charcoal put in the pen now and again is appreciated by the pig. Change of food is welcome, and a varied ration results in the best growth." He had kept an account of the cost of feeding two Yorkshire-Berkshire cross pigs, which were born on October 25th, weaned on December 26th, and killed on April 26th. During that period the pigs consumed 9½bush. of pollard, costing 9s. 6d.; 6bush. crushed oats, 12s.; 4bush. wheat, 14s.; ½bush. bran, 6d.; and skim milk valued at 2s. The dressed weight of the pigs totalled 250lbs., which at 6d. per pound returned £6 5s. against an expenditure of £1 18s., thus showing a profit of £4 7s. He was convinced that pig raising was a profitable venture, and was worthy of more attention. A most interesting and instructive discussion followed. Mr. R. Cleggett, sen., said the Berkshire sow was the best mother. He advised purity of breed on both sides in crossing. While having tried various other crosses he was convinced that the Essex-Berkshire cross was the best. He had found that all long-nosed pigs were hard feeders. A separate compartment for the feeding of young pigs was advisable. Mr. Blesing said pollard was the best food for sows prior to farrowing. Pollard would increase the milk supply while bran would make fat. His experience had been that a cross-bred mother had proved the best, and he had not had very much success with pure breds. The Essex sow proved a bad mother. Essex were comparatively small eaters, in fact one could fatten three Essex with as much food as it would take to fatten two Berkshires. At the present price ruling for pigs almost any breed would pay. He had found the Poland-China pigs inveterate eaters, and the same applied to the long-nosed variety of Yorkshires. Mr. W. Stevens had met with considerable success by raising pigs from a Berkshire hog and Essex sows. All the speakers expressed their belief in feeding with damp crushed corn. The value of skim and separated milk and its effects upon pigs was also discussed, the general opinion being that while separator milk was good fattening feed discretion should be exercised in the quantity given, especially if given direct from the separator.

LEIGHTON (Average annual rainfall, 16in. to 17in.).

April 3rd.—Present: 13 members and three visitors.

Rib Roller.—Mr. R. McWaters contributed a paper, in which he strongly recommended the use of the rib roller in this district. For the last three seasons, owing to the scanty rainfall, he had gone over with the plain roller a considerable portion of the land intended for sowing. Some portions of the land became so tight after the rain that the wheat did not come up, and in other portions hard clods had been forced into the ground. The rib roller left the ground in a very uniform condition. He was convinced that if he had rolled all the land under crop last year he would have had a much heavier yield. The implement was very useful for loosening the soil round the roots of tussocks, which were usually very troublesome. By rolling the land and then harrowing, most of the tussocks were gathered with little trouble.

LEIGHTON (Average annual rainfall, 16in. to 17in.).

May 11th.—Present: 16 members and one visitor.

Pickling Wheat.—It was thought wise to pickle wheat only so far ahead of sowing as would ensure free running through the drill. The strength of solution recommended was 1 per cent. (1lb. bluestone to 10galls. water).

The Agricultural Bureau.—Mr. R. Humphrys read a paper dealing with the advantages of the Agricultural Bureau system, mentioning it as an excellent educational medium. He advised steps to increase the membership of the Branch, and urged the necessity for loyal support on behalf of members.

MOUNT BRYAN (Average annual rainfall, 15·81in.).

May 4th.—Present: eight members.

Seeding.—Mr. J. Trallagan read a paper. It was necessary, he said, to procure the wheat most suitable for the ground in which it was to be sown. For limestone soil Dart's Imperial, Marshall's No. 3, Yandilla King, and Purple or Red straw were recommended for grain or hay. Early Para and Majestic, whilst yielding lighter grain returns, made hay of superior quality. For heavier and richer soils he recommended Federation, Marshall's No. 3, Purple straw, and Yandilla King. The seed should be pickled in a solution of 2½lbs. bluestone, 3ozs. lime, and 5galls. water, which would provide sufficient to treat 20bush. If the seed were being sown on fallow prior to rain, the roller should precede the drill and the land should in no case be left solid or lumpy. On light limestone soil, or stubble, the scarifier or cultivator should be used. For seeding on clean land he would use not less than 60lbs. of wheat per acre. The drilling should run north and south, thus protecting the crop against the high westerly winds. After the wheat was well above ground it was an advantage to go over it with light harrows.

NORTH BUNDALEER.

May 6th.—Present: 11 members and three visitors.

Lime.—Mr. Smart said some of the lighter soil in this district was deficient in lime, which, if applied, would encourage the growth of clover and natural grasses, and so introduce nitrogen into the soil, of which it was deficient. Mr. Jas. Pollard did not think nitrogen could be got into the soil through grasses; a crop such as peas was much better, as then a sufficient number of sheep per acre could be kept on the land, and sheep manure was rich in nitrogen. Lime would flocculate the soil and keep it mellow. In many places in this district there was an abundance of carbonate of lime which could be used. Distributors could be procured to do the work of spreading.

PORT BROUGHTON (Average annual rainfall, 14·44in.).

May 15th.—Present: seven members and one visitor.

Co-operative State-Assisted Experimental Farms.—Under this title, Mr. Whittaker contributed a paper, in which he suggested that 25 farmers should be selected in different parts of the State to conduct experiments on their own farms. Each farmer should receive £200 per annum, together with seed and super., the farmer supplying labor, horses, implements, &c. The total cost of this scheme, including supervision, would not be above £7,500 per year, which would be amply repaid in the course of a few years to the State. The proposal applied more particularly to new land. Mr. Hill thought the idea well worth consideration. Mr. Dolling opposed the scheme, and Mr. A. J. Fletcher thought the scheme formulated at the Congress of Agricultural Bureaus at the last September Congress would be more effective. Mr. Vanstone, the Chairman (Mr. T. E. Pattingale), and the Hon. Secretary (Mr. J. H. Fletcher) thought the scheme would be of no value in the settled districts, although it might be of use in the new country.

PORT PIRIE (Average annual rainfall, 13·21in.).

May 9th.—Present: nine members.

Conservation of Fodder.—Mr. W. Munday read a paper on this subject. As much of the agricultural and pastoral land in South Australia was in the comparatively dry zone, it was necessary for the farmer who would guard against the loss of stock in the dry years to go in systematically for the conservation of fodder. Most of the losses which had been experienced might have been avoided had such methods been adopted. The very luxuriant growth in good years was a big temptation to landholders to overstock, and this was the explanation of their being left with bare paddocks and a large number of stock on hand when the dry years occurred. He suggested that farmers should plant the stubbles with oats or barley, or with a mixture of both, adding a little rape. Later, sorghum could be sown if the conditions were favorable. He believed in planting summer crops earlier in the spring than was often the practice. In the good seasons quantities of hay should be stored, well thatched and protected from mice. By the adoption of such practices as he had outlined he had been able to tide over the worst drought experienced, and had often been able to supply dry fodder in bad years to his neighbors. If farmers in similar country would order their practice somewhat in this manner, the results would bring them great satisfaction, and their incomes would be materially augmented. Mr. Welch thought more could and should be done in years of plenty in the way of storing sufficient fodder to tide over dry seasons. Mr. Eagle believed in having at least two years' supply of hay on hand. Mr. Greig deprecated the practice of overstocking.

REDHILL (average annual rainfall, 16·79in.).

May 22nd.—Present: 12 members and four visitors.

Poultry on the Farm.—A paper dealing with this subject was read, in which attention was drawn to the negligence on the part of many farmers to provide suitable accommodation for their fowls. Iron houses were recommended, and the paper continued—"These can have some straw thrown in and burned, which is the easiest way to kill vermin. Failing all iron, I suggest wood and iron closed in on three sides, with plenty of ventilation but no draught. Perches should be hung from the roof by wire with kerosine rags wrapped round. Wet the rag about once a week and no vermin will cross it. Care must be taken to see that no perches touch the wall. Erect lower perches from the ground so that the fowls can get up to the top without having to fly. The chickens will roost earlier if they can get up in this way. All perches can be of iron in a warm district like this. Old piping is very suitable. Clean the house occasionally to keep down the vermin. Build it in a sheltered spot, if possible, to protect the birds from cold, especially east, wind. A few trees or shrubs make a good breakwind. Give them plenty of room. Provide a fox-proof yard, putting the netting in ground about 6in. The birds should be fed regularly, morning and night. About one hour before sundown is about the best time for the evening meal, which should be of corn. The best results are got from using good mixed corn, not damaged, weevily, musty stuff, which is bound to tell on the birds. In the winter a warm meal of boiled wheat, barley, oats, mixed with a little mustard is relished. In the summer months a bran mash two or three times a week keeps the fowls in good health when green-feed is scarce. The farmer's fowls generally run at large and do not require so much attention, as they will find grit, lime, &c., for themselves. The drinking vessels should be kept clean and in a cool place. It is advisable to clean the vessels once a week with a strong solution of Condy's crystals, and a little added to the drinking water keeps it pure. This will be found the best preventive for all diseases of fowls. Nests should be made in a sheltered place, and the litter in them changed once in a while. The chicks should be hatched as early as possible in April, May, and June, to get winter layers, as eggs are always a good price at that time. I would advise an incubator if the farmer has the time to look after it; but the trouble is rearing the chicks after they are hatched with the machine. They need care for the first few days. Keep them in a coop with plenty of dry litter. They do not require any food for at least 24 hours after they are hatched. Stale bread crumbs with some crushed grain is the best for the first day or two. Have plenty of grit available. Keep water in shallow vessels or they will get in it and get cramped or drowned. Feed several times a day till they are able to look after themselves. I would not recommend any man to have one strain only, as they frequently become delicate owing to inbreeding. All young cockerels should be penned, fattened, and sold as soon as they are big enough; only keep those required for stud purposes. The hens will not lay if they are worried by a lot of young cockerels. Hens should be penned up as soon as they become broody, and not left on the nest a week and then shut up. I recommend getting a fresh rooster every season. It is better to pay a good price to a well-known breeder for a rooster than keep one bred on the farm. There should always be pure blood on the roosters' side. Whatever breed one goes in for it is best to keep on introducing fresh blood, and in a year or two a good hardy flock will be secured." Mr. F. A. Wheaton agreed that iron roosts were preferable. Mr. W. Pengilly thought fowls should not roam at large, owing to the damage they did to machinery, &c. Some members favored purebred fowls, whilst others thought the crossed fowls were more healthy.

SPALDING (Average annual rainfall, 20·25in.)

May 15th.—Present: 11 members and one visitor.

Pickling Wheat.—Mr. J. H. Pluckrose dealt with this subject in a paper. He thought it wise to pickle in a weak solution of bluestone (*i.e.*, 1lb. to 10galls. of water) all the wheat intended for seed. Grain from a smutty crop should not be sown, even if pickled. A strong solution of pickle would impair the germination of the seed. The bluestone could be dissolved by being enclosed in a hessian bag, and suspended half in the water. The grain, in butts, should be immersed in the pickle for three minutes, and vigorously shaken, so that every grain became wet. The solution should drain back into the cask after the wheat was taken out; the grain should be sown the following day. The paper continued: "Mr. Ross, Chief Inspector of Agriculture in New South Wales, says that 'the action of bluestone while pickling has the power to impair the vitality of the grain, and even to kill the germ.' To guard against this the following measures should be observed:—If there is no prospect of immediate germination, that is, if a dry sowing is made, the bluestone wheat should, after having been allowed to drain for 10 or 15 minutes, be dipped into a solution of limewater, which is made by stirring ½lb. of freshly-burnt lime into 10galls. of water. This mixture is allowed to settle, then the clear lime water is decanted, and into this the bluestone-treated seed is dipped for from two to three minutes. The lime neutralises the effect of the bluestone, and so preserves the full vitality of the wheat germ. If, on the other hand, a 'wet' sowing is made and an immediate germination of seed is likely to follow there is little need to dip the bluestoned wheat into lime water. Should it be found impossible to obtain freshly-burnt lime, it is recommended that ½lb. of slaked lime be mixed with 10galls. water, thus making milk of lime, into which the butts of the bluestoned wheat should be dipped for a period of two or three minutes. Milk of lime differs from lime water in so far that in the former the particles of lime are not dissolved, but held in suspension, whereas in the case of clear lime water the particles are dissolved. When using lime water care should be taken to make a fresh mixture now and again, as the constant dipping of the bluestone saturated butts of wheat into the lime water will change this eventually from an alkaline into an acid solution, in which state it would be useless, For that reason bluestone and lime should never be mixed together in a solution used for pickling wheat. The chief advantage gained from using lime water in addition to bluestone are—Firstly, that a farmer following this practice is in a position to pickle all his seed wheat in March ready for sowing in April and May, without running any risk of the germination being affected; secondly, that a better germination will be obtained if the sown seed should lie in the ground some time before rain falls and germination takes place. Little extra trouble is involved in the bluestone-lime treatment, and farmers are strongly advised to adopt this method in preference to the bluestone treatment only. A method I would not recommend is placing a full bag of wheat in the pickle, as I have opened bags thus treated and found that some of the grains have not come in contact with the solution at all." Members preferred dipping the grain to floor pickling, but in lesser quantities than a bag of wheat at a time. A perforated copper cylinder was the best to hold the wheat during pickling. Mr. Jones thought bluestone more satisfactory than formalin. He pickled white oats, but not the brown varieties. Mr. Hacklin recommended 1lb. of bluestone to 10galls. of water, the grain being treated some time before it was sown.

WHYTE-YARCOWIE (Average annual rainfall, 13·91in.).

April 18th.—Present: 12 members.

Farm Management.—The following paper was read by Mr. E. F. Pearce:—"*Fallowing.*—Fallowing is the first job to which the farmer turns his attention. This should be commenced as early as possible after the first winter rains, when the ground is in a nice soft condition. The average depth to which most farmers plough their land is from 3in. to 4in., and they get into the habit of doing this year after year. This is foolish, as the land just below the depth the plough turns up gradually becomes beaten into a solid crust, into which the roots of plants find it hard to force their way, and in consequence the plants suffer. It will be found a much better plan to vary the depth of the ploughing year after year, thus lessening the tendency of the ground to set down. If possible, get the fallowing done by the end of August, as land fallowed later does not get the benefit of the heavy winter rains, which help to break down the rough surface of the soil, and also cause vegetable matter to decay more rapidly and form humus in the soil. The main objects in working the land are to conserve moisture and to destroy weeds; therefore the system of working that will retain most moisture in the land and cause weeds to grow is the system which should be carried out. Harrowing down the fallow is a great factor in the conservation of moisture. The harrows should be got to work as soon as the fallowing is finished, or better still, an extra team should be put on to do the harrowing as the ground is ploughed. After the ground has been worked down well, and the weeds have started to grow, the cultivator should be brought into requisition. Care should be taken in the selection of this implement, as it is of great importance that it should destroy as many weeds as possible, and yet leave the surface fine and level. The skim plough seems to be the best implement for this work, both as a weed killer and also a land leveller. If good rains fall in the summer or early autumn it will be found profitable to harrow the fallow again, because a certain amount of moisture will be kept down, and also, the seeds lying on the surface will be buried, when they can germinate and be killed during seeding time. It is a good practice to work up any dirty land that it is intended to fallow in the slack time after harvest and before seeding time. This will be found the best way in which to get weeds to grow. Seeding operations should not be delayed too long, neither should they when once started be allowed to drag out for any longer than can be helped, otherwise one will run the fallowing too late, and lose more by that than is gained by late sowing. When drilling be very careful not to bury the seed too deeply, especially in ground which is inclined to set or run together. It will pay better to risk leaving a little grain on the surface. *Stock.*—One of the many duties of the farm manager is to see that his stock are well looked after, for a farm is not half managed when the stock are allowed to go just anyhow. The horse is entitled to the best of care, not only because of its value, but because of the greater usefulness of a well cared for animal. A good stable and yard are absolutely necessary if one is going to keep horses up to the mark. No horse will do well if it has to feed out in the open in the cold weather, or if it is kept in a draughty, badly ventilated stable. When a horse is working hard it should be fed three times a day. The morning feed should consist of from 8lbs. to 10lbs. of good hay chaff. If there is very little grain in the chaff it will pay to add a small amount. The mid-day meal should consist of from 6lbs. to 8lbs. of good hay chaff, to which has been added a fair allowance of grain, preferably crushed oats or bran. If good hay, not too rank, is available, feed long hay at night, and sufficient should be given just so that the horse can clean it up before morning. If chaff is given at night the horses are inclined to eat it too fast. The horse should be groomed once a day when working, to remove the dirt and dried sweat from its body. The stables should be kept clean and dry. *Sheep.*—Next to wheat-growing come sheep as the most profitable activity for the farmer. Upon his management depends largely the profit he will make out of them. The best all-round sheep is the Merino. Whatever deficiency there may be in the carcass is fully compensated for in the value of the wool. For lamb-raising, the ewes' lambing season should be over before the cold weather sets in. At the price sheep are now and the prospect of good prices for some time to come, it is wise to seriously consider the subject of hand-feeding sheep. A paddock of fairly good feed should be kept back, on which to put the ewes and lambs during the lambing season and for a few weeks afterwards. The paddock should have some warm sheltered places, wherein the ewes can camp in the cold weather; but it should not be too large, or the ewes will lose their lambs when they are travelling across it. Choose a fine warm day during a period in which the weather is likely to hold fine for a week or so in which to tail the lambs. If it comes wet and cold just after the operation the lambs are bound to suffer much more than they otherwise would. The knife will be found to give better results than the searing iron, besides being a much simpler and quicker method. The knife should be wiped on a rag which has been soaked in some antiseptic. This precaution, if resorted to after every three or four lambs have been tailed, will minimise the risk of blood-poisoning. Sow a few acres to some fodder plant, on which to top up the lambs for the market in the spring. Do not keep any old broken-mouthed sheep on the place. Fatten and sell them before their teeth get too bad and make it impossible for them to get in good condition. *Farm Buildings.*—One of the main aspirations of the present day farmer is to have a homestead of which he can be proud. One thing which needs very careful consideration is the choice of a site on which to erect the farm buildings. Many farmers seem to have got hold of the idea that any useless piece of ground is good enough on which to make their homestead. No greater mistake can be made than to place the homestead in a bad position or on a poor piece of land. The ideal spot is on a piece of good rising ground or on the slope of a rich hillside. Of course, a person must consider his chances of getting a good well of water, without which no homestead is complete. Nothing beautifies a place more, or provides such shelter for stock than a good plantation of trees; therefore pay attention to tree-planting. One mistake noticeable in many homesteads is that the rubbish and manure from around the stables and sheds blows directly in and around the doors. This rubbish spoils the appearance of a place very greatly, besides causing much trouble and inconvenience to those who have charge of the home. All this trouble need never be if the one responsible for the laying out of the homestead would exercise a little judgment and forethought. The barn and the machine sheds also should be placed so that rubbish cannot blow in and about them. A position between the house and the stables will suit them if no better can be found. Do not bunch the buildings together more than can be helped, but keep the stables, pigsties, and so forth well back from the house, say, not closer than three or four chains. In all departments of farm management the farmer must experiment and take note of what he hears, sees, and does, and prove for himself what will best suit his peculiar conditions. In this way, and in this way only, can he hope to be successful." This paper was well received, and members generally agreed with the writer. There was some difference of opinion as to deep and shallow drilling. Mr. Hunt favored deep, and gave an instance from last season, when a deeply-drilled piece germinated better and maintained the advantage throughout the season, and gave the best results at harvest. Some other members thought that much depended on the nature of the soil and the season. Last season was exceptional, owing to heavy rains in the early part of March, followed by an exceptionally dry winter. Members were also at variance with the writer in reference to early lambing. The Chairman (Mr. G. F. Jenkins) and Hon. Secretary (Mr. E. J. Pearce) both thought the middle of April to the middle of May safer in this district, although last season, owing to early autumn rains, the early lambs came out well. Members were agreed that it was well in laying out a new homestead to study situation, soil, and water supply, and even if unable to straight away erect up-to-date improvements, to have an up-to-date plan in mind that could be worked out as opportunity and means allowed.

WHYTE-YARCOWIE (Average annual rainfall, 13·91in.).

May 11th.—Present: 11 members and one visitor.

THE FARM HOMESTEAD.—The Chairman (Mr. G. F. Jenkins) read a paper, as follows:—"Whatever the character of the first house may be, even if it is only a tin hut, care should be taken in the selection of the site, as, naturally, the farm buildings will grow around the first home. One cannot lay down any hard and fast rule for the building of the homestead, as much depends on circumstances, water supply, &c. If it is possible, however, the house should be on rising ground, in order that there may be a natural drainage. For the home itself, if one makes a start with a two-roomed house it is just as well to look a little ahead and build them so that they may be added to without spoiling the appearance of the house from an architectural standpoint. Indeed, no matter what size the house may be, it should not be only a roof over one's head, but a home in reality. I fail to see why so many farmers should be content with any sort of a home in the country, but if they should retire to town to live later on the best house in the street is required. Personally, I should like to see the farmhouses of this country reflect the prosperity of their owners; and if farmers would endeavor to make their homesteads as attractive as possible an added charm would be given to the farm and to country life generally. Having selected the site for the house, an equal thought should be given to laying out the farm buildings. These should be placed well away from the house, and always at the back. Nothing spoils the appearance of a well-built farmhouse as much as a lot of unsightly sheds built about the front and sides of the home. It is well to keep the farm buildings together, and as compact as possible. The stables should be built of stone, if circumstances will permit, and should be constructed so that the horses may be fed with as little labor as possible. If the stable is built to allow for a run, say 5ft. wide, at the back of the manger, leading into the chaff house at one end there will be very little inconvenience or danger of being kicked when feeding the horses. The hay yard should be immediately behind the stable and enclosed with a stone wall at least 4ft. 6in. high—the most efficient firebreak possible. If the barn is constructed with an entrance at both front and back, and preferably with a gable roof, a leanto on either side will provide good implement sheds blacksmith's shop, &c. A good plan for the implement shed is to have sliding doors working past one another in the front of the shed, so that implements can be put in or out with the least possible inconvenience. As time and circumstances permit trees should be planted to beautify the home and provide shelter from the high winds that prevail on these northern plains, as well as being a useful shelter for stock. What could be more attractive than an avenue of beautiful shady trees leading from the entrance gate to the homestead, while plantations planted between the house and the stables would serve to hide these buildings from sight of the house and also prevent dust from blowing from about the yards to the homestead. Care should be taken, however, not to plant trees too close to the house or garden, as they are great robbers of moisture, and it is almost impossible to get flowers or vegetables to thrive within a chain of a row of gum trees. I am sure that a little trouble and foresight used in laying out and beautifying the home would be more than repaid by the additional comfort enjoyed by the owner, while such would materially add to the attractiveness of farm life to the younger generation. The country homes of Australia should rival in attractiveness the city and suburban residences." In the discussion, Mr. Wittwer said the homestead should, if possible, be centrally situated, for convenience of working the farm. He had seen straw roofs on stables with wire netting under and over; this prevented the wind raising the straw and the nesting and scratching of sparrows and domestic poultry, which destroyed the roof. Mr. Hunt preferred straw to iron as a material for the stable roof. It was cooler in summer and warmer in winter, and if properly put on would last a long time. Mr. McGregor preferred iron. All things considered, he had found it a difficult matter to maintain a good straw roof. Many farmers had purchased their farms already improved, and could not afford to discard the structures already in existence, although they were unsatisfactory, and in some instances an eye-sore. Mr. G. W. Mudge said even when the pioneer farmer had the chance to select a site and lay out the improvements he seemed to select the spot on which he happened to camp the first night, or in some equally haphazard way make his selection. He agreed with Mr. Wittwer that it was advisable to have the homestead centrally situated, not only for convenience of working, but to avoid trouble with neighbors through pigs, turkeys, &c., trespassing on neighbors' property. The Hon. Secretary (Mr. E. J. Pearce) had seen costly residences erected on farms, which in a few years became actual encumbrances, when (consequent on the sons wishing to set up for themselves) the property needed to be subdivided. He was, however, in entire agreement with the writer when he said the farmer should set out to make a home in the best sense, not merely a shelter from the weather. In reply, the writer of the paper said he would not have a straw roof for a stable, much preferring iron. If proper provision were made for ventilation it would not be too hot in summer. It was permanent, and in appearance and every other way more desirable. He emphasised the statement made in the paper that he did not advocate large houses, but well designed, tasteful, and homelike structures, whether of two rooms or 10. If more well-to-do farmers built nice homesteads in the country instead of retiring to the city the country would reflect the prosperity which rightly belonged to it

---

YONGALA VALE (Average annual rainfall, 13in. to 14in.).

May 9th.—Present: 12 members.

Seed Wheat.—Mr. T. H. Battersby read a short paper. The farmer should sow nothing but the very best and cleanest wheat for seed, he said. It would be found payable for each farmer to sow two or three 5-acre plots of varieties specially for seed. When these had grown to about a foot in height, they could be handweeded, and when the grain was out in ear and just beginning to turn yellow strangers could be picked. Members considered the introduction of seed plots and hand-picking a step in the right direction. Some thought it better to pick a bushel of the best heads of each variety for seed.

BEAUFORT, May 7th.—An interesting and instructive report of the proceedings of the conference of Northern Yorke Peninsula Branches was delivered by the Branches' delegate, Mr. J. Sampson. Special reference was made to the excellent work being done by Mr. F. Coleman, of Saddleworth, in connection with the improvement of wheat.

MOUNT BRYAN EAST, May 14th.—A paper dealing with bacon-curing was read by the Chairman (Mr. J. Thomas), who also read an article by Professor Ewart, dealing with the effect of trees on rainfall. It was reported that good rains had been experienced, which had started the grass well, and the prospects of the season were bright.

PORT PIRIE, April 4th.—Mr. A. Bond read a paper on "How to Beautify the Home and make Farm Life Attractive." He advocated planting trees for shelter and ornamental purposes. Vegetables should be grown if sufficient water were available. A small garden well cared for was preferable to a larger area neglected. Mr. F. Johns thought it would be difficult to secure sufficient water for a garden on most farms in the district. Gums, and such like trees, should not be planted too near a garden. Mr. Welch and the Chairman (Mr. D. L. McEwin) also spoke.

REDHILL, April 24th.—Mr. M. Coffey delivered an address dealing with the aims and objects of the Agricultural Bureau.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BLYTH (Average annual rainfall, 16·46in.)

May 2nd.—Present: 27 members and five visitors.

Spring or Bridle Draught in Ploughs, Etc.—A short paper was read by Mr. E. Lehmann. He thought the spring draught better for a plough or cultivator, as with it the implement worked to a more uniform depth. When the spring was directly over the body it held the share more firmly, and was less likely to miss weeds. There was less jarring on the horses' shoulders, and as each body jumped independently there was less likelihood of the implement becoming hung up in stumps. He urged the wisdom of Branches conducting field trials.

CLARE (Average annual rainfall, 24·30in.).

April 10th.—Present: 21 members.

Well-Sinking.—Mr. F. G. Hicks read a paper. After selecting the site for the well, he said, a collar set, say 6ft. by 3ft. by 6in., should be placed in position, and side pieces 10ft. or 11ft. long would be required. One side should be dressed up with bush timber, as straight as possible. With an adze or broad axe sufficient 5ft. or 6ft. sets should be cut to log up the brace and provide a good tip for the soil. After fixing the windlass, sinking could be commenced. If the proposed well were circular, two stout nails should be driven into the collar set, 3ft. 6in. or 4ft. apart, according to the size of the well. The circle should be described from these after sinking a few feet. A plumb-bob should be hung on each nail, and lowered as sinking progressed. With a square well the plumb-bobs should be hung in each corner, but on no account should a well be sunk without those. The sides should be trimmed with a pick, and not a shovel. A square or oblong well was preferable, as, if bad ground were struck, it was easier to secure. If the ground were bad for standing, square sets of 6in. by 6in. timber should be put in at every 4ft., 6in. by 1½in. laths being placed behind. If the well were in drift sand, or running ground, every square set should be hung from the collar set with iron rods, cut to the required length, and key-hole punched either end; the keys to be about 1in. by 3in. by ⅜in. In running ground a bridge should be put at the back of each square set, by placing a lath 3in. wide at the back thereof, and wedging it back about 3in. In very bad ground the laths should be kept driven well down below the bottom of the well. When about 2ft. or 2ft. 6in. below the bottom of the lowest square set, a false set, wider than the permanent sets, should be put in. This was to catch the ends of the laths, so that there would be ample room for the next permanent set. When sinking in hard ground a round well should never be attempted, nor should the well be commenced too small, *i.e.*, less than 7ft. by 4ft. A larger well gave more room in which to work, and a better lift for blasts. When the ground was fairly bad for a certain distance, good deep hitches should be cut out, a bearing set put in, and the bad ground timbered up from this; 8in. by 2in. sawn timber would be found most suitable. In very hard ground it was advisable to cut hitches every 8ft. or 10ft. to carry bearers, in case a pump were eventually placed in the well. When it was intended to deepen a round well properly bricked up on an iron ring, if it were rather small in which to work, hitches should be cut under the ring with a short-handled, single-ended pick. Into these 4in. by 4in. stringy or jarrah bearers should be worked, a hole being bored in each end of the bearers close to the walls, and the bearers hung to the collar set with ¾in. iron rods, or stout wire rope. Provided the bricks had been properly packed in the first place, the weight on the bearers would not be very great. After sinking, if storage room were required, a drive 7ft. by 4ft. could be put in at the bottom. If the ground were bad for standing it could be timbered with bush timber. Mr. Elliott stated that if a person wished to sink a bricked-up well deeper it was quite safe for him to do so, providing the bricks were laid properly, and the usual precautions were taken. In reply to questions, Mr. Hicks stated that timber was preferable to bricks for building up a well. He considered that slabs were the cheapest timber to use for a shallow well, but would advise using square sets for a deep well. A bow-line knot was safest to use on a rope for lowering an amateur down a well. To find out whether there was foul air in a well he would drop into it a piece of lighted paper. If it went out he would not go down. To get the foul air out he advised using a wind-sail. He did not believe in the divining rod for finding water, which opinion was shared by Mr. Sincock. Mr. Pattullo and Mr. J. Maynard both believed in the divining rod, and gave instances where it was used successfully to locate underground springs.

Blasting Powder.—The following paper was read by Mr. E. L. Elliott at the March meeting:—"Blasting powder is used mostly for splitting timber, removing stumps, and quarrying stone for road metal and building purposes, and for excavating work. Of late years powder has also been extensively used in orchards and vineyards. It must be kept perfectly dry, and handled with great care. When using blasting powder it is necessary to have the bore-hole dry and clean. To explode the charge no dynamite is necessary; simply cut the fuse a little on the slant and insert it into the charge, add a little more powder, and then the tamping, which should consist of fine sand or dry clay. This should be tamped down very firmly. Sometimes a charge will miss fire. Do not approach the hole for 20 minutes, and if it is 5ft. or more deep give more time. To extract the charge, bore out the tamping in the same way as when boring the hole, using plenty of water, and when the tamping is nearly all out let the charge soak for a while, and then jump lightly and slowly. The charge will come up black, like ink. When this is completed, dry out the hole thoroughly, recharge, and fire. The powder tamping rod should be made of wood, but after the powder is tamped an iron rod with a copper end should be used. The copper end is to prevent sparking."

LYNDOCH (Average annual rainfall, 23·01in.).

May 7th.—Present: 19 members and one visitor.

Manuring Fruit Trees.—The Hon. Secretary reported having in 1913 applied to one acre of peach trees and one acre of apple trees, 2cwts. bonedust and 1cwt. sulphate potash per acre. These dressings were applied in May and ploughed down. In September ¾cwt. of sulphate ammonia per acre was added and harrowed in. The results so far were very disappointing. The peaches on the manured trees were inferior to those on the unmanured. The apples were no better than elsewhere in the orchard, where no manure was applied. The rainfall for the season, from May to April, was the lowest on record. Mr. F. Moore had for several seasons past used lime ash amongst his fruit trees, at the rate of 5cwts. per acre. The cost of same was 10s. 2d. per ton landed in his shed. The lime ash was spread with shovels from the back of a dray and thus a thin coating was evenly distributed over the orchard. He used 7 tons each season. Two men spread the ash in three days. The orchard was then ploughed. This was the only manure he had used for several years. The growth of the trees Mr. Moore considered equal to anything in the district. The fruiting powers had been liberally exerted for the last few years. He recommended all orchardists whose ground was either heavy or sour to try a liberal dressing of lime, as since he had been using lime ash he had succeeded in eradicating sorrel, which had for years almost complete control of the soil. Other members had little or no experience in use of artificial manures. Mr. H. Springbett preferred subsoiling with gelignite to applications of artificial manures.

MALLALA (Average annual rainfall, 16·88in.).

May 4th.—Present: 13 members.

Trees for Shade, Ornament, and Fruit.—Mr. J. Arnold read the following paper:—"I put ornamental trees first for two reasons, because here, on the plains, a fruit garden cannot be successfully grown without the shelter afforded by a belt of gums or other suitable trees, and because of the permanent and effective supply of firewood they yield. Trees for a windbreak shelter should be planted all around the fruit garden, if possible, but on the west and north sides they are necessary to success. I have seen gardens in my district without any shelter, and although the trees grew apparently as well as in sheltered gardens, there was very rarely the same quantity or quality of fruit on them, as the rough winds damaged the buds, flowers, and fruit. I would plant at least eight or nine rows, and, if possible, more on the north and west sides, and perhaps less on the other sides. It is rarely that the east winds affect the trees, but I have occasionally experienced an easterly blow that has laid my apples and pears on the ground. I would plant principally sugar gums for clayey soils and South Australian blue gums for rubbly soils for the outsides or plantations. The inner rows next the fruit trees should be carob, tamarisk, tagasaste, kurrajong, almonds, &c. Gums are great robbers, and should not be planted within, at least 40ft. of fruit trees, and so two or three rows should be planted between with the above-mentioned non-robbing varieties. I would plant gums about 12ft. apart—roughly 300 per acre. The shelter trees should be planted about one or two years before the fruit trees, to keep ahead and provide shelter as the fruits grow. Sugar gums are ready to cut down for firewood from about seven years onward, and make really good kitchen wood, which burns bright and free and does not smoulder and char as the matured gum does. It is very hard to chop, and should be sawn, if possible. I have cut the sugar gum at all heights, but think that nearly level with the ground has given the best results. The second growth will come much more quickly than the first, and will usually make two or three stems, so that the value of the plantation—from a firewood point of view—is yearly increasing. Sugar gums should be cut down, even if not wanted for firewood, to keep them free growing and bushy. A good plan is to cut, say the outside and centre rows right through when the trees are about seven years old, and the next year cut the rows inside those cut last year, and so on year after year, thus giving you a plantation in all stages of growth, and making a much better windbreak than the usual plantations of gaunt bare gums. Aleppo and Remarkable pines make a very pretty plantation and a splendid break, but are very slow of growth and do not grow after being cut down. Gums should be planted in August or late in July on good, deeply-worked fallow, and should be worked with a cultivator continuously, both winter and summer for about three years, or until the trees are big enough to kill all grass around them. If worked in the driest part of the summer the trees will at once put on extra growth. About four acres, or about 1,200 trees, will keep a farm homestead in firewood permanently; also a lot of handy rails, &c., can be cut from the plantation. The trees can be procured from the various Government nurseries on application, free of charge. Get plants in bamboo tubes or in pots. I have had the best results with the tube plants. I have bought the seed and reared gums in old pots and jam tins, but this involves considerable trouble, and I would not advise it. For the fruit garden I would plant 70 trees, which would be sufficient for an ordinary farm homestead's requirements and to spare. But as a few extra trees make very little difference when working a garden with a horse and cultivator, it is better to have sufficient, and also there is always a ready sale for fruit here. I would plant the following varieties and quantities:—Six apricots (three Oullin's Early and three Moorpark), six peaches (one Foster, two Elbertas, and two good early, and one good late variety), six apples, three pears, four plums (one American Cherry, one Greengage, and two Japanese), two loquats, one mulberry, four quinces, one walnut, two cherries, three figs, and 12 almonds—costing about 48s. I would complete the 70 trees with 20 oranges and lemons, which do fairly well about here, if planted on any soil except very stiff red clay. Those would cost about 50s. The fruit trees should be planted in July, and will be very little trouble to start if it should be a normal rainfall year. It is a good plan to water the trees during the first year. I would also plant 50 vines, a judicious selection of which, beginning with Green's Early and currants and ending with Doradillas and Wortley Halls, gives a ripening range of nearly four months. These would cost about 12s. to 15s. I would plant a lawn in front of the house. Buffalo grass is the best. Secure it unmixed with the couch grass, as the latter is one of the worst pests that can be introduced into a garden. There is almost an unlimited variety of roses and shrubs that look well around the house and lawn and between the lawn in front and the hedge. Some of the prettiest and best are Oleander, Wigandia, Hibiscus, Lauristinus, Jacaranda, brooms, bush roses, &c. I would, in laying out a garden and grounds, follow roughly the following plan:—Plant a lawn in front of the house and plant shrubs and standard roses around the house and lawn; also some flower garden, and not forgetting the homely kitchen garden at the back. Outside that, on both sides and the back, I would plant the fruit trees and vines. Always remembering to put the softest fruits closest in, to afford them more protection from birds. Outside that a few rows of non-robbing trees, and then the big plantation of gums. All farmers should at least grow enough timber for firewood. The State supplies the young trees (forest and ornamental) free of cost, and that and the other advantages far outweigh the trouble of planting and the three years' working. Farmers should also grow all their own fruit and vegetables. With Barossa water fruit will grow in any part of this district; and as nearly every landholder about here has water laid on he need have no fear of the result. Considering our climate, rainfall, and soil it is a great pity that there are so many bare farm homesteads in South Australia. I do not think that it is a want of taste, or apathy, on the part of the farmers, but rather a failure to grasp the possibilities of our wonderful country. I have been growing firewood sufficient for our own use on about three acres of gums, and also more than sufficient fruit on about 60 trees. I have found it a pleasure and have been amply repaid for my work."

NANTAWARRA (Average annual rainfall, 15·90in.).

May 7th.—Present: nine members.

The Blacksmith's Shop.—A blacksmith's shop on the farm, Mr. T. Dixon said, in a short paper, would enable the farmer to considerably reduce working expenses. The necessary fittings were bellows, a forge (which could be made from part of a 400gall. tank), anvil, and cutter, 10lb. hammer, 2lb. hammer, and several pairs of tongs of different shapes. A drilling machine and bits, stock and dies, taps, would be wanted, together with chisels and punches, which could be made in spare time. Handy sizes of iron, bolts, nuts, and coal should be kept on hand. This outfit would enable the farmer to draw out his plough shares, make swings, eyebolts and rings, S and C hooks, and many other small requirements. Too much time, however, should not be spent in the shop; all that was necessary could be done on wet days. Mr. E. J. Herbert strongly favored a blacksmith shop on the farm. Some of the jobs, however, were not as easy as they appeared, and a good deal of the rough and unsatisfactory work was due to not having the fire in a fit state before commencing. By not attending to small breakages, &c., and getting them repaired at once when they occurred, neglect often led to greater inconvenience. With a small shop handy this need not be, and for the same reason he did not agree with the paper in leaving the work for a wet day. Mr. Sleep considered a small blacksmith shop a great saver of time in case of small breakages, &c. He concurred with the previous speaker that the fire should receive proper attention before starting. Amateurs should not attempt big repairs, but have them done by skilled labor. Mr. R. D. Nicholls said a blacksmith shop on a farm did not possess all the advantages claimed for it. A great many of the breakages that occurred must be attended to at once and could not be left for spare time or a wet day. The farmer should reckon the cost of making against the purchased article; A great many things, such as bolts, &c., could be bought much cheaper, and a stock of these could be kept on hand. Unless there were someone on a farm whose duty it was to attend to odd jobs he failed to see where the saving of time or money was effected. Mr. A. F. Herbert agreed that it was cheaper to buy bolts, &c., but very often those in stock were too long for requirements, or other small alterations were needed. Mr. R. P. Uppill said that when small breakages occurred he was usually able to proceed with his work by keeping a stock of small accessories, until he could take a number to a tradesman for repairs. Wet days could usually be employed in other ways than blacksmithing. Mr. J. H. Nicholls was dubious about the value of the shop from a monetary point of view. No doubt it was convenient to make little things, and the maker derived a certain amount of satisfaction from his handiwork, but looking at it from a cash standpoint, he considered it cheaper to buy the smaller articles and have the repairs done by a skilled blacksmith. A farmer's opinion on the matter depended a great deal as to whether he was a handy man or not. Mr. Sutton heartily supported the paper. In reply Mr. Dixon said he only advocated doing small jobs in the shop. He favored keeping a stock of small articles, such as bolts, &c., but often a farmer ran out of these or did not have the right size, &c.

NORTHFIELD (Average annual rainfall, 19in.).

May 5th.—Present: five members and one visitor.

Fencing.—Mr. E. W. Kelly read a short paper dealing with fencing. He said all fences should be sheep-proof. A good well-built fence kept one's cattle, &c., from annoying one's neighbors, and in so doing fostered a good feeling. In making such a fence he would use as posts timber (red gum for preference) 7in. x 4in. by 5ft. 9in., with about 2ft. of the post in the ground, with good heavy strainers sunk into the ground about 3ft. The corner posts should be buried 4ft., the posts being from 16ft. to 18ft. apart, and the struts set at an angle of 45°. The wires should be 5in., 10in., 16in., 22in., 31in., and 42in. from the ground, the top two wires to be barbs, viz., 12 x 3 and 14 x 3, drawn through the posts, the holes having been made with 1¼in. bit. Mr. D. Rowe preferred a higher fence, say 4ft. or 4ft. 2in., and did not like too much barbed wire. He thought it better to break a wire or two than injure stock. He would use posts 8in. x 4in. wider apart, say 27ft., with two droppers between. Mr. Eastwood thought it unnecessary to make the fence so high as Mr. Rowe suggested for domestic cattle; inland it might be required, but not in this district. He preferred posts 8in. x 4in., and would put them closer together than was suggested by Mr. Rowe. Mr. J. Williams (Chairman) had done many miles of fencing, and experimented a good deal. He favored a fence about 3ft. 9in. out of the ground, with posts about 27ft. apart, with two T standards between them and strainers every five chains of 10in. the small end and 7ft. long, well strutted. The stability of the fence depended largely upon the kind of strainers and struts and how they were put in. A seven-wire fence was better than a six-wired one. Very few sheep, even crossbreds, got through it or under it. Four barbed wires were not too many, and his experience taught him that cattle and horses had a great respect for barbed wire. For the other wires he found the resist steel, Nos. 10 x 11 or 11 x 12 the cheapest and best he had ever used.

TWO WELLS (Average annual rainfall, 16·36in.).

May 12th.—Present: seven members and four visitors.

Seed Selection.—Mr. A. Pratt gave a report on the results which had attended his 12 years' efforts in selecting wheat with the object of securing a first-class flour-producing grain. The results of his labors had been very satisfactory. After having tried various pickling solutions he had come to the conclusion that the best was salt and bluestone, used from one to two weeks before sowing. His opinion was that formalin would not prevent flag smut.

WATERVALE (Average annual rainfall, 27·17in.).
May 4th.—Present: eight members.

Kangaroo Island.—The Chairman (Mr. E. E. Sobels) gave a very interesting account of a recent trip to Kangaroo Island. He was greatly impressed with the island, which he considered had great possibilities. There was land there, he believed, that if it were on the mainland would be worth £20 an acre, but there was other that was not worth 2s. an acre. He saw fruit of an excellent sample and flavor. The timber was very fine, and better than any that he had seen in this district. The trees were very straight, and it would be possible to get as many as 200 posts or more out of one tree. He was of the opinion that the timber would be suitable for railway sleepers, but did not think any industry would flourish until a railway was put from one end of the island to the other.

YORKE PENINSULA DISTRICT.
(TO BUTE.)

BUTE (Average annual rainfall, 15·42in.).
May 5th.—Present: 12 members and one visitor.

Care of Horses' Feet.—Mr. A. E. Bryant read the following paper on this subject:—"The feet of horses, asses, mules, and zebras have an outer wall or crust, a sole, bars, and a frog. The wall is highest in front and lowest behind, where it turns abruptly round and forms what are called bars, between which is situated the frog. The sole occupies the greater portion of the ground surface, and is carried backwards on either side of the frog. These horn structures have corresponding soft ones to which they are attached. The crust is held to the soft laminæ by fine ridges, which dovetail into the inner surface of the insensitive horn. There are hundreds of these, which may be seen by inspection of the hoof. The sensitive sole is attached to the insensitive one by a number of mushroom-like bodies called papillæ, or horn of papillæ. The attachment of the frog is just the same as the sole of the foot itself. The bars are the hardest part of the ground surface, being reflections of the crust, and of denser material than the contiguous structures known as the sole and the frog. The long pastern bone will be all visible; the short pastern, or coronal bone, will be found partly above the hoof and partly within it, while the pedal or coffin bone is wholly governed by the laminæ to which it is attached. Winged projections or extensions of the pedal bone exist on either side, and are called cartilages. These are important, being the seat of the side bone. A change in their structure from cartilage (which means gristle) to bone, constitutes side bone. On the under surface of the pedal bone is a very small shuttle-shaped bone. This is called the navicular bone. Its importance to the horse owner is its liability to a disease known as navicular lameness. This is supposed to be incurable, and will be chiefly found in horses running about the cities on paved streets or hard roads. The hoofs of all animals are attached above to a band which secretes the outer layer of hoof, and is called the coronet or coronary band. The growth and renewal take place from the laminæ and from the papillæ of the sole and frogs. Like the human nails, hoofs are always growing, to allow them to stand the wear to which they are necessarily subjected. The diseases to which a horse's foot is subjected are seedy toe, thrush, quittor, sand cracks, corns, and canker."

MAITLAND (Average annual rainfall, 20·08in.).
May 2nd.—Present: seven members.

Mr. Hill reported that for many years he had made a practice of putting down a pit of ensilage for autumn feeding to dairy cows. No trouble would then be experienced with the animals picking up bones, horsedung, &c. Dry bible would also be less prevalent. Mr. Jarrett said cows, if fed on ensilage in the late summer and autumn, would keep in better health, as the natural herbage then was dry and indigestible. Mr. Tossell advised the provision of an abundant supply of rock salt.

Exhibits.—Mr. Hill tabled a sample of ensilage made from Cape barley, cut with the binder and placed in the pit in sheaves. Members considered the sample rather coarse, and thought it should have been chaffed into the pit. Mr. Hill also tabled samples of hay chaff and grain separated from it. The hay was cut when the corn was in the dough stage and was then chaffed in the usual manner. The chaff was put through the motor winnower to recover the grain. Mr. Tossell had formerly tried this plan, but had given up the practice, as it involved too much labor. Both old and young stock had done well on straw and hay chaffed and mixed in equal proportions. The straw should be cut as soon after the stripper as possible. Farmers should have enough fodder on hand to last two years. Mr. Bentley said stock did well on molasses and chaffed straw. The straw was more palatable after it had remained in the stack for two or three years.

MOONTA (Average annual rainfall, 15·22in.).

April 25th.—Present: 10 members and two visitors.

Seeding.—Mr. P. Ford contributed a paper on this subject. He said—"If the fallow has been worked back since harvest, and is of a fine tilth, the shallower the cultivator is worked over it the better, so long as the rubbish is killed. If the fallow has not been worked back since the spring, it needs deeper cultivating, as it will be set rather firm. If it works up lumpy it should be harrowed before it is drilled. The drill should be kept close up to the cultivator in case of rain, or the soil will become set and will not bury the seed nearly so well. The shallower the seed is drilled in the better. It will germinate more quickly and with much less rain, and the roots go down through sweetened soil, which is not the case if it is drilled deep and on the hard bottom. The pressure springs should be released as much as possible. The weight of the hoe or disc is quite sufficient to bury the seed, providing the soil is not too wet. It pays to leave the drilling for a couple of days after heavy rain, as the soil is then too dead and sticky, the seed does not bury well, and wheat that is sown a week later will grow far better. The cultivator shares should be kept as sharp as possible, as this makes lighter draught for the horses, and cuts the weeds better. The drill should be well cleaned not less than once a week, and always be kept well oiled. For oats, 1½bush. of seed and 70lbs. of super. per acre should be sown, and for wheat, 1bush. of late varieties and 1¼bush. for early varieties with 1cwt. of super. per acre gives the best results. It is not wise to sow late wheats after the first week in June. If the soil is wet I prefer to pickle the grain, but if sowing under dry conditions I fail to see that any advantage is gained in pickling, as the grain that is not pickled will germinate more quickly and will come up thicker than wheat which has been pickled. I prefer the dipping process, that is, if the grain is in butts, so that the wheat is loose, and the solution can get through it easily and quickly. A 1¼ per cent. solution of bluestone is quite strong enough. The wheat should be in the pickle for two minutes. In a season like the present no wheat should be sown for at least a fortnight after the rain; after the rubbish has had a chance to grow." Mr. B. Fergusson agreed with the remarks of the writer of the paper. Mr. C. Nankivell had had good results from drilling in wet ground.

KADINA, May 2nd.—The subject of homestead meetings was considered at length, and it was eventually decided to accept an invitation to visit the farm of Mr. D. N. Martin.

WESTERN DISTRICT.

COLTON (Average annual rainfall, 17·01in.).

May 16th.—Present: nine members.

Rabbit Destruction.—Mr. Kenny read a paper dealing with this subject. The appointment of a travelling inspector last year, he said, had resulted in a great deal of good work being done in destroying rabbits in this district. In the event of a landholder not taking sufficient steps to check the pests on his land, the inspector should have the power to do the work at the landholder's expense. There was a large number of poison carts in the district which were not being used. Poisoning with phosphorus and, in the wheat paddocks, with bisulphide of carbon, would effectively check the rabbits, and he thought an inspector should be again appointed to see that the work was carried out. Mr. Barnes expressed his pleasure at the good feeling among farmers respecting the Board's efforts to bring the pest under control. He explained the portion of the Vermin Act relating to the summoning of defaulting landholders.

COORABIE (Average annual rainfall, 11in. to 12in.).

May 9th.—Present: 15 members and three visitors.

Shed-Building.—The following paper was read by Mr. V. S. Kingsley:—"In response to a request from the Chairman for a paper dealing with shed-building, I think that the most suitable shed to describe will be a barn or implement shed. The suggestions I make should only be regarded as applying to the particular type described; for as there are 'more ways than one of killing a pig,' so again are there many ways of putting up a shed. I do not recommend anyone to erect a building of any kind unless it is well and substantially constructed, so that it may withstand a good many years' storms and rough usage. Circumstances alter cases, as sometimes we have only a limited amount of material or capital at our disposal, and yet our requirements seem to demand a much larger shed than the capital warrants. Yet, with some amount of study and contrivance, it is possible to erect a shed nearly half as large again for the same money; but it would only be a flimsy affair, and would require stiffening and constant attention, until such time as the farmer could afford some more sawn timber. I wish to emphasise this fact, right at the beginning, that it is preferable to have implements under a roof in the off seasons than out in the sun and weather. Whereas, if in such hard times as we are at present experiencing, I say build a flimsy shed rather than have none at all, bear in mind all the time during its construction the necessity for adding more timber into its framework when your pocket permits, so that every piece of timber put in at the beginning must be so placed relatively to receive the extras as time goes on. It is suggested that we have an implement shed about 60ft. long by 30ft. wide. Such a shed will contain all the field implements of an average farm, and yet leave room to stack the season's super. and seed wheat. The latter can easily be protected with wire netting affixed to the upright posts of the building, to preserve it from the depredations of the fowls. But do not forget to give the cat a chance to inspect occasionally, according to her own free will. There is another very important item to be remembered with regard to the seed wheat, which may affect the actual position of your shed. That is the matter of 'pickling seed,' for you require to have your pickling plant fixed close by, and also your supply of water readily available for this purpose, so that you may perform this work under cover on wet days and so save time. For the uprights of the shed 3in. by 3in. jarrah is quite stiff enough. Of course, again, if your purse is small, you may use bush timber uprights, but I recommend stone uprights, say about 14in. square, instead of rough bush timber. I do not recommend plain concrete posts unless they are reinforced. The fascia, or roof plate, should be not less than 6in. by 2in., rafters 4in. by 2in., and purlins 3in. by 2in., binders and king posts 3in. by 2in., with joists of 5in. by 2in. This does away with the necessity for an inner row of uprights to support the ridge of the gable roof. The roof frames should be constructed on the ground and then elevated into their position, leaving a slot at the apex of each to slip in the 7in. by 1½in. ridge piece. With the roof frames it is of advantage to erect one of the ends first, and then, perhaps, the middle one, staying them into position temporarily with prop sticks and then with nails, and then put on the first portion of ridge piece and secure all together; after which the intermediate frames can be handled much more easily and slipped into their positions more readily. If, however, it is your wish to divide the shed into sections with partition walls for chaff and other storage, then perhaps it would be advisable to erect centre uprights at the beginning, and these posts would then carry the ridge; on the other hand I do not advise the centre posts being put in, for they always seem to be in the way afterwards. The roof should be covered with corrugated galvanized iron, 26 gauge, in 8ft. sheets, allowing a one and a half corrugation lap, the purlins beneath being placed about 3ft. 10in. apart for a flat pitch, or up to 7ft. or 8ft. for a steep pitch. The flat pitch of roof should have about 3ft. rise to the ridge from the gutter levels, whereas a steep pitch should be double this; ceiling space would then be given for hanger hooks to suspend carcasses of meat, &c., out of harm's way. The eaves, or ends of the shed, should be partly enclosed, that is to say, down to the levels of the gutters. The gutters should be not less than 4in. for a flat pitch or 5in. for the steeper. The height of the shed from the ground level to the gutters will depend upon the type of implement to be stored. For binders and harvesters not less than 8ft. is required; whereas for drills, ploughs, &c., it need not be so high. There is no particular advantage in building a shed too high, except for the reasons already mentioned. A good storage tank is necessary." Illustrations of construction, showing thrust and stress, were given on the blackboard.

Bare Fallow or Catch Crops.—Mr. G. B. Gardner read the following paper:—"It has often occurred to me that bare fallow in a district with a good rainfall is not always the most profitable system of working a farm. The practice may hold good in districts where it is essential to conserve as much moisture as possible in order to give the crop a good start in the early autumn, or to conserve enough moisture in two seasons to grow one crop, or where one has rough land that bears but little feed and which is improved by breaking up, and, of course, scrub land that has but little feeding value. However, to take one crop only in two seasons off good paddocks seems to me a wasteful process, and I think we should get the equivalent of the grass we plough under from some catch crop, when we take into consideration that grazing the land can be made very profitable with wool and meat at anything like present prices. I am inclined to think it is well worth considering the wisdom of ploughing up well-grassed paddocks in the early spring, thereby losing the summer feed. Then there is the question of humus, which sooner or later will become depleted under a system of continual bare fallow. There seems to be a general opinion that bare fallow will always give very much better results than stubble ground. I do not dispute that such is the case in the majority of instances, but some of the difference is the result of the extra and more thorough working the fallow receives over the stubble land, which in the majority of instances is merely skimmed over once, and often ploughed and sown before the weeds have started, with the result that the weeds take as much out of the land as the crop, and the returns are unsatisfactory. I am, therefore, inclined to think that in this district, with its usually good rainfall, it would be more profitable to utilise the fallow to provide fodder crops for the summer and early autumn—a time when we are generally short of feed. On a well-appointed farm the paddocks should be small, and so arranged as to have permanent water in each. One of the many advantages of having paddocks of convenient sizes is that one may be planted some time before the other, and so one can avoid having the feed all coming on at the same time. I have found field peas a suitable crop on early fallow. These leave the land almost as clean as fallow that has been worked, as sheep will clean off everything, and the returns from the crop will be very satisfactory. By ploughing stubble land as early as the season will permit, that is, after the grass and weeds have started, and again cross-ploughing with the skim plough before drilling, we will obtain results that will more than pay for the extra labor. It is more profitable to have a limited area thoroughly cultivated and get good results than to scratch over a large one, half working the land, with the great chances of more or less failure. I have mentioned field peas as a payable catch crop because I have proved them to do well over a succession of years. I also tried kale last year with very good results, although grubs attacked it rather badly in the spring. It has made wonderful growth since the first rain, and is now giving a large amount of feed for the ewes and lambs. Some of the kale crop was ploughed under about six weeks ago, but it has shot up and is now quite a foot high, and making rapid growth. It seems to thrive well on sandy soil. Last year I also tried some lucerne sown with the hay crop, and although the season was very unfavorable it did fairly well. I sowed about ½lb. seed to the acre. I find that it does best on the stiff land. It has been ploughed since the early rain, and the lucerne is springing up through the furrows, seemingly none the worse for being loosened up. It would be profitable to sow a few pounds of lucerne seed to the acre with the manure, especially on land that is to be left out the following year. I do not suggest this as a substitute for a lucerne paddock, as I think it would be profitable to have several small paddocks thoroughly worked and manured and sown with about 10lbs. of lucerne to the acre. Anything we can do to improve the stock-carrying capacity of our holding is of as much importance as increasing our wheat yield, and we should be well advised to experiment in this direction." The paper created much discussion as to the respective merits of kale and peas as catch crops, both having been successfully grown in the district. It was contended that peas would give the greater quantity of feed off the same area, as kale would have to be ploughed in during autumn to make way for the cereal crop. Mr. Gardner said his experience was that kale did well on sandy land, rape on heavier soil, but peas did well anywhere, and, further, left the fallow clean. He considered that to fatten four sheep per acre on peas was a low estimate. He also favored sowing peas broadcast and ploughing or disking them in, as the drill did not seem to bury them well.

MITCHELL.

May 9th.—Present: 17 members and two visitors.

Horses.—Mr. R. Merchant read a paper. Horses should be fed four times per day, and given just as much as they would eat. On Sundays they should be given half the usual ration and run in the paddock. Rock salt should be in every manger, and salt should be mixed with the feed occasionally. Crushed oats and cocky chaff made good feed when hay was scarce. Separate stalls should be provided for mares with foals. The latter should be weaned at six months, being allowed to run in the paddock, the mares being confined. The team should be well groomed every day, special attention being given the shoulders. Well-fitting collars were necessary, and bags could well be used as false collars. The thick-set, nuggety animal was the best stamp for farm work. Generally, this was a good mover, and kept condition well. Horses should not be broken until 2½ to 3 years old. Water should always be provided before the animals were fed. They should not be worked after sundown. A spare horse should always be available, so that in case of accident to one it was not necessary to stop the team. Stalls and stables should be kept clean. On account of the danger of fire it was unwise to tie up the animals over night.

Sheep.—Mr. D. Ness also read a paper. He preferred the Merino sheep for this district, but if a cross for mutton were desired he advised the introduction of Romney Marsh rams. At three months well-fed lambs should weigh, dressed, from 35lbs. to 40lbs. For farm Merinos he recommended mating Canowie four-tooth ewes with Caroona four-tooth rams. When the lambs were four-tooth they should be mated back to Canowie rams. The rams should be put in with the ewes about November 20th, which meant that lambing would commence about May 1st. If shearing were commenced during the first week in October, these lambs should cut about 3lbs. of wool each. As soon as the sheep were full-mouthed they should be sold. Mr. Trimble thought it wiser to mate the ewes later than advised by Mr. Ness, there would then be more feed for the early lambs. In reply to a question, Mr. Ness said that when two-tooth ewes were mated the progeny generally were small and stunted.

Farm Implements.—Mr. J. Oats said the plough should be of medium weight and used for fallowing a good portion of the land proposed to put in. Often a good deal of draught was necessary if the ground were consolidated, and if the plough were too light it would strain. If it were necessary to again work the fallow a light skim plough or disc cultivator should be used, as this was much more economical than the heavy type for this purpose, and also for ploughing after the harvest if stubble land were to be put in. The wide drills were an advantage if the country were free from stumps and stones. But where stones or stumps were plentiful it was a mistake to have it wide, as the wide drills, when full of wheat and super., were very heavy, and with the bumping over the stumps and stones the wheels were liable to give way and the drills to sag in the centre. If over 13 hoe or disc it should have two drives for the wheat feed, or the bar was liable to twist. He preferred a drill of light draught, so that the horses could travel at a fair pace without being unduly tired. If the crop were a fair one, the binder should be used, as there was not so much waste as with the mower and rake, and a considerable amount of time was saved in the carting. During the past two years many farmers had found the mower and rake very useful, as the crops were too short and light to bind well. It was necessary to leave the sheaved hay in the paddock much longer than loose hay. In this district the stripper and motor winnower were preferable, on account of nearly, if not all, the farmers requiring a considerable amount of cocky chaff each year. During seasons like the past two the harvester could not be used to any great extent, and it would be found necessary to keep a stripper or two so that they could be used when the crops were light. If the country were loose or sandy a wagon with broad tyres (6in.) was preferable, because a full load could then be put on in the paddock, which effected a great saving in hauling. If the country were firm, the roads good, and the distance to market short, a wagon with tyres about 4in. wide might be better, as with the wide tyres the boxes were more liable to break. Mr. James Stiggants thought the stripper and motor winnower preferable to the harvester, especially on stumpy ground, as the harvester often caused a good deal of trouble. Mr. P. Farrelly would cut with the binder if the crops were good enough but found the grass cutter very useful during the past two years, as he did not take his binder out of the shed. Cocky chaff was useful, and he thought it would always be necessary to keep the strippers. Wide tyres for wagons were better in this district; he was using a 4in. tyred wagon and 50 bags was as much as he could put on at the heap. Mr. J. B. Oats found the binder a great save in labor. Sheaves were handy, and he had had no trouble to get the horses to eat the sheaved hay. He had had no experience with the harvester, but thought it unsuitable for hilly and stumpy country. He had used both the 3in. and 6in. wagon tyres a good deal and found the 6in. more suitable for the loose country. Mr. J. C. Stiggants said the harvester saved labor, but the stripper saved the chaff. If the paddocks were large and the crops good he favored the stripper and motor winnower. The wheels of wagons should be higher than they were usually made, as the higher wheels were lighter of draught. The Chairman (Mr. A. Shepard) was in favor of the narrow drill. With a wide drill full of wheat and super. and a 12-stone man on the footboard it meant a great strain on the implement going over stumps. The binder worked well if the crop were thick enough, but he would not bind a short, thin crop. With a grass cutter one could always secure some hay, if it were only a light crop. The harvester was not suitable where it was necessary to save the chaff, and it would not last so long as the ordinary stripper. If the bags were left unsewn the birds wasted a good deal of wheat. Great care was also needed with the motor winnower, as it was possible to waste a good deal of grain if it were not set right. As for wagons, it depended a good deal on the nature of the country. He had a 4in. and a 6in. wagon. If one got off the track the wide tyre was much better, but he also found they were much harder on boxes,

UTERA PLAINS (Average annual rainfall, 12·06in.).

April 11th.—Present: 15 members and four visitors.

Experimental Plots.—Messrs. Guidera, Gale, and Hornhardt undertook to conduct experiments on behalf of the Branch.

Bureau Work.—The Chairman (Mr. N. Guidera) read a paper, in which he said that every farmer could profit by membership in the Agricultural Bureau. Agriculture was a progressive science, and one of the means of keeping abreast of the times was by the education received through the medium of this institution. Experimental work should be undertaken by Bureau men, as the most reliable information could only be gained by practical tests on the individual farms.

Crows.—Mr. A. Venning read a short paper. He drew attention to the loss which crows had caused in eggs and chickens. Shooting did not seem a satisfactory method of destroying them. Poison had proved a failure. He had made a frame 12ft. by 14ft. and covered this with wire netting. One side of this was propped up with two props 6ft. long over the offal of a sheep. At the bottom of each prop a wire 15ft. long was attached; the two wires being joined to a single wire at the end. The latter was sufficiently long to enable one to pull away the props and allow the framework to fall on any crows that were attracted by the offal. Last year he had destroyed 90 crows and one eagle in this way.

Seed Wheat Selection.—The Chairman also drew attention to a paper in the *Journal of the British Board of Agriculture* in which this question was put—"Does continuous selection improve the seed and the crops, or does the want of selection end in deterioration? The authors of this paper—C. and A. Hagedoorn—state that about 1843 to 1850 Vilmorin selected typical heads of wheat of each variety then cultivated. From each he took a single grain, and propagated a crop in successive years. The original heads were labelled with their name and date and put away. In the year 1911, about 60 years after, this collection of heads was discovered in a drawer. Heads of 12 varieties of wheat were put alongside the original ones, the new heads being the lineal descendants of the old. Absolutely no difference was apparent between the old and the new. One reason adduced for this is, that corn crops, such as wheat, oats, and barley, are self-fertilising, and consequently each keeps its own strain, as it were, perfectly pure; and therefore apparently we can grow indefinitely any particular variety of corn without deterioration, so long as it is pure and is kept free from admixtures, and selection does not appear to improve it. It is in the case of plants where cross fertilising takes place that there is room for improvement and development, such. for instance, as with peas and potatoes, and even rye. With such crops there may be either improvement or deterioration, and therefore artificial selection must be practised. It would be instructive to have the comments of some of our seed growers on the above discovery, as one of the great points in connection with corn growing has been not merely to select seed from the best part of a crop, but actually to select the best heads, and from those the best single grains, with the intention of further developing, or at least keeping each strain pure. From the above it appears that this is quite unnecessary, but it is desirable to have the matter thoroughly thrashed out."

UTERA PLAINS (Average annual rainfall, 12·06in.).

May 9th.—Present: 16 members and seven visitors.

Oats.—The Hon. Secretary (Mr. J. Abrook) read a short paper. After experience of New Zealand Potato, Scotch Grey, Algerian. Cape, and Tartarian oats, he had come to the conclusion that the Algerian variety was the best suited to this part of the State. The chief advantage with these was that the crop did not go down. Oats gave a better crop than wheat in a dry year, it discouraged takeall and added more to the humus content of the ground. Members generally agreed with the opinion of the writer of the paper.

YADNARIE (Average annual rainfall, 14·09in.).

May 9th.—Present: 17 members and three visitors.

Horses.—Mr. A. J. Hutchinson read a paper dealing with the care of horses. A colt to be handled should be run into a loose box and tied up, he said, but on no account should it be choked down. It should then be rubbed well about the head, and encouraged to lead. If it became necessary to use a whip the animal should be lightly touched just behind the forelegs. When the colt was sufficiently tractable to be put in harness, it should go in the near side of the body of the wagon. Here it should be handled as quietly as possible. If it worked too hard for the first two or three days and then became stale, it should not be forced, but given a few days spell, after which it would feel more at home in the harness, and probably work better. During the first week, at least, after the animal had been unyoked, its shoulders should be washed with cold water. The collar should fit well. The horse should be given a name, which should be made use of when it was made to stand over, &c. Kindness and firmness were essential. When teaching a horse to jump it should be first of all schooled over a sheep hurdle with plenty of lean, the pace, and the height of the hurdle being gradually increased. A lengthy discussion followed. Mr. W. Brown, Mr. H. S. Bauer, and Mr. R. B. Deer all thought it unwise to handle young foals before they were being broken in.

YALLUNDA (Average annual rainfall, 18in. to 19in.).

May 9th.—Present: six members.

POTATOES.—Mr. P. Provis read a paper on the subject of planting potatoes. He said —" One of the best ways to keep potato seed is on a piece of good, firm, dry ground, in the shelter of some evergreen tree. Spread the tubers thinly and turn them often ; the more they are exposed to the light and, if possible, the sun, the hardier they become. A tuber that has become green will resist an ordinary frost, and may remain exposed the whole winter on the surface of the ground without rotting. The rules to observe in cutting seed are—First, look for the well-formed eyes, which throw out the strongest shoots, and then cut the tuber in order to have at least one to each set. In a dry season, or in districts with light rainfall, large sets are the best, as the plant in the early stages of growth depends largely on the parent tuber for moisture. It is better to have more than one eye, as all do not throw out shoots. A large set with many eyes is just as liable to rot as a smaller one with only one eye ; it is the condition of the tubers and the state of the land that cause seed to rot. Sets with a single eye should only be planted in well-prepared land suitable for potato-growing. On the question of cutting nearly everyone has his own ideas. From 4in. to 5in. has been found the most suitable depth to plant. If planted too near the surface early varieties or crops in early districts suffer from the potato grub. In ordinary soils 27in. to 30in. has been found a suitable width between the rows, with from 18in. to 24in. between the sets. Seed should be planted the day that it is cut. It is not necessary to use any material to dry the cut sets, as a cut tuber does not bleed. The potato is composed of starch, and naturally dries quickly; if it does not it will rot in the ground. If the seed is wet it is liable to rot. After rain, do not start planting with cut seed until the ground is dry." Mr. G. Teakle strongly favored Redskins for this district.

GOODE, March.—Mr. L. Will thought the most profitable method of cultivation to adopt in this district was to clear as much scrub as possible at first, take off three successive crops, and then let the paddocks remain under grass alternately. By keeping sheep a good deal of expensive working could be obviated. Mr. N. Packer advised the use of the horse rake to gather roots and rubbish, which could be burnt on the stumps. The harrows could then be used more frequently.

WHEAT STANDARD.—At a previous meeting members expressed the view that it was not advisable to fix the wheat standard too high. A resolution was carried that—" More satisfaction would be felt if the standard were fixed earlier in the season, and the Government should assist in fixing the standard."

ROBERTS AND VERRAN.—It was decided to conduct tests with different quantities and different grades of manure.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

BERRI.

March 7th.—Present: 22 members and five visitors.

CITRUS CULTURE.—The following paper was read by Mr. F. Arndt:—

Introduction.—Before I came to Berri, some three years ago, my experience of citrus had been chiefly confined to the Adelaide plains, and therefore the observations made on my own and on other citrus plantations growing under the conditions pertaining to the Murray Valley have not been of very long standing. To obtain further information regarding the culture of citrus under local conditions I have written to some of the largest growers along the Murray, and am much indebted to the following gentlemen for valuable information and advice :—Messrs. F. J. Olorenshaw, W. E. Muspratt, C. H. Peperkorn, and H. S. Taylor, of Renmark, and Messrs. F. W. Pickering and T. S. Dove, of Mildura ; also to Mr. Geo. Quinn, the Government Horticulturist.

The Question of Site.—The elements that citrus growers have most to contend against in the Murray Valley are high winds and frosts, and the grove should, if possible, be so located as to escape their ravages. The greatest enemy to be feared is, no doubt, frost, for although the evil effects of heavy winds can to a considerable extent be modified by planting belts of shelter trees, frosts cannot be evaded by such simple means. It is a matter of common observation that frosts are the most severe in valleys, hollows, and low areas, while the adjacent hillsides or elevated lands remain comparatively untouched. A citrus grove should therefore never be located in a hollow, basin-shaped depression, or in a narrow gully. The ideal position is on a slope facing the east, as experience has shown that the rays of the rising sun are less injurious to frosted plants than they are if the sun is some distance above the horizon before it strikes them; while the slope of the ground will allow the cold air to drain off into lower levels. Of course, a situation facing the east, although desirable, is not essential for the location of the grove, the one thing necessary being that the plantation has perfect air drainage so that the cold air can drain away, and therefore a position on sloping ground is the best. The planter should not plant any evergreen shelter trees along the boundary at the lowest portion of the grove. Such trees, being in full leaf when the frosts occur, prevent the cold air from passing freely away and force it back upon the plantation, thus causing frost on the lower portion of the grove. Should a breakwind be required along the lower boundary it should consist of deciduous trees.

Suitable Soil.—Experience has shown that loose rich soils which have perfect drainage have given the best results. This does not mean that citrus will not grow on rather heavy land. On the Adelaide plains I have known oranges to do remarkably well on heavy clay soil, full-grown trees averaging about four cases of fruit to the tree per year. Young trees, however, are difficult to start in such soil, and their growth for the first three or four years is very slow. Citrus of all kinds do remarkably well in deep sandy loam, and such land is to be found by the thousands of acres on the pine and mallee rises along the Murray Valley. The chief essential of citrus land is that it must have perfect drainage, and therefore shallow soils, or very heavy soils whereon the water stagnates must be avoided by the planter. The drainage of a piece of land depends chiefly upon the nature of the subsoil, and land that has a very heavy subsoil should be avoided. The prospective citrus grower who selects a deep, rich, loamy piece of ground, having a fair even slope to allow for the underdrainage of moisture and for the drainage of the cold air from above, will have made about as good a selection for the site of his grove as can be obtained under river conditions.

Preparing to Plant.—To have the land grubbed will cost from £2 to £7 per acre at Berri, according to the amount of timber and undergrowth on the land. The land must then be ploughed, and all irregularities graded off so that it has an even surface. The next thing to do is to have the irrigation channels, from which the land is to be watered, put in. This work is usually done by the Irrigation Department, the settler directing where the channels shall go. Great care should be exercised by the settler in this matter. More mistakes have been made by settlers at Berri and at other irrigation places along the Murray in the laying down of their channels than in anything else. As the loose soils, of which the irrigation colonies largely consist, make the furrow system of irrigation the only one possible, it stands to reason that the first trees of a row will always obtain more water than the last ones, as the water will have flowed a considerable time past the first tree before it reaches the last one. Therefore the longer the rows the more water will the first trees receive and the less will the last ones. For this reason the channels should be so laid down that the rows of trees they have to water are short. Five chains is quite long enough to water in one section. Under no circumstances should rows be watered over seven chains long. In fact, in dealing with citrus, it would be wiser to make two sections out of a seven-chain row. Of course, short rows mean much channelling, which greatly adds to the first cost of the plantation. But in the long run it will be found to pay, as in watering long rows the top land ultimately becomes waterlogged, and, unless the underdrainage is unusually good, the surplus water will appear lower down the rows as seepage, bringing alkalies to the surface and killing the trees in its vicinity. Another thing the settler must see to, and that is that the channels are so situated that the grade he will have to water along is neither too steep nor too level. A too steep grade will cause the top land to wash away, while with a very level grade the water will take too long to reach the bottom of the rows. Local experience has shown that it is a mistake to water straight down steep sandy rises, as the water invariably washes out deep gutters at the top of the block, silting up the furrows about one-third down the rows, which causes the water to spread over the land at this portion of the holding while very little water at all gets to the end of the rows. On the loose sandy loam of the Berri slopes a fall of one foot to the chain will be found quite enough, while anything under 4in. to the chain is too little.

Pegging Out.—After the land has been cleared, ploughed, graded, and channelled, it should be pegged out ready for planting. This is usually done with the aid of a wire line, in which tags have been inserted at the distance apart that it is intended to plant the trees. The line is stretched tight at the required angle the rows are to run, and a peg driven in at each tag. First of all the breakwind along the boundary should be pegged. If the breakwind is to consist of almonds or pears (which are usually planted here) 12ft. is far enough apart. The land for the citrus trees should then be pegged out. Headlands of 20ft. to 24ft. should be left all around the piece pegged, and where the citrus rows approach the windbreak about 26ft. should be left. Citrus are usually planted 20ft. to 24ft. apart on the square. Most of the older citrus groves at Berri have been planted with the trees 20ft. apart, but where the soil is very rich 24ft. apart will probably not prove too great a distance in years to come. As citrus take many years to come into bearing interplanting with other varieties of quick-bearing trees, such as apricots or peaches, is often resorted to, with the object of getting some early return from the land, and to root the interplanted trees out when the citrus come into bearing. This method is not to be recommended, as the almost invariable result is that the quicker growing trees rob the citrus of plant food and moisture, and that just when the interplanted trees are beginning to bear profitable crops in their fourth and fifth years, they must be rooted out to give the citrus a chance to develop.

Cover Crops.—Owing to the heavy spring winds that sweep along the Murray Valley, the planting of cover crops in among young trees to protect them from wind-blown sand becomes a necessity. The cover crop should be sown before the trees are planted, so that the young trees have shelter from the start. So far, wheat has proved itself to be the best cover crop at Berri, which, besides affording excellent shelter for the young trees, is profitable to the settler in the form of hay. The wheat should be drilled in between the rows after the block has been pegged out. A strip 12ft. wide is quite enough for the first year, while a 6ft. strip is enough to protect the trees in their second and subsequent years. It is not advisable to broadcast the wheat and plant the trees in among the crop later, unless an 8ft. strip is ploughed in where the rows of trees are to be; for if the cover crop is too close to the trees it will rob them of moisture, and become a curse instead of a blessing. To get the best results the cover crop should be drilled in early, say in May or early June, and the land should be ready for the drill by then; but if not, it should be put in, no matter how late the season, as even a moderate growth will keep the land together. Citrus growers along the Murray learned a severe lesson during the spring of 1912, when, through the neglect of planting cover crops, the fierce September and October gales killed the young trees by the hundreds with sand drift.

Ordering Trees.—Long before the land is ready for planting, the prospective grower, if he is wise, will have given in his order to a reliable nurseryman, and thus be certain of getting his trees. The chief thing to remember in ordering is to get *good* trees. To stand the check from shifting from the nursery to the orchard a young orange tree should be sturdy, healthy, and have its wood well matured. A tree two years old from the bud will give the best results, and, providing it receives reasonable care in removal from the nursery and in planting in the orchard, should grow right away. Forced trees, with young, sappy growth, should be avoided by the grower. However cheap, they will prove dear at any price. Good, strong, well-matured trees will very probably run £2 per 100 more than forced immature ones, but the grower will gain this in his first year in the smaller percentage of misses he will have. Now as to the varieties to order. The Washington Navel is still first favorite wherever it can be successfully grown, and is no doubt likely to remain so for many years to come. For size and quality it cannot be beaten, and in California it has practically driven all other varieties out of the market. Another variety now becoming popular in California is Thompson's Improved Navel, said to be an improvement on the Washington Navel, in so far that it ripens considerably earlier than the Washington, and that its fruit is of a somewhat smaller size. The Valencia Late also comes with a big reputation from America, but so far has proved itself a shy bearer in South Australia. In mandarins, Dancy's, usually called Tangerine, is perhaps the best variety to grow. It has a handsome appearance, excellent flavor, and is said to ship better than other varieties.

Stock.—Another thing the planter will have to consider is upon what stock the young trees are budded. In Australia citrus trees are usually budded upon Seville, sweet orange, and lemon stock. Of the three the Seville stock makes the hardiest tree, and American and Australian experience seems to be at one in this matter. The Seville is not so liable to collar rot as the lemon and sweet orange, and can therefore be grown on wetter land than either of the other two. In Florida, which has a 50in. rainfall average, the Seville stock has proved itself able to withstand floodings and to grow in fairly moist situations. The Seville as a stock causes slow growth to the variety budded upon it, makes for a rather dwarf, bushy tree, and the fruit, although of good quality, is smaller than that grown either upon sweet orange or lemon stock. The sweet orange as a stock makes for a quick-growing, vigorous tree, and is now generally preferred in South Australia to all other varieties. Messrs. Muspratt, Peperkorn, and Olorenshaw, of Renmark, however, hold with the Seville stock, as it is less liable to collar rot. On a good loose, loamy soil, where water does not stagnate around the butts of the trees, and where the drainage is good, the sweet orange stock gives good results. It gives a large and vigorous tree, and induces a good crop of good-sized fruit. For well-drained land this stock is recommended by Mr. F. W. Pickering and Mr. T. S. Dove, both of Mildura, gentlemen well famed for their knowledge of citrus fruits, and by Mr. Geo. Quinn, the Government Fruit Expert. As a stock, the lemon is the least hardy of the three varieties under consideration, as it is more liable to collar rot and is impatient of much moisture around the roots. Trees on this stock should not be planted on soil likely to be flooded by rain or irrigation water, but will succeed on dry situations having good drainage. Lemon stock is the favorite stock at present used in Sydney, having practically superseded the Seville and sweet orange for that purpose. The lemon stock gives rise to a tall, vigorous tree with large-sized fruit, and trees budded upon it grow more quickly than those budded upon any other variety of citrus. In my young plantation Washington Navel trees budded upon sweet orange and lemon stock were planted side by side, at the same time and in the same class of soil; and at the present time not only have the trees on the lemon stock beaten the others in growth, but in fruitfulness as well. However, owing to the fact that the lemon is more liable to gum disease, and cannot withstand much water-logging of the soil, care should be exercised in planting this stock only on soils having perfect drainage. Mr. T. S. Dove, of Mildura, in reply to my inquiries regarding citrus stock, has summed up the matter in a nutshell: "Lemon stock on dry situations with good drainage; sweet orange on dry situations with good drainage and medium to light soil; and sour stock on wet land likely to be flooded."

Planting Out.—The land having been prepared and pegged out, and trees of the required kinds ordered from the nurseryman, the next operation for the settler will be planting the grove. At Berri, and along the river generally, citrus are usually planted in September with the first irrigation. Autumn planted trees, watered with the last irrigation, have also been known to do well, but the risk is great if the winter should be cold and dry (as is often the case), and no irrigation water is delivered the settlers during the winter months. When the young trees arrive from the nursery they should be heeled in a shady place and watered. Before planting out into the orchard, the roots of the trees should be lightly pruned, cutting off all injured or straggly roots. The tops should also be cut back, according to the size and vigor of the tree. However, it is not advisable to head a tree higher than 2ft., while under 18in. is rather low. The trees are best planted while the irrigation water is running along the furrows, or just before the irrigation is taking place. A square hole is dug alongside of each peg large enough to hold all the roots of the tree without cramping. The trees should not be planted deeper than they stood in the nursery bed. A planting board, made out of an ordinary piece of board with a notch cut in at the centre, will be found very handy in setting the trees. Place the board over the centre of the hole along the line of pegs, place the tree in the notch at the mark showing the depth it stood in the nursery, and fill it carefully with earth. By this means the trees will be planted the right depth. Citrus never do well if planted too deeply, and if planted below the bud are liable to develop collar rot tendencies if water stagnates around the union of the scion and stock. After the tree has been planted it should immediately be given a bucket of water, and receive a good irrigation within a few days.

Irrigation and Cultivation.—After planting the grove the most important factor governing the success of the settler's enterprise is good cultivation. This cannot be too strongly insisted upon. Living in a climate wherein the temperature often remains at 100 degrees or over for weeks at a time it is absolutely necessary for the grower to conserve all the moisture the land receives, either in the form of rain or irrigation water. Within the Berri Irrigation Area the settler receives 24in. of irrigation water per annum, which is generally supplied in six irrigations. This averages 4in. per acre per irrigation, which is ample, provided the grower cultivates his land well. In fact, after the trees are once established, I consider from 16in. to 18in. of irrigation water per annum is sufficient for young citrus trees before they come into bearing. The careless cultivation that some citrus groves have received at Berri has resulted in great losses of young trees during the last few years. Flooding the land with copious supplies of water and cultivating but little is a most foolish policy for the grower to adopt. By such means the top layer of soil, wherein the roots of the young trees exist, soon dries out, and the trees suffer from drought, while the water that has sunk down more deeply is liable to soak along the subsoil and come out in the lower portion of the grove as seepage.

Dealing with Cover Crops.—If the grove has been laid out in the manner previously suggested, with a strip of cover crop down the middle of each row, it will only be possible to cultivate a strip of land about 3ft. wide with a single horse cultivator along each side of the rows for the first two irrigations. All weeds in between the trees along the rows should be hoed out, and the whole 8-ft. strip along which the trees have been planted should be kept perfectly loose and clean of weeds. As the evaporation during the early spring months is not severe, this cultivated strip of land will be found sufficient for the satisfactory growth of the trees. After the cover crop has been removed, about early November, the cultivated strip should be enlarged, by a two-horse cultivator or disc harrow driven once along each side of the rows. After December, when the winds have subsided, the whole plantation should be disked up. By disking, the stubble of the cover crop remains on the surface, thus preventing sand drift should there be heavy January winds, which sometimes occur. For the rest of the season there should be thorough cultivation of the whole grove after every irrigation or after every rain of any consequence. In the autumn the land should be ploughed, harrowed, and a 6-ft. strip of cover crop drilled in between each row of trees. As the trees become older they will shelter themselves more, and the necessity for a cover crop will not be so great. More cultivation must then be resorted to, as the trees will be taking more moisture out of the soil, and the cultivator will have to be kept busy throughout the entire season.

Pruning.—As a whole no class of fruit trees require less pruning than citrus trees· At the time of planting the young trees should be cut down to about 18in. to 2ft. When growth commences young shoots will spring out all along the stem. All shoots below a foot from the ground should be rubbed off, thus allowing a clean stem of at least 1ft. where the trees have been cut back to 18in. Where the trees have been left 2ft. high a clean stem of 18in. should be left. Some years ago it was the custom to grow high-headed trees having a bare trunk of 4ft. or over. Experience having proved that high-headed trees are more liable to suffer from strong winds, more liable to have their stems injured from sunburn, and that the fruit is not so cheaply gathered as from the low-headed trees; some citrus growers went to the other extreme, and headed their trees but a few inches above the bud. This made for a low bushy tree with branches very close to the ground, which brought a portion of the fruit into contact with the earth. Present Californian experience favors a tree with a clean stem from 1ft. to 18in. in height, which is practically the same that Australian citrus growers have adopted. Citrus trees usually make from two to four growths during the season. The young growth is often so rapid that it cannot support itself, and bends down until it touches the ground. It is not advisable to have the branches as low as this, as on frosty nights the cold is greatest nearest the ground, and the fruit is liable to be frostbitten. Therefore, whenever the branches bend down too low they should be cut back to an upward bud at the place where the downward arc commences. The main branches of a citrus tree should have an upward tendency. The natural drooping habit of a tree so trained will soon assert itself again through the formation of side branches, and through the weight of the fruit. Citrus trees that have become too dense in the head should be thinned out somewhat, to let in a little light and air, as darkness is conducive to the growth of insect pests. All dead wood should also be removed. The best time to prune citrus trees is during their growing season, that is, during spring and summer, and it is best not to leave the operation until too late in the season, as it is liable to force out late growth which may be injured by early frosts.

Manuring.—Of all the operations connected with the growing of citrus fruits the subject of manuring is one of the most important. However rich the soils may naturally be, through continually cropping they will sooner or later become impoverished unless sufficient fertiliser is applied to the ground to replace the plant food removed. The elements which enter into the composition of plants are carbon, oxygen, nitrogen, hydrogen, potassium, calcium, magnesium, phosphorus, sulphur, and iron. Of these, all except nitrogen, potash, phosphorus, and sometimes lime, are usually present in sufficient quantities for the needs of the trees. Of the three essential elements, nitrogen, potash, and phosphoric acid, nitrogen causes strong, vigorous growth, potash plays an important part in the formation of plant starches and sugars, while phosphoric acid is necessary to the formation of a class of nitrogenous compounds. known as proteids. Young citrus trees require a liberal supply of nitrogen if they are to make vigorous wood growth. When the trees come into bearing very large amounts of nitrogen are no longer necessary, as they impair the fruitfulness of the trees, wood formation taking place at the expense of fruit. Citrus trees of all ages should always be supplied with a liberal supply of phosphoric acid (phosphates) or the health of the trees will suffer, and the fruit will not develop normally. For the formation of citrus fruits a plentiful supply of potash is essential, as it plays an important part in the production of plant-starches and sugars, of which the fruit greatly consists. Harold Hume, of the University of Florida, the great American citrus expert, says of potash manuring in respect of citrus trees—"If large amounts of potash are taken up by the trees it will be found that the rind of the fruit will be much thinner than otherwise and the amount of rag will be greatly lessened. A plentiful supply of potash in the fruit has an excellent influence on its keeping quality. If too little be present the fruit will be soft and is likely to break down shortly after removal from the trees. To increase the keeping and carrying quality of citrus fruits a large amount of potash and a small amount of nitrogen should be used." The Agricultural Experimental Station of the University of California has computed that 800lbs. of oranges remove from the soil about 1⅞lbs. nitrogen, 2lbs. potash, and ½lb. phosphoric acid. According to these figures a crop of 200 cases of fruit, weighing roughly about 4 tons, would remove from the land about 24lbs. of potash, 6lbs. phosphoric acid, and 14lbs. of nitrogen. In addition to this provision must be made for an unknown quantity of plant food which leaches out of the soil, and for the food supply necessary for the tree to form new branches, roots, and leaves. Hume considers that the total plant food removed from the soil is about three times the amount removed by the fruit. Therefore, supposing that the 200 cases of oranges were produced from one acre of land, the total depletion of plant food would amount to 72lbs. potash, 18lbs. phosphoric acid, and 42lbs. nitrogen to the acre. As the chemical fertilisers in use only contain from 16 per cent. to 50 per cent. of the necessary ingredients of plant food, the grower will have to use about 1½cwt. of muriate or sulphate of potash, 1cwt. of phosphate, and 2cwts. of sulphate of ammonia to make good this loss from the soils. The demands of young and old trees being different, the fertiliser supplied to the soil should be different in character. Young trees require a large amount of nitrogen, while bearing trees require relatively less nitrogen and more phosphoric acid and potash. Hume considers that for young trees the fertiliser should contain about 4 per cent. nitrogen, 6 per cent. phosphoric acid, and 8 per cent. potash, while one containing 3½ per cent. nitrogen, 8 per cent. phosphoric acid, and 12 per cent. potash should be applied to bearing trees.

Renmark and Mildura Practice.—To obtain information regarding the manuring of citrus groves along the Murray I have asked some of the leading citrus growers for their ideas on this subject, and the following are some of the replies:—Mr. W. E. Muspratt, of Renmark, says that on good virgin land orange trees should not require manuring for the first five years; at six years 2cwts. bone super., 1cwt. potash, and the ploughing in of a green crop of peas to supply nitrogen; but when the trees are full grown half a ton of fertiliser to the acre would not be too heavy a dressing. Mr. T. S. Dove, of Mildura, uses half a ton of blood manure, 6cwts. of bonedust, and 1cwt. of potash to the acre. Mr. Dove is of the opinion that organic manures are best for citrus trees, and believes in the regular ploughing in of green crops of peas, tares, and vetches. Mr. F. W. Pickering, of Mildura, recommends for trees in full bearing 3cwts. blood manure and 3cwts. bonedust to the acre every alternate year, and a cover crop of field peas and beans mixed every other year. The cover crop should be given a dressing of 2cwts. of superphosphate to the acre at time of planting, and when mature should be disked in and not ploughed in. The citrus groves planted on the fertile Berri slopes will probably not want much manuring for some years to come, but when fruiting commences a good supply of potash will have to be given to the trees. In land so well supplied with nitrogen as most of the Berri land is, where the native vegetation was dense, the disking in of cover crops of peas or vetches to add nitrogen to the soil is hardly necessary for a start, but will, no doubt, have to be resorted to in years to come, when this class of plant food becomes depleted. For citrus trees planted on stiff clay soil, the disking in of cover crops to add nitrogen and humus to the soil should be commenced early, so as to get the soil into a loose, friable condition.

Pests and Diseases.—The South Australian portion of the Upper Murray Valley is in so far favorably situated for the growing of all kinds of fruit as it is practically free from insect pests. The greatest of all citrus pests, the red scale, seems to be unknown here, and it is to be hoped that it will remain so. The *red scale* is a small circular insect of a somewhat reddish-brown color, which increases very rapidly under favorable conditions. The only effective way of getting rid of it, should it make its appearance in a citrus grove, is by fumigating with hydrocyanic-acid gas, which is generated by treating potassium cyanide with diluted sulphuric acid, the gas being liberated under a tent which covers the tree. The genus of *Lecanium*, or unarmoured scales, are more widely distributed. Of these, the *brown scale* is the most common. The full grown insect is about one-eighth of an inch long, broadly oval, convex upon the disc, surrounded by a thin flat margin, and of a brownish color. This scale lives upon the bark and leaves of the branches of the trees, especially those not exposed to the sun and air. The brown scale is fairly common along the Murray Valley, and although not of so dangerous a nature as the red scale is, nevertheless, best got rid of. The treatment consists of fumigating for very bad cases, and of spraying. Spraying with red oil or kerosine emulsion is effective. Kerosine emulsion is the better of the two, as it does not burn the leaves so much as red oil does. I have found the following formula for kerosine emulsion very effective:—Two gallons of kerosine, ½lb. soap, 1gall. water. Dissolve the soap by boiling in the gallon of water. Take off the fire and add the kerosine slowly, churning the mixture with a spray pump for 10 minutes or so until a stable emulsion is formed; then add another gallon of warm water to bring up the solution to 4galls. The best time to spray is in the summer months in between the growths, when the trees are dormant. For spraying at such times, dilute each gallon of the emulsion with 10 of water. I have not found this preparation too strong for the trees. Should the trees be in active growth, however, 15galls. of water to one of emulsion will be strong enough. Spray at intervals of a fortnight for two or three times, which ought to be sufficient to eradicate this scale. One of the worst diseases of citrus trees in America is mal-di-goma, or foot rot. It is also prevalent in Australia, although not to so great an extent. Foot rot attacks citrus trees at the crown roots, extending a foot or so above the ground and downward among the roots. The presence of the disease is first noticed by the discharge of gum at the diseased spot. Later on the bark rots away, and the tree eventually dies. The disease seems to be caused either by water standing around the roots, the crown roots becoming injured through careless cultivation or otherwise, or too deep planting. As these matters rest greatly in the hands of the grower, the careful orchardist will see that his trees do not needlessly suffer from these causes. Where the land has to be flooded to water the trees, the trees should be budded on the Seville stock, as American experience has amply proved that both sweet orange and lemon stock are liable to suffer from foot rot if planted in wet situations.

Yields and Prices.—Compared with most varieties of fruit trees citrus trees come rather late into bearing. Although a few fruits may form in their third year, citrus trees do not usually bear a paying crop until they are seven years old, while they are usually not in full bearing until their tenth or twelfth year. The average Californian crop per orange tree is about one and a half cases of about 80lbs. each, or about 120lbs. per tree per annum, according to statistics lately published in the *Pacific Rural Press*. Of what I can see from the information I have gathered from riverside settlers, the average crop of a full-grown tree along the Murray Valley is about four cases. At present prices this is a very paying proposition. To secure the best prices for his fruit the grower must be very careful in the harvesting and handling of his crop. As an orange is easily bruised and injured by the finger nails of the picker entering the rind, gloves should be worn by the picker, and the fruit picked into a padded picking bag. From there it should be carefully placed into cases, the fruit being placed in, not tipped or rolled in. After the fruit has been brought into the storeroom it is usually placed on shallow shelves, and allowed to remain there for a few weeks until a great portion of the moisture has dried out of the rind. This process, which is called "curing," causes the rind to become tough and leathery, thereby rendering the fruit safer for shipment.

The Over-Production Bogey.—With hundreds of acres of oranges now being planted along the Murray as well as at other places, the question naturally arises what the future of the citrus industry is going to be. In more than one quarter the idea has been expressed that the orange is being overplanted, and that citrus growers will soon be faced with an over-production of their fruit. One thing appears certain, and that is when all the recently-planted groves of Washington Navels come into bearing, the price of this fruit will fall, and growers will have to be satisfied with much lower prices than are at present obtaining. Washington Navels at 10s. per case wholesale are rather a dear article for the average Australian working man to buy by the time he purchases them from the retailer. It is no doubt a fact that for the average Australian the navel orange is still a luxury. Were the prices of navels reduced by one-half, I have no doubt that the Australian consumption of this fruit would be enormously increased. I believe 5s. per case at the orchard for Washington Navels would still be a paying proposition for the grower. Even at the small average of two cases to the tree, and allowing 100 trees to the acre, the gross return to the grower would still be £50 to the acre. Allowing £12 for cultivating, £6 for manures, £2 for water rates, £3 for picking, and £2 for other expenses to the acre, the grower would still clear £25 net per acre.

Export Prospects.—Even at such cheaper rates, should the production exceed the Australian consumption, exporting will have to be resorted to. Australian oranges arrive in Europe during July, August, and September, when the market is bare of citrus fruits. There should not be any great difficulty in opening up a big trade with England, Germany, France, and perhaps even with the United States of America, if we can land a good clean article in these countries, So far Australian oranges have not shipped too well to Europe, a great proportion of the fruit going bad on the way; but with careful picking, careful packing, pre-cooling at the shipping port, and the keeping in cool storage on the voyage at an even temperature, there seems no reason why oranges should not be as successfully shipped to Europe as other fruit. The few Australian oranges that have been sold in England have realised about £1 per case. At this price there is but a limited demand. Major Norton, the South Australian Trade Commissioner, says that at 12s. per case, about 30,000 cases of Australian oranges could be sold in England per annum. Even at this price the majority of Englishmen could not afford to buy Australian fruit. Through the expenses of transport, Australian oranges could not be sold any cheaper in England than 10s. per case, if they are to yield the grower a payable return. As the English demand for such priced fruit is limited, the markets of such prosperous and populous countries as Germany and France would no doubt pay for exploitation. The idea has often been expressed that the Washington Navel as grown here is too large, and that for export purposes an orange should be sent home that would retail for a penny apiece. There does not seem much prospect of ever selling the Navel at a penny apiece at a profit. Even allowing as many as 120 oranges to the case, and the case at 10s., this would still work out at a penny each wholesale. The only orange that would perhaps pay to retail at a penny apiece in England in the Mandarin; and the variety Dancy's, said to transport well in America, may possibly fill the bill. Should the local over-production of oranges become so great as pessimists predict, the citrus growers of Australia will have to form themselves into a co-operative body, as has been done by the citrus growers of California, and, like the Australian Dried Fruits Association, keep up profitable local prices and export the surplus.

Conclusion.—In conclusion, I would like to remark that there is, perhaps, no horticultural industry in which the personal factor counts for so much as in citrus-growing. Right from the time the young trees arrive at the orchard until years later, when their fruit is packed ready for shipment, the citrus grove will require the constant care and attention of the grower. No class of fruit trees respond more readily to good treatment than citrus, and no trees do worse if neglected. The grower who gives his grove intelligent attention will receive his reward in profitable crops, while the man who neglects his trees will have to carry on his grove at a loss. But if the grower has located his grove on a situation having perfect air and water drainage, plants good trees, irrigates intelligently, cultivates well, manures liberally, sprays or fumigates for insect pests if necessary, and harvests his crop with care, there is no reason why he should not make a financial success of his undertaking, as hundreds have done in the past, and as hundreds are still doing.

Discussion.—In the discussion which followed the reading of Mr. Arndt's paper, Mr. Taylor said that the wonderful influence of gypsum in ameliorating stiff and clayey soils should not be overlooked. Many thousands of tons of gypsum had been used at Renmark with the happiest results. Very few Valencia Late oranges were grown in Renmark, but in Mildura this orange had proved even more profitable than the Navel. Several shipments of 1,000 cases of Washington Navel oranges had been made from Renmark to London. It was true that as high as £1 a case had been realised for some of this fruit, but 16s. would probably be nearer the average. Mr. Moss said that at Salisbury the Thompson Improved Navel produced a larger and heavier fruit than the Washington. Being a more solid fruit it would probably export better than the ordinary Navel. Salisbury experience, also, was in favor of a heavy soil for fruit quality. A hearty vote of thanks was accorded Mr. Arndt for his paper, the Secretary (Mr. Lewis) remarking that it was the most valuable ever read before the Bureau.

BORRIKA.

May 9th.—Present: 24 members and seven visitors.

Breaking Horses to Saddle.—The following paper was read by Mr. Geo. Back:—"Horses differ considerably in temperament, and the measure of success which attends the breaker's efforts will depend a great deal on his ability to adapt his methods accordingly. Experience and observation of the operations of a professional are essentials which no amount of theoretical knowledge can replace. Nevertheless, the breaking of an ordinarily quiet-natured, farm-bred colt or filly does not present insurmountable difficulties to a horseman of average intelligence, judgment, and activity. *The Yard.*—It will serve no good purpose here to go into elaborate details of an enclosure designed on purpose for this particular job. The main point to be considered is to be sure that the yard is strong enough and high enough to successfully baffle all attempts at escape on the part of the horse. It should be large enough to enable the breaker to keep out of the danger zone of the colt's hoofs when occasion demands. As most farmers' horse yards are rectangular, it is advisable to put a few rails across each corner. This will greatly facilitate catching operations, and in subsequent manœuvres the colt will not be liable to get the breaker cornered. A stout post set solidly in the ground should be placed near the centre of the yard. It is well to have no projecting ends of rails, or any obstacle which would injure the horse whilst rushing about or falling. *Apparatus.*—The apparatus necessary includes a catching rope about 50ft. in length, strong enough to withstand any neck-pull, and not so large as to be inconvenient for throwing. A steel ring should be fixed at one end, which, when a noose is formed in the rope, will allow it to run freely. A couple of large-sized ropes, about 16ft. long, to be used as leg ropes. A ring at an end of each of these will also be of value. A hobble chain, with a swivel and pair of strong straps. Another piece of chain with a large link at each end, and long enough to reach from the fore-foot to the hind-foot, on the same side, and another hobble strap. A length of strong plough or leading reins, and one or two short pieces of line about as large as is usually required for couplings. An old saddle of any description for the horse to fall about on if he so desires. A strong bridle with neck strap, chin band, and nose band, with a detachable bit. It is advisable to have a proper mouthing bit, with keys in the centre. In any case do not use a narrow bit; it cuts the corners of the mouth too much. For choice, the saddle for the rider's use should have large knee and thigh pads and a deep seat. It should have girth, surcingle, and crupper, all of good quality. The stirrup-leathers should be strong, and the stirrup-irons of large size. When attaching the stirrup-leathers to the saddle, do not raise the latch at the back. By observing these precautions the rider runs less risk of being dragged in case of a fall. For the same reason do not ride in boots with toecaps, low insteps, half-soles, or soles studded with large-headed nails. Elastic side boots are preferable for rough-riding. In all dealings with partly-broken horses remember the motto—'safety first.' Have two or three discarded branbags handy. *Catching.*—I will take the case of a colt which has not previously felt the touch of the human hand since he was branded, possibly some two or three years previously. Get him into the yard along with a handy and docile worker; the said worker having on a pair of winkers with a short rein or coupling attached. Form a running noose, about 12ft. in circumference, in the catching-rope. Stand near the centre of the yard with the noose held in the right hand, and the remainder of the rope coiled in the left. Cause the colt to move around from right to left, so that when the noose is thrown it will fall from behind the horse's head. You will probably not succeed at first throw, but when the cast is successfully accomplished draw the noose tight as quickly as possible. When opportunity offers pass the free end of the rope around the centre post and pull up the slack. Have your assistant (if one is available) frightening the horse from behind. When the colt's head is brought close to the post let the assistant take hold of the rope. Now take hold of the bridle, which should have the bit unfastened on the near side, and the chin strap undone. Stand behind the post and, stroking the animal's face with the left hand, gradually pass the bridle into position with the right. If, during these proceedings, the colt chokes down, immediately slacken the rope. If he falls to the ground it is a good opportunity to fix the bridle, but be careful not to be struck with the fore-feet if the colt endeavors to recover when the bridle is fixed. Next blindfold the horse, using a folded bag, and make sure that he is blinded. Slacken the rope off a trifle, so that he can breathe freely. Now proceed to fix the hobbles and side line. This can be accomplished by putting the before-mentioned quiet horse between you and the colt. Stroke the colt's legs lightly with a stick before putting your hands close to them. Having completed hobbling the fore-legs and fixing a side line between the near fore-foot and the hind leg on the same side, undo the rope from the post and make a hitch under the colt's neck so that the noose cannot tighten, then pass the end of the rope through the near side bit ring, and take away the blindfold. Fasten a bag to a stick about 5ft. in length and quietly flop the colt about the neck, legs, and body, on both the near and off sides. Of course, the colt will endeavor to make off whilst this operation is in progress, but having three legs shackled he cannot get away very fast, and after some time he will become tired of trying to escape and stand. Keep on bagging him until he will let you get close enough to get your hands on him. Then pat him, commencing about the neck and shoulders, and gradually working back towards the tail. If he resents, get the bag to work again, and continue at this until he stands quietly while you handle him. Also raise the tail as though about to fasten a crupper. This handling should be done on the near side, that being the side where the hind leg is shackled. It can be more expeditiously accomplished if the assistant holds the head slightly towards the operator. Now put an old saddle on the colt, with crupper, &c., also an old collar, as it is as well to get him accustomed to these as soon as possible. Handle him on the off side in the same manner as was done on the near side. When he submits quietly, proceed to pick up the legs as required for shoeing, commencing with the fore-legs. To get at the hind legs take a strong piece of rope and form a noose, fastened so that it will not tighten, and placed around the neck just in front of the wither. Now get the colt to put his foot into a loop formed by the remainder of the rope, the end being drawn back inside the noose close to the neck, a turn being taken around the noose so that the leg can be drawn up as the horse kicks, and retained there. Keep at his legs until the colt will allow you to pick up his legs without trouble. Now dispense with the hobbles and side line, and start teaching the colt to lead. *Leading.*—Fasten a pair of driving reins to the bridle and persuade the colt to walk about the yard in front of you. Endeavor to turn him first to one side and then to the other. If he is sulky, give him a spell for a while and then try him again. He will be very awkward at first, but will gradually improve. These exercises will fully occupy the first day. Tie a piece of rope around his neck to enable him to be more easily caught next morning. Take the gear off and let him loose for the night. On the second day get him into the yard again with a quiet horse, and with a little trouble you should be able to catch and bridle him. Only on rare occasions is it necessary to rope the colt a second time. Pick up his legs, as on the previous day. Get the driving reins on again and pull him about as described before. When his mouth has become fairly tractable, it is well to continue the driving operations outside the yard. Have one rope around his neck and through the bit ring. This gives the operator a better chance if the colt tries to get away. It will probably require two men to hold the colt when he is first taken out. When you find that you can stop the colt and pull him to either side as required he will probably lead without much trouble. Take him back to the yard. Select a strong post, preferably outside the yard, and tie him to it by means of a strong rope fastened around the neck so that it will not tighten, and through the bit ring on the near side. Now endeavor to cause the colt to pull back by waving a bag or similar article before him. Do this several times until your pupil has satisfied himself that he cannot get away. Then leave him tied up for a short time. If this lesson is learned thoroughly you should have no trouble in the future with broken bridle reins. The colt's education should now be far enough advanced to enable you to mount him; for which purpose take him into the yard. Mounting a colt correctly takes a little practice, and if you have had no experience in rough-riding, it will pay to take lessons on a quiet horse first. Put the reins over the neck in the usual manner. Take a firm grip of the mane with the left hand slightly forward of a point half way betwixt the withers and the ears. Draw the near rein as tightly as the horse will allow without his backing or rearing. The off rein does not require to be held so tightly. Stand close to the horse's neck and take the stirrup in the right hand. Place the left foot in it so that the ball of the foot is on the bar. Do not place the foot right in. Allow the left knee to press against the horse's shoulder. Grip the pommel on the off side with the right hand. A monkey strap is very handy in mounting. This is a loop fixed to the two front D's on the off side of the pommel, just large enough to allow of a grip being taken. It affords the rider a firm and sure hold. From the rider's position, as already described, it takes only the faction of a second for him to swing himself into the saddle. In mounting a colt for the first time, however, it is well to do this gradually. Raise the right foot slightly from the ground and then come back again several times before finally crossing the saddle. Keep the hands in the positions described until the right foot is in the off stirrup. In dismounting use the same holds and alight close to the horse's shoulder. After mounting, ride around the yard a few times. Then let your assistant open the gate, mount a horse himself, and accompany for a short ride in the open. If the colt is inclined to go quietly, do not bustle him. There is no necessity to make him buck, and if you have handled him well he will probably not do so. At the same time be prepared for emergencies. He will, of course, be awkward to guide during the first few days, but by the exercise of patience and watchfulness on the part of the breaker, the colt will soon become resigned to his fate."

Cocky Chaff.—The Hon. Secretary (Mr. C. W. B. Traeger) contributed a paper. The best method of feeding cocky chaff to horses, he said, was first to sieve out the roughage, and then add for each feed a pint of molasses, sufficient water to dampen it, one pint of pollard, and one pint of scalded oats. One pint of bran could also be added if it were thought desirable. Boiled wheat was too heating. Roughage removed from the chaff could be fed last thing at night.

CLAYPAN BORE (Average annual rainfall, 16in. to 17in.).

May 5th.—Present: 10 members.

Selection and Pickling of Seed Wheat.—Mr. H. Colville read a paper on this subject. In the discussion which followed, the Hon. Secretary (Mr. L. McCormack) explained that smut was a fungus The most effective method of destroying it was to pickle the wheat loose in a trough. If dipping were practised the wheat should be in moderately free bags. Mr. J. Entwistle used the McCabe pickler, and Mr. J. Gray spoke in favor of this. Not only were the grains thoroughly pickled, but the smut balls floated to the surface, and could be skimmed off. The process was slow, however, and ordinarily, dipping in bags was quite effective. After smutty wheat had been put through a drill it should be thoroughly cleaned.

COONALPYN.

May 8th.—Present: eight members and three visitors.

Sore Shoulders.—Mr. A. Samwell, in a short paper, said the best preventive measure to adopt for sore shoulders was to wash the horse's shoulders after it came in from work, and work it with a clean branbag under the collar. The bag should be washed at least every other day, and thoroughly dried before being used. Greasy substances applied to sores collected dirt. The causes of the trouble were feeding too much grain after the animal had had a spell, or working a newly broken-in horse in sultry weather, when it was apt to become overheated. Members thought the advice good. The Hon. Secretary (Mr. G. E. Venning) advised the use of well-fitting collars, the moderate feeding of corn, especially wheat, and reasonable work after a long spell.

FORSTER (Average annual rainfall, 10in. to 11in.).

May 9th.—Present: five members.

Water Conservation.—Mr. J. Searle, in a paper dealing with this subject, said the cheapest and surest method of securing a water supply in this district was by means of a bore. This should be as close to the house and stables as was possible. The drawback with a well was that timber was expensive, and did not last for any length of time. Mr. E. Towill thought a bore more satisfactory than a well. Mr. W. Searle preferred a well timbered with gum. It was a good idea to case the well with iron. To avoid working in water when sinking, he would use a well pump with a 4ft. length of pipe on top.

Cultivation.—Mr. E. Towill thought nothing was gained by ploughing in stubble, as this practice encouraged takeall. Mr. W. Searle would not burn straw if it were wet enough to plough down. Ploughed under in sandy soil it would prevent drift. Mr. J. Searle favored early fallow; his practice was to crop, graze, then fallow.

MANTUNG,

April 9th.—Present: six members and four visitors.

English Lads for South Australian Farms.—Mr. J. N. Baker read a paper on this subject, in which he commended the proposition. Boys of the right type could be profitably employed on any farm. A resolution was then carried in favor of the scheme.

Windbreaks.—Mr. A. Tonkin read a short paper. He had noticed cases in which large areas of sandy country were completely cleared of timber, with the result that considerable trouble was experienced with drift. He thought it wise to leave growing scrub on the tops of the sandhills, and a strip of timber along boundary and division fences where practicable. In this district, even on the stiffer soils, it was advisable to leave timber for shelter to both stock and crops. Mr. Stewart said it was very hard to save mallee, as the scrub burn killed it. Mr. L. Pearce thought mallee took too much out of ground. He advised planting pines in clumps; not in strips. Mr. Hannaford thought pines hard to grow. Mr. Baker would not leave scrub on sandridges. He thought shrubs preferable to trees for windbreaks. Every farmer should plant a few trees each year. Tamarisk was very suitable. Mr. J. P. Tonkin agreed; this plant also provided good stock feed in dry seasons.

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).

Present: 17 members and two visitors.

Mallee Land.—In a short paper dealing with working mallee land, Mr. G. Gogol advised first firing the rubbish and then picking up and burning any that remained. The land should be ploughed as early as possible and left to the sweetening influences of the weather. Stubble or grass land should be ploughed after rain. Seeding should be completed by the end of June, and mallee shoots cut as soon after as possible. Stiff land should be fallowed early; sandy land, if fallowed, was liable to drift. One member advised the use of the firerake.

PARILLA (Average annual rainfall, 16in. to 17in.).

May 7th.—Present: 14 members and two visitors.

Mixed Farming.—Mr. M. Shannon read a paper, as follows:—"This district is well adapted for mixed farming on account of there being an abundant supply of good water for stock and for irrigation purposes. It is a great advantage to be able to keep stock all the year round and to grow fodder crops for summer use. A portion of the farm should be in crop, a portion fallow, and the balance out for grazing. Oats can be sown on the stubble land that is left out for grazing purposes, and peas, rape, sorghum, &c., can be sown on the early fallow. Lucerne will do well and give a good return in summer with irrigation. Sheep pay well on farms in settled districts, but it is questionable whether cattle would not pay better in this district, as wild dogs are so troublesome. Cattle do not require much attention, while sheep have to be yarded every night. Stock are required on the land in order to keep it free from weeds. It is much better to send these to market in the shape of beef and mutton than to be continually cultivating the land during dry weather. Any good mares on the farm can be utilised for breeding purposes so that losses can be replaced. By keeping a few cows and fowls, which do not require much attention, the domestic requirements can be supplied and the storekeeper's account reduced, but to go in extensively for mixed farming and to neglect the more important factor on the farm, viz., wheat growing, would be a mistake. Where a farmer has already made a good start in mixed farming and has a number of boys and girls to do the work, then he could operate on a more extensive scale, and success would almost be assured." Mr. Lewis thought sheep a better paying proposition than cattle in this district. Dogs were not so troublesome as was generally supposed. Lucerne grew very well in the low-lying country. Mr. Cyril Foale thought it difficult to irrigate any considerable area of lucerne. He advised mixing about 2lbs. of lucerne seed per acre with the super. when seeding, this would provide greenfeed in the stubbles. Mr. G. E. Gregory strongly advocated keeping sheep. Mr. A. J. Stevens thought sheep more profitable than cattle in this district. He advised farmers to sow a good proportion of oats each year to ensure a stubble burn and thus destroy mallee shoots. Mr. C. E. Moyle advised farmers to keep dairy cows and sheep. Breeding mares were also profitable. Mr. J. J. Foale expressed the opinion that sheep were very profitable. They involved little trouble and improved the land. Poultry and dairy cows should also be kept. Mr. J. Gray (a visitor) had found that sheep would do much better than cattle in this district, as the feed was sometimes too short for the latter. The returns from a few sheep would more than pay the interest on the cost of fencing the farm. Pigs, poultry, and vegetables were very good paying lines. Water could be pumped by engine power at a cost of 1s. per 1,000galls.

PARRAKIE (Average annual rainfall, 16in. to 17in.).

April 18th.—Present: 13 members and four visitors.

Afforestation.—Mr. H. Diener read a paper, as follows:—"Tree planting has been sadly neglected in this State. The natural timber has been ringbarked and burnt, and little or none has been planted to replace it. This ruthless destruction of our valuable trees will ere long prove itself expensive. The world's timber supply is diminishing so fast that it is only expected to last a few years longer. At the present time nothing is being done in this State. There are thousands of acres of land along roads and railways which could and should be planted with trees. Apart from their value for timber, their beauty and usefulness as windbreaks and shelter for stock are sufficient justification for planting them. They also help to increase the rainfall. Around Mount Gambier a little tree planting was done many years ago, and the lonely clumps of pines help materially to beautify the district. I do not claim that equal results would be obtained everywhere, but from Murray Bridge and Port Victor to Eudunda and Crystal Brook and Petersburg the soil and rainfall are quite good enough to grow good serviceable timber. Every farmer should plant a few acres of trees, especially in this district. With the sandridges running east and west a good plan is to plant a strip a couple of chains wide across the flats. These break the wind and provide shelter for stock. The sugar gum stands easily first as the most suitable tree to plant. It grows quickly, is shady, when not too young makes good timber, and is very hardy, growing well even in a dry district. The red gum is nearly as good, and stands the frost better than the sugar gum. Pepper trees make good shade and shelter, but are of no use for timber. Poplars would be suitable for windbreaks, as they grow very tall, and a few acres of tree lucerne would always be a help in a time when feed was scarce. I have seen New Zealand swamp oaks in this district doing well. They grow very quickly."

Mr. R. L. Beddome also read a paper. He said—"The question of afforestation is one which is claiming attention all the world over, and is of vital importance in Australia, where the area under forest trees is naturally very small. The forest area of Australia has been depleted at such a rate that already the supply of timber has almost reached the vanishing point. There are other aspects to the tree question, however, which are of equal or even greater importance to this country, and which, strangely enough, have barely been recognised by a great number of people. The connection between trees and rainfall is acknowledged in all the older civilised countries, and it is generally regarded as an axiom that the presence of trees materially increases the average rainfall. In Australia this fact is by no means generally admitted, though it is well known that a timbered country as a rule enjoys a greater rainfall than one which is bare of timber. In the newer mallee districts of South Australia and Victoria it is, of course, impossible to come to any definite conclusion, as a very great area is still covered with scrub. If the present reckless system of clearing obtains for many years we shall probably find that the average yearly rainfall will be appreciably diminished, and everyone must admit that such a result would be disastrous to the prosperity of the district. Surely it would be wise to take advantage of the experience of other countries in this matter, and either leave a certain proportion of the country under its natural timber or else substitute a vigorous policy of tree cultivation. Another and probably the most important aspect of the question, as it affects our own district and other mallee districts with a light and sandy soil, is the necessity for windbreaks for the purpose of checking the drift of sand and for providing shelter for stock and crops from cold and hot winds respectively. As the country becomes cleared of scrub the winds are certain to be more troublesome, particularly in a flat or mildly undulating area, such as that constituting the South Australian mallee. The prevalence of high winds, particularly in spring time and during the ripening period of the crops, has a very detrimental effect on the grain yield; so that it behoves us to obtain for the crop as much shelter as possible. For the purpose of windbreaks and stock shelter the natural timber of the country, viz., mallee, would appear to be at once effective and economical. Tree planting on a scale to be of any practical use would be too expensive to be undertaken by individual farmers, or even by district councils, and would probably tax the resources of the Government. This district hardly lends itself to the cultivation of any really useful timber, though, no doubt, sugar gums flourish when once established, and probably many kinds of pines would do well and prove useful for reducing the wind velocity. The planting of trees to be any distinct advantage, however, would be a very large undertaking and of doubtful success. Of course, many bushes and shrubs could be established which would serve a useful purpose, and would involve a very much less expense than the planting of trees. Tagasaste, tamarisks, African boxthorn, and many other plants will grow fairly readily without much attention, but any purpose served by such bushes would be served quite as effectively and infinitely more cheaply by mallee. The great drawback to the scrub is that it harbors rabbits. In my opinion the simplest and most effective scheme that could be adopted would be for all landowners to retain a moderately broad strip of scrub round each paddock. A mere fringe of scrub or bushes does not offer any serious check to the wind, and would simply encourage the formation of sand drifts. To be really effective the windbreak should be at least three chains wide, and the advantage gained by the protection of the crops from the wind would easily compensate farmers for the additional trouble in coping with the rabbits. By pursuing such a policy we should reap a double advantage—check the ill effects of the wind and also ensure an appreciable amount of timber for the purpose of inducing the precipitation of rain." Mr. Temby did not favor the growing of sugar gums, as they had a tendency to rot off at the ground when about three years old. He favored blue gum for growth and timber, but would not have them for windbreaks as they grew too tall. Pines, if planted thickly, would answer better. Mr. Beelitz grew Aleppo pines, sugar gums, and New South Wales swamp oaks. The lastnamed was the hardiest and fastest grower. Sugar gums were affected by frosts, whereas the New South Wales swamp oak was not. Mr. Diener contended that a tree to serve as a windbreak should be one that grew high. A tree that grew thick and bushy blocked the wind altogether. Mr. Jose favored growing bamboos between pines or gums. These could be utilised as feed for sheep.

PINNAROO (Average annual rainfall, 16·74in.).

May 9th.—Present: 25 members and two visitors.

SANDDRIFTS AND WINDBREAKS.—A paper was contributed by Mr. Josiah Bonnin. He said—"I do not think drifting sand will ever be such a serious matter with agriculturists as it is with some pastoralists. My reason for this belief is that farmers have always a ready means, with their ploughs and drills, of checking it by sowing a crop of some kind. Once a crop starts to grow, and stock are kept off it—and this is imperative—it will soon form a crust of roots and stalks that will check and ultimately stop the drifting sand. With sheep it is different, and unless the drift is fenced off as well as sown it will never be prevented, for the feet of the sheep soon break up the surface again, and should this be on a bit of a rise or hillock, it is just the spot healthy lambs will select to play upon, and break up as bad as ever. Sanddrifts to a pastoralist, in addition to, perhaps, covering up some of his best grass land, are very detrimental to the fleeces of the sheep, much depreciating the selling value of the wool. On the estate that I managed for so many years, I had to deal with small sanddrifts constantly, and learnt, first of all, that it was necessary to fence off the drift, to entirely keep the stock off it. The next step was to sow it with something hardy. I tried several things, amongst them rye and evening primrose. The former was by far the most successful; it usually stopped the drift the first year. After sowing, we left it to seed itself. After about three or four years it would run out, but by that time, what with the old roots and stalks of the rye, and the native grasses and herbs that sprang up, a good surface would be formed, which, so long as the stock were kept off it, would not drift again. Where the drift was upon the face of a hillside that was much exposed to the wind, the method adopted was to strew branches of trees and leave them there; or to dig up the ordinary coarse tussocks of that part and strew or pack them over the surface. In the poorer class of white sand we tried planting marram grass, and this did very well on the low sandhills near the edge of the lake, and formed, as well as a check to the shifting sand, a rough fodder for the cattle when the seasons were late or backward. But this grass, although it would grow in the red sand, was not a success there, and spread but slowly; therefore I do not think it would be a success in this district. It is, besides, expensive to plant, each root having to be put in separately. *Roads.*—Sanddrifts are a great nuisance to district councils by reason of the cost they involve in keeping the road clear, and especially metal roads. I was in one council where, in order to check the drift which was covering the road, we were put to the expense of fencing off the drift and planting it with rye (for the owner of the land declined to do this), besides the cost of scooping hundreds of tons of sand off the metal, which was on the main road to the Wellington Ferry. Before leaving the subject of drift sand, I am of the opinion that it would be wise to leave strips of mallee growing on the poorer sand rises to act as windbreaks. These would check the drift—likely enough, prevent it altogether—besides forming a shelter for stock and fuel for the future, when the mallee is scarce, as most assuredly it will be in the not very far distant future. *Windbreaks.*—It is unnecessary for me to point out to you how useful shelter is for both livestock and trees, if they are to be grown profitably. All I can do on this subject is to let you know the names of the trees I have had planted and grown on an exposed sandhill near the shore of the lake, for both ornament and protection to the homestead, and to tell you how they succeeded. Those trees that grew and did best, and I name them in the order of success, are, first the tamarisk, the pepper tree, lagunaria, white cedar, hardshell almond, myoporum, some sugar gum trees, and a tree named phytolacca—the latter is an Algerian native, I believe, which grew up into fairly shady trees. The pine trees were *Pinus insignis* (Remarkable pine), *P. Canariensis*, *P. Maritima*. The pines were very slow in growth, never reached any height, and only did moderately well, and did not appear to appreciate the strong west and southerly lake winds; the best, however, were the *Canariensis* and *Insignis*. The *P. Maritima* were a disappointment, for we had hopes that these would do well, as they flourished on the sand dunes on the west coast of France; but those we tried were straggly, poor specimens, neither useful nor ornamental. The trees that suited the locality best were the tamarisk, and they did very well indeed, and there is one now growing that must be about 25 years old with a short trunk pretty well 2ft. in diameter. I believe that on Hindmarsh Island the tamarisk has been tried as a hedge plant. This tree is very easily grown; it only needs the young green shoots to be stuck into the ground when it is wet. The next most successful tree was the pepper; it did very well, but was mostly of a straggly growth, and very hardy, if not very ornamental. It is, however, a great robber, and extends its roots a great distance in search of moisture. The *Lagunaria* grew fairly well; they were hardy and pretty trees, but scarcely suitable as shelter trees, and were comparatively slow growers. The white cedar did well and was an ornamental tree. My successor has planted a few more since I left the estate, but this tree can hardly be called a shelter tree. The *Myoporum* (otherwise named on the sea coast as the 'cockatoo bush,' for some unknown reason) did very well; it is very hardy and an evergreen, and might be useful as a shelter plant. The hardshell almonds did very well and were hardy, and make good stocks for peach and nectarine, and, I believe, apricot grafts. I had some peach and nectarine grafts put on to one of our almond stocks by a professional gardener, and they did very well indeed, until they were one day wrenched off by a heavy south-west gale of wind. We had a couple of fig trees that did well and bore delicious fruit. There was also one mulberry tree that did fairly well in a sandy hollow, but the birds had most of the fruit. The whole of these trees, with the exception of the mulberry, were grown on a whitish-grey sandy rise, and I feel perfectly sure they would mostly all grow well in this district, where the sand and subsoil is much superior to that of the sandy rise mentioned, and with a very similar average rainfall of about 15in." Members evinced much interest in the paper. The Chairman (Mr. P. J. Edwards), in urging the importance of planting trees, said his experience was that sugar gums were easily the best for stock shelter in this district. These were more rapid in their growth than any others he had tried.

WILKAWATT (Average annual rainfall, 16in. to 17in.).

May 9th.—Present: 20 members and four visitors.

GREEN FODDER IN MALLEE LANDS.—Mr. M. Neville read a paper. He said—"It is not necessary for me to emphasise the need for green food for all classes of stock on the farm, especially during the dry periods of the year. For a summer crop I prefer lucerne, which can be profitably grown on almost any class of mallee soil. We have been very successful with a plot of this fodder on the side of a white sand rise. From October till May we have had six cuts, the second and third cuts ranging from 2ft. to 2ft. 6in. in height. In a favored spot it reached a height of 3ft. A piece of red sand would have produced at least two cuts more during the same period, and the labor entailed would have been 25 per cent. less than on the white sand. For convenience in irrigating I prefer a gentle slope; this, at the same time, answers admirably as a drain, which is important in lucerne cultivation. Farmers in new country, who are about to lay out a homestead, should place the bore at the top of a red sand rise. if it is possible, and reserve a good area of this for growing fodder crops and for garden plots. For lucerne, one essential is a perfect seed bed; well-worked fallow being admirable. Before fallowing dress the land heavily with stable manure, and all weeds germinating from it can be destroyed. The end of July, the following year, should see the fallow worked lightly, after it has been thoroughly rolled and a liberal dressing of superphosphate applied. Grade the plot as soon after as convenient, and form a small bank on the three low sides, to prevent waste of water. This being done, work lightly and sow evenly over an acre 10lbs. of South Australian harvested lucerne seed, which will make a nice thick crop. Cover the seed with at least 1in. of soil. When it germinates on the surface it never stools as well as the plant that has a firm root hold. Good fallow will contain an abundance of moisture to germinate the seed and maintain the young plants until late in the spring, when the plot can be irrigated without fear of loosening the roots. When the crop is about 6in. high mow it and leave it on the ground as a mulch. When the next growth is nearly ready to cut, start watering at the top of the slope. I usually irrigate four days or a week before cutting (as advised by Mr. Colebatch), and find that when the crop is removed the next growth is already 2in. to 3in. high, thus saving at least a week, and little or no evaporation takes place. It is necessary to irrigate again when the young crop has fairly covered the ground. If the land has been graded before seeding there is no trouble in flooding the plot from the top. The best indication as to when the crop is ready to cut is when the lower leaves turn yellow. One cannot always depend on the flower in cool weather. Rust spot disease (which we have experienced and which I should say is common) can thus be guarded against, for the yellow leaves are the first effects of the disease. One early cutting will wipe the disease out of the plot and leave it healthy. At the beginning of each spring a good dressing of manure (fowl manure can be used) should be worked into the ground with the harrows, and a 2in. mulch of short stable manure applied all over. In the winter months, when the lucerne is lying dormant a quick-growing, early-producing crop of green-food is needed, and it would be hard to find a crop more prolific than mangolds. They supply an enormous quantity of leaves, which can be stripped about once a fortnight. When the lucerne comes on again in the spring the mangolds themselves can be fed to the stock; pigs and poultry are particularly fond of both leaves and roots. These can be grown either in the garden or on the fallow without any trouble.. A moderate dressing of any manure will result in a profitable crop, and the land will be enriched by the mangolds. A good breakwind is half the battle in growing any vegetation, and can be satisfactorily constructed with a few loads of mallee stumps." Mr. P. Maher thought the Yellow Globe mangolds best to grow in this district.

WINDBREAKS AND STOCK SHELTERS.—Mr. W. J. Bowman read a paper. He said—"After five years' residence in this district I am more than ever convinced that windbreaks are an absolute necessity. From year to year, as the clearing of the mallee goes on, the country will become more subject to the sweeping winds of which during the past two years we have had experience. Those settlers who were wise enough to leave a good clump of scrub around their homesteads can fully realise the benefit of protection from the dust during the summer months, the keen cutting east winds, and also the squally south-west winds. Many of us, when clearing our land, made a very great mistake in not leaving clumps of mallee studded about in the paddocks, say on sandhills, as shelter for the stock. Stock-raising will not be the success it should be here until protection from the weather is afforded them. Road breaks should be preserved until something better can be substituted. The Government acted wisely when surveying the country by leaving the road or windbreaks, but the roads should have been laid out in the centre of the breaks. Had such been done, occupiers on both sides would have had the benefit of the break. As it is now one occupier has all the benefit and the other none. The labor involved in the destruction of vermin would have been equally divided also. The time is to come when the stockholders will realise that they must go in for a system of tree-planting to provide shelter for their stock, and if the present windbreaks are destroyed it will be necessary to replace them." Mr. McAvancy believed that the windbreaks on the roads were too wide. They should be narrower, on account of harboring vermin. He did not like the mallee shelters, but favored planting ornamental trees, such as sugar and blue gums. Mallee gave little shelter in summer. Mr. D. F. Bowman favored the idea of planting trees in the centre of paddocks. Almonds would do well and also be profitable. Tamarisk and boxthorn were suitable. Mr. J. Ivett said boxthorn made a good breakwind, but it spread too quickly and would probably become a pest. Mr. W. J. Bowman thought there was no necessity to plant a hedge as a breakwind, trees 10ft. apart was all that was required. Mr. M. Neville thought the gum the most suitable tree. A visitor suggested silver wattles. Mr. A. Neville suggested Port Lincoln wattles, and Mr. J. Cushion thought the best breakwind a farmer could have was a stack of straw in the paddocks, and so shelter the stock as well as feed them. Messrs. Neville Bros. are carrying out manurial experiments in regard to quantities; a committee of five were elected to watch proceedings to ensure accuracy.

CLANFIELD, May 9th.—POULTRY.—Mr. A. T. Franklin read a paper. The selection of a good breed, he said, was an essential for poultry for the farm. White and Brown Leghorns were, perhaps, best for egg production, whilst for the table the Black Orpington-Indian Game cross was recommended. Houses with good ventilation on a dry, sandy site were needed. The pens should be cleaned once a fortnight. A number of remedies for different diseases were recommended.

GERANIUM, May 9th.—Mr. W. J. Mitchell read a paper on "Fallowing." He did not think it wise to work new land much, as excessive stirring would not sweeten it and put it in heart. Sunshine and air alone could do this. On all new land in the mallee this could be laid down as a broad principle, and it was not until a crop or two had been reaped and the stubble burnt that the land would respond to heavy cultivation. Even then, apart from a ploughing and one cultivating, the harrows was the best implement to use.

FODDER GRASSES.—At a previous meeting Mr. F. Norton delivered an address. He advised sowing grass seed on well cleared and prepared land. When the Geranium country became clear of stumps, &c., pastoral pursuits would play a large part on the farms in conjunction with agriculture. In this locality it was advisable to sow grass seeds in the autumn. The grass was then well established before the frosts and later the hot winds were likely to affect it. The seed should be sown lightly and brushed over with bushes or bags tied behind the drill, and then rolled. Lucerne, he considered, was the best fodder to plant, and then in order of relative value rye grass, Melilotus, *Orzyopsis*, and Bokhara clover. He had applied potash, bone super., blood manure, and basic slag, and had been satisfied that it paid to manure grasses. Mr. Mitchell had found it better to sow a small area of clover and attend it well than to put in a larger acreage for stock to graze on at random. Barley was not a suitable cover crop for lucerne. Mr. Jacobs favored distributing the lucerne seed over a wide area.

MORGAN, May 9th.—Members discussed the proposal of the Government Geologist that information regarding underground water supplies throughout the State should be tabulated. It was unanimously agreed that this data would be very valuable to landholders, and the hope was expressed that farmers would facilitate the collection of the information.

WYNARKA, May 16th.—SEEDING.—Mr. Colton advised sowing from 40lbs. to 45lbs. of seed per acre, according to the variety of wheat being sown. Mr. C. Schultz said Gluyas should be sown at the rate of 60lbs. per acre. Mr. J. Boyce advised sowing shallow.

Mr. Bartlett preferred deep sowing. Mr. Colton thought 45lbs. of super. per acre sufficient for new burnt land, whilst Mr. C. Schultz recommended 80lbs. It was generally agreed that if oats received heavier dressings of super. in this district better results would be secured from this crop.

SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.).

May 18th.—Present: 20 members and three visitors.

Harvest Results.—Members reported on the harvest for the year just closed. Mr. A. A. Magarey said—" My trees are only in their fifth year, and not much can therefore be expected from them. The stone fruits gave the best results. Of these the Elberta peaches and Moorpark apricots were a long way ahead of the rest, the fruit being clean and of fair size. Of the apples the Rome Beauty and Rokewood gave the best returns, although they were somewhat affected with codlin moth. Cleopatras (mainly those shaded from the morning sun) were also affected with the scab. No preventive measures were taken in either case. The peach and apricot trees were sprayed with Bordeaux mixture for curl leaf and shothole, and this effectively checked these diseases. About 30 trees were sprayed with Bordeaux powder, and the result was equally as good, if not better than with those treated with the Bordeaux mixture. The former is cheaper and more easily handled. I intend trying it again next season, and if it is satisfactory I shall use it exclusively. A variety, which I think is new to this district, fruited this year, namely, the Glengyle Red. The growth of the tree is very similar to that of the Rome Beauty, and the fruit ripens about the same time, but is somewhat different in shape, and of a dark-red color." Mr. G. W. Summers reported that—" The fruit harvest for 1913-14 has been fairly good. Stone fruits were not as good as usual, nectarines, especially, being short. Pears, with the exception of Josephine, Capermont, and L'Inconnue were practically a failure. Apples in most cases cropped heavily. Owing to the dry winter, practically all fruit was on the small side. The outstanding feature of the apple crop was the unprecedented attack of *Fusicladium*, which practically ruined the crop of Cleopatra, although my orchard was not so badly attacked as many others. Two sprayings of Bordeaux mixture were applied, which partially stayed the ravages of the disease. The spraying was not done until the first appearance of the blight. The apples exported were Cleopatra, Dunn's Seedling, Jonathan, and Strawberry Pippin, the larger proportion of which were of the 2½in. grade, but few were 3in. I have fruited the apple ' Senator ' this season and think that it will prove to be a very useful variety, being of good color and flavor. The rough and careless way of tearing off the fruit, with fruit buds attached, means a very serious loss. Certainly it has been a little bit difficult at times in some varieties of apples to get them off without the bud, this no doubt being caused by the dry season, there being a lack of sap in the trees. There has also been a very uneven ripening of apples this year, some failing to mature weeks after they have been picked." Mr. A. R. Ashby said—" Our fruit crop this year has been very satisfactory on the whole. The size of the apples has been good ; averaging 2¾in. The Jonathans bore well, especially in the cases where the laterals have been left long. The fruit on the young trees filled out well, but was not quite as clean as that on the older trees with heavier crops, where they were practically free from codlin moth, black spot, and bitter pit. The reason for the fruit on the five-year-old trees not being so clean was that they were cut back fairly hard in the winter. Consequently they made vigorous growth in the spring, which prevented the spray from reaching the fruit. Jonathan apples exported ranged in size from 3¼in. to 2¼in. A 2¾in. Jonathan is a very good apple to pack. We used the combination case, with corrugated cardboard for the top and bottom. The fruit was packed on the diagonal system. The Cleopatras cropped very well. They were of a splendid size, averaging 3in., but the young trees were affected with black spot and bitter pit. Bitter pit was worst in the case of trees which had been severely pruned. Old trees were practically free from it, except the terminal bunches on the leaders which had been cut. We gave the trees the first application of Bordeaux mixture at the time of the second spraying for codlin moth. If it had been applied between the first and second sprayings for codlin the fruit would have been practically free from black spot. Rome Beauties yielded a light crop. The fruit was of good size and free from bitter pit and scab. The terminal buds on the leaders all developed into flower buds, which bloomed a month earlier than the normal flowering time, and set seven or eight in every bunch. This had the effect of checking the growth of the trees, bringing the limbs out and letting the light into the centre, and should so improve the buds for next year. The fruit on these leaders developed very quickly, and it was fit for picking and packing by February 24th. The Rokewoods cropped heavily and have filled out very well in the last few weeks. They are of splendid color and free from disease." In Mr. J. Turner's orchard, which consisted chiefly of Cleopatra apples, the crop was a complete failure. Bitter pit and *Fusicladium* affected the fruit badly, and he had come to the conclusion that, on account of the amount of spraying that had to be done, this variety was not profitable. Although the trees were sprayed with Bordeaux mixture as the buds were bursting, and twice after, it proved a waste of time. A late brood of codlin moth attacked the apples, particularly Jonathans, just before they were ready to pick. Glengyle Red, a sport from the Rome Beauty variety, but more highly colored, less conical, but more flat at the apex, fruited for the first time. Fruit from a grafted tree in a damp spot developed bitter pit very badly, but this might have been attributable to the strong growth. Mr. L. Winser said the crop was satisfactory considering the nature of the season and the difficulty in getting the soil to a good tilth. *Fusicladium* was the cause of most trouble, but he had sprayed the trees when they were blossoming, with fair results. Arsenate of lead was applied four times to destroy codlin moth, and the effect was good. The majority of the apples exported were of 2½in. diameter, ranging from 3in. to 2¼in., the varieties being Jonathan and Cleopatra. Beurre Clairgeau, Glou Morceau, and Madame Cole pears also were shipped. The majority of the members disagreed with Mr. Turner's remarks regarding Cleopatra apples, and considered this variety the best for the district. It was more liable to be pitted when grown in damp spots.

CHERRY GARDENS (Average annual rainfall, 35 03in.).

May 5th.—Present: 12 members.

Preparing Hides and Skins for Market.—Mr. T. Jacobs, sen., contributed an instructive paper on this subject. Hides and skins carefully prepared always command a better price in the market, he said, than those carelessly handled. The hide should be carefully removed from the beast, and on no account should it have holes cut through it or be scarred. It should be spread out flesh side upwards and liberally dressed with crude salt. It should then be folded lengthwise, the two edges meeting in the centre; the folding should be repeated, the hide rolled from the neck, the tail being used as a band. the hide then being placed in a bag and hung to drain, and marketed as early as was convenient. Calf skins should be treated in a similar manner. Sheep skins should be carefully hung lengthwise over a rail, wool downwards, and left until quite dry, when they should be promptly marketed. When skinning a fox, it was necessary to open the skin from the extreme point of the chin, along the belly, to the tail, and from the inside of each foot to the former opening. Skinning should commence from the front legs and head. Gristle should be removed from the ears, as this prevented their drying quickly. When the skin was off the head, it should be worked off towards the tail. The skin along the tail should then be opened for about 2in., the skin being carefully worked off to that point. Then, by gripping the tail tightly between the third and middle fingers, and placing one foot on the carcass, the skin could be pulled off to the tip of the tail without further opening. The advantage was in that it was easier to open the skin of the tail without damage after it was off. For stretching and drying a board 5ft. by 3ft. would meet requirements. The skin should be placed fur downwards on this. The front feet should be extended to a point level with the point of the nose and as wide apart as possible, and secured by a 2in. wire nail in the point of each. A similar nail should be placed in the point of the nose. The body of the skin, behind the front legs, should be similarly secured to the board, there being equal distances between the nails on each side. Each end should then be nailed across, the skin being stretched to its fullest extent. The tail should be secured with one nail at the extreme tip. The skin should then be hung in a shady position until dry. For skinning rabbits, first a cut should be made behind the ears, and another between the hind legs, close under the tail. From this opening the skin should be turned forward, and with this in one hand and the hind legs in the other, one vigorous pull would clear the skin. The skin should then be stretched fur inwards on a bow of fencing wire and attached to a wire in the shade with clothes pegs. Rabbit skins should be marketed in a compact bundle, tied with binder twine. Domestic cats could be skinned in the same way as foxes, except that the head was not required. Members agreed with the ideas of the writer of the paper.

IRONBANK (Average annual rainfall, 33in. to 34in.).

May 9th.—Present: six members and four visitors.

SPRING CABBAGES.—Mr. W. Slater read a short paper, in which he advised saving the best cabbage stumps, from the second cutting, for seed. Seed should be sown about March 10th, in a position where the plants would get the full benefit of the sun. If thrip appeared on the young plants, they should be dressed with a solution of two handfuls of sulphate of ammonia and 4galls. of water. They should be ready to plant out about the first week in May. The bed should be dug to a depth of 1ft., and heavily manured. The plants should be 18in. apart and the rows 22in. apart. Six weeks after planting they should be hoed and lightly dressed with ammonia. The hoeing should be repeated two months later, and when the plants began to make hearts about 1cwt. of ammonia to each 1,000 plants should be applied.

KANMANTOO (Average annual rainfall, 17·90in.).

May 9th.—Present: eight members.

THE FARM HOME.—The Hon. Secretary (Mr. H. R. Shepherd) read a paper, from which the following is extracted:—" In this district it is difficult to make a homestead look attractive, owing to the unsuitability of the soil and climate for growing the more ornamental shrubs and trees, only a few varieties of gums and pines doing at all well. However, we might improve the look of our properties by planting the few varieties of trees that will grow. When they have attained maturity they will come in for posts and firewood, as well as affording shade and shelter for stock whilst they stand. We should have no ungainly looking sheds or rubbish heaps close at hand, as they are only a breeding ground for vermin. Good sheds and yards improve the look of a place considerably, but these should be removed some distance from the house, but not at an inconvenient distance. Stables, &c., should be at least 100yds. from the house and on the side away from the prevailing winds. Great care should be taken when planning a home to so build the house and sheds that they can be added to at any time without inconvenience. Keep the house, sheds, and gates well painted, as this not only improves the appearance but adds very much to the durability of the timber. I prefer good hedges around the home, but they involve a considerable amount of work to keep them trimmed. It is most essential to have good gates properly hung. We might all make farm life more enjoyable if we worked more systematically, by keeping our machines and tools in good order and in their proper place. Always buy the best machines and tools, as a good implement more than makes up the difference in the price in the end, and it does more satisfactory work. Have a place for everything, and when finished with a machine or tool always put it in its place. One of the most interesting, as well as helpful and instructive occupations is the experimental plots. Where one has time it is well to carry on a considerable number each year, as everyone should know what to use on his land and how much he can use. The time must come, and is not at all distant, when the land will have to be worked more scientifically, and it behoves the young men of South Australia to make a shift in this direction, as through a thorough knowledge of the soils and manures they will add considerably to their own incomes, as well as benefit the State generally. Any person attempting to take up experimental plots must go to some little trouble, weigh seed and manures properly and book all results as a reference on which to work at a future date. Even if we do not make it pay, it renders enjoyment and varies the routine of our daily work. Farming is one of the most healthy occupations, and why should we not make it as enjoyable as any other by each attaining a thorough knowledge of his own particular branch and by having a reasonable amount of recreation."

MACGILLIVRAY (Average annual rainfall, 19in. to 20in.).

May 5th.—Present: seven members and one visitor.

FERTILISERS.—The Hon. Secretary (Mr. H. C. Williams) read the following paper:— " A good deal of public attention has been given to fertilisers recently, and it would seem that to practise true economy in this item careful discrimination is necessary However it might be in the drier parts of the State, the practice of using mineral super. exclusively does not answer in this locality. In choosing our manures we are guided by the requirements of the different crops, the nature of particular soils, and other factors. Minute experiments do not appeal to the average scrub farmer, but there is room for something in the way of manurial tests with barley on light soil. In Germany potash is considered essential for barley crops. Of any soils, those of a light nature should respond to this fertiliser. Some local barley growers use expensive nitrogenous fertilisers, such as top dressings of ammonia. Equal success is won by other growers with guano super. Unless it is intended to harvest the barley with the binder or reaper-thresher, nitrogenous manures, by making too much straw, may cause heavy loss at harvest time. Last season I used 1cwt. of guano super. and 1½bush. of Prior barley on fallowed dark loam. The crop was thick and lodged badly, and probably would have been worse still if bone super. or ammonia had been used instead of guano. Bone super. at the rate of 1cwt. per acre, under similar tillage and soil conditions, produced a good yield of wheat. Oats sown on narrowleaf country with 1cwt. bone super. failed to make stubble enough for burning. It is doubtful whether manure of any kind will do as much as tillage to secure a burn on shoot land. Peas—2bush.—and ½cwt. guano were drilled in during August. The peas podded better than some which were sown with 1cwt. the previous season, and planted much earlier than last year's crop. For hay I prefer bonedust or bone super., which, used at the rate of 1cwt. both on fallow and after peas, gave a good cut last harvest. Peas as manurial agents are well known. They can be left until after the barley is planted and sown at the rate of about 2bush. per acre. Wild turnip is one of the pests with which they associate, and it is advisable to put a quick growing crop on land lately held by peas, so that all rubbish shall be outgrown." During the discussion it was stated that bone super. had failed to show special results for the year of application, but feed showed the benefit later. Potash manuring had not shown any difference at sight in strips sown alternately with plain super. Nothing accurate could be estimated, however, unless scales were used in checking results. The season following its use land had shown the advantage of a 1cwt. dressing, as against ½cwt. Standard 36-38 super. was shown to be cheaper than guano per unit. The guano was not as soluble.

MOUNT BARKER (Average annual rainfall, 30·93in.)

May 6th.—Present: 45 members and two visitors.

Management and Feeding of Poultry.—Mr. E. F. Stevens read a paper, in which he said:—"*Selecting Stock.*—Whatever kind of fowl the novice takes up let it be a pure breed, as a high standard of laying cannot be attained by a system of breeding that causes the mingling of bloods. Only by careful selection and keeping the blood line pure can success be hoped for. It is absolutely necessary that the very best stock one can get within a range of fair and reasonable prices should be secured. In looking for laying qualities in a hen one cannot go far wrong if the following are noted:—Movements active and alert, fine in bone, but not frail. What is meant by fine in bone is bone in fair proportion to body. Sometimes we see hens with shanks quite double the thickness they should be, and in those cases the hens are coarse throughout; the breast bone is long, pelvic bones hard and coarse and set closely together, and the head is invariably coarse and heavy. These show no breeding and are poor layers. The hen with the fine bone usually possesses a fine, snaky head, sharp eye, comb and wattles fine in texture, and in the case of the small-combed variety, the heel of the comb does not follow the arch of the neck, but takes an upward cut. The breast bone is short and straight, and free from flesh. The pelvic bones are soft and pliable, and set well apart. The latter is not so important as the former, but the pelvis must be soft and free from fleshy substances or fat. I would suggest that, if you are going to select your breeding hens from your present stock, make your selections on a dark night when you will not be influenced by anything other than the sense of feeling. In the absence of any knowledge in regard to any hen's breeding or laying powers such a course would be preferable to any other method you could adopt. Hens often have peculiarities, such as a light faltering step when alarmed; they will stand on one leg and hesitatingly bring the other to the ground. This I have noticed is a very good sign of heavy laying and sound constitution, and the pullets or progeny of such a hen usually prove themselves good layers. It will be noticed in any photo. of a pen of hens which have given an extraordinary yield of eggs for the year that several of them are standing on one leg, with the neck stretched in an alarmed attitude. The beginner should be observant and content to improve on his initial stocks if they come under the heading of 'fair,' and should refrain from purchasing from outside blood after the first year's mating. The motto should be—'Keep the virtues of the blood intact, and improve by selection.' Do not expect every egg that your best hen lays to produce a strong chick, or every pullet to be as good as the mother, or start to lay before she leaves the brooder, for there are many other deteriorating influences at work. There is the fact that fowls bred naturally for thousands of years before they were domesticated. We therefore cannot expect to accomplish in a few short years by scientific breeding methods what Dame

Nature has been doing for thousands of years. The beginner should work on his own judgment as soon as possible, and richly benefit by failures, thus realising the truth of the old saying, 'that experience is the best schoolmaster.' Pullets should on no account be used as breeders, and the cockerel should be well matured when mated with aged hens. The use of immature stock (either male or female, or both) is the chief cause of small eggs, and I have proved that the weight of eggs can be reduced from 28ozs. to 19ozs. to the dozen in two generations by using pullets as breeders. I have also proved that aged hens laying rather small eggs, say 20ozs. to the dozen, mated to a cockerel bred from a hen which was a layer of large eggs, invariably gives progeny that will produce eggs with a considerable increase in size. This then is an important point, and great care should be taken. The male bird should be from the very best hen one can secure from type and egg-laying point of view, because of the fact that the male bird exerts a greater influence than the hen. Particularly is this so in the case of the pullets, and a good hen's qualities are not usually found in her daughters, but in her grand-daughters given through her son. *Heavy or Light Breeds.*—There is justification in asserting that there is a widespread reaction set in in favor of the light breeds. This seems to obtain throughout the Commonwealth, and particularly throughout the eastern States, and if the data supplied by the other States can be accepted as evidence of the general trend of popular opinion, breeders are beginning to realise that more attention will have to be bestowed on the table side of the industry. The scarcity of prime table birds and the attractive rates that they realise in the open markets almost all the year round, can do little else than hold the attention of the man ready to make the most out of his poultry. Whilst I am fully cognisant of the fact that the White Leghorn will ever dominate the situation in regard to the annexation of prizes at laying competitions, that is not all, for when one sets out to keep poultry on a commercial scale large flocks of young fowls have to be handled each season, and usually more than 60 per cent. are cockerels. The difference in market value will be found fully 50 per cent. in favor of the heavy breeds. The hens are more saleable when their term of laying is completed, which in itself is only a small item as compared with the advantage of having a class of fowls that is easily shut in or out, as the case may be. Whatever breed is taken up it must be remembered that like begets like in a general way, and if you do not have the good qualities in the parent stocks you cannot reasonably expect to produce well-bred or profitable birds. The foundation stock of even a small plant should be the very best obtainable. If you start well you will secure year after year birds that will show their breeding and will be a source of pleasure and profit. *Sanitary Conditions.*—Good sanitary conditions must always obtain. This should be made one of the cardinal principles of management. Clean out the roosting places frequently, and keep vermin in check. Kerosene is most deadly to all sorts of fowl vermin. See to it that fresh water is supplied at least once a day; especially is this necessary in windy weather, as dust will most readily contaminate water, and the drinking vessels should be thoroughly clean ed out two or three times a week. Small vessels are preferable, as large ones may be neglected, and the mouth and throat slime dropped by the hens in the act of drinking falls to the bottom of the vessel and is a hotbed for germ life. Especially is this so if any fowl is suffering from a throat trouble. I have found Epsom salts good. Use one packet to three gallons of water once a week. To tint the water once or twice a week with Condy's crystals is also good, and entails very little bother. Provide a dust bath in each yard, and also plenty of shell grit. Sponge scaly legs with kerosene, as clean legs add greatly to a bird's appearance and usefulness. No other industry offers such good profits for the capital invested as the poultry industry. In arriving at a decision as to the breed of fowls to keep quite a number of things has to be considered. Local climatic conditions are in favor of the heavy breeds, and these will, as a rule, give a preponderance of pullets. The cockerels and hens are more saleable. The eggs are brown-shelled. The birds lay well in the second year, and are often profitable in the third. They are handy for hatching, rendering a machine necessary only for a short time in early spring. They do not require such high netting yards, and are greater vegetarians than the light breeds. This is an important item where an abundance of greenfeed can be grown, as it means a great reduction in the feed bill. There is no better time than the present to make a selection of breeding hens. Those still carrying their old feathers and still laying are the only worthy specimens for the breeding pen. They often present a very scraggy appearance, being minus neck feathering and are bald headed, but still have plenty of color. This is one of the surest signs of strong constitution. If mated with a cockerel bred from a hen of similar quality they cannot fail to produce heavy layers. The cockerel, in addition to possessing the above-mentioned qualities, should have a smooth comb and large wattles—large wattles denote breeding—and he has the power to transmit his mother's qualities to his daughters. Stocks bred from such mating will be found good autumn and winter layers. *The Feeding of Young Stock.*—Feed for young stock should be bulky, and from chickenhood they should be forced to extend their crops. The use of the more concentrated foods should be avoided, as the laying hen must have a stowaway, just as a dairy cow must have a good barrel. Feed mash in the morning consisting of three parts greenfeed, two parts pollard, and one of bran. The greenfeed should be chaffed and moistened with water, in the absence of milk, or meat-meal soup. Then dry off with the bran and pollard. Spurted oats or barley at noon, and wheat, oats, and peas in rotation at night. Feed the evening meal early, and feed with chaffed greenfeed before the birds roost. This will be much appreciated by the fowls. If one has not the time to mix mash in the morning, feed the bran and pollard dry. This can best be done by cutting a kerosene tin from side to side about an inch from the bottom, by pressing the top portion in and the bottom out, thus making a slot or trough into which the feed trickles as the fowls use it. This acts splendidly if fed under cover, but if in the open it must be rendered waterproof or the food clogs and ceases to run. When this style of feeding is adopted use plenty of greenfeed at noon. The best greenfeed is lucerne chaffed, then comes cabbage or kale, green barley, mangold wurzel, silver beet, or maize. I am of the opinion that mangold, if put through a mincer and reduced to a pulp, would prove a splendid food to dry off with pollard and bran—this I intend to try. Sieve all your fire ashes and crush the charcoal, and feed this with the mash. There is nothing better to keep them healthy and hungry. Keep all breeding stocks on a hard grain diet, as stronger chicks will be hatched. If a vigorous cockerel is placed with a flock of hens until about 4 o'clock in the afternoon, and then placed with the stud hens for the rest of the day it will be noticed that he will throw more pullets than cockerels. This I have proved beyond all doubt. The eggs should be handled carefully when gathering from the nest, and it will be noticed that those eggs having a thin shell or that produce a metallic sound when rubbed together or in the palm of the hand, are infertiles, also eggs dropped from the roost at night are infertiles. The eggs with smooth solid shells will invariably prove the best hatchers. Misshapen eggs are 'clinkers,' seldom fertile, and rarely hatch. I have proved, to my satisfaction at least, that mental suggestion is a factor that has to be counted with in breeding fowls, and that birds of various breeds should not be in sight of each other during the mating period. To me this explains the reason that the man who runs one breed only can excel, and the man who takes up several breeds and pens them side by side is often confronted with many freaks and miss-typed birds. One of the most important points for the breeders of the future is the breeding of a class of fowls that will lay for several years at a profit. This breeding of young stock each season to take the place of last year's birds is costly and fraught with many risks due to chicken mortality through the various epidemics. I consider that one of the most pressing needs in connection with present egg-laying competitions is the inclusion of a section for second year and even third year hens. These I am sure can be bred, but not on the same lines as the sprinter, or those that lay the bulk of their eggs during the first year. Tests in the eastern States have shown that the pens that won handsomely through the first year did not lay the most eggs in the aggregate when the second year was taken into account. I will conclude by expressing my wish that a resolution go from this Branch to the Poultry Expert, recommending that a second year test be instituted at the next year's competition."

MYPONGA (Average annual rainfall, —in.)

May 6th.—Present: eight members.

INTRODUCED FODDER GRASSES AND CLOVERS.—The following paper was read by Mr. J. Muller:—" In dealing with this subject I will endeavor to describe what I have found best suited to this district, and what might be classed as good utility fodder plants. In grasses, as in all other herbage, there are two classes, namely, annual and perennial; but as I have tried only perennial and have seen only good results from two annuals, I will deal chiefly with perennials. The two annuals mentioned are White Dutch clover and *Trifolium subterraneum*. Both these clovers do well in cool wet districts. Besides these two there are the cow grass clover and lucerne. White Dutch clover does best on wet soil, and will grow well into summer if the soil is damp. It does not grow very high, but forms a thick mat, and will stand grazing better than most clovers. It is much relished by all kinds of stock, especially sheep, which do exceeding well on it. One prominent grower in this district prefers it to lucerne. *Trifolium subterraneum* also does extra well, but it does not stand the warm days of spring like the White Dutch. It has the peculiarity of burying its seed, so there is no danger of stock eating it out. It thrives on almost any kind of soil, particularly on rich soil. In the Blakiston district, which is similar to this, the carrying capacity of sheep is now two and a half per acre, whereas it only carried one before the introduction of this clover. As the seed is rather expensive, it is well to include it in a mixture, and in about two or three years it will spread all over the paddock. Cow grass is a perennial, and is very much like lucerne in its habits. It will stand grazing, and will keep green right through summer without irrigation. It is the best artificial clover I know of where irrigation is impracticable. Unlike the *Trifolium subterraneum* it will not spread of its own accord, and requires to be sown at the rate of about 10lbs. per acre. The seed is not very expensive, costing about 1s. per pound; so that for a small sum a good crop of excellent fodder can be had in a few months after sowing. The three clovers mentioned require about the same treatment and time of sowing. Work up the ground, which should be fallowed the spring before sowing to a good tilth, the finer the better. Then just before the early rains can reasonably be expected sow the seed evenly and harrow lightly. I am of opinion that 1cwt. each of lime and superphosphate per acre, drilled in previous to sowing, would be beneficial. The hoes or discs must be taken off or the seed will be buried too deeply to germinate. A good plan is to substitute a board for the seed to strike to ensure even sowing for any kind of grass seed that a drill will handle, but if preferred the Rangoon knapsack seed sower is a very handy contrivance, the cost of which is about £1 1s. Even broadcasting by hand, if the seed is mixed with sand, will answer the purpose equally well. In any case the seed must not be covered too deeply. A good plan to cover it is to use a chain with a spreader like the harrows, or rolling will also answer. As lucerne is so well known very little need be said regarding that plant as to its qualities, habits, &c. It will thrive on any loose friable soil, the richer the soil and the hotter the climate the better it grows. But to get the best out of lucerne it must have an abundance of water. If the water can be reached by the roots there is no need to irrigate after once the roots have gone down to it, but where a greater depth is required it is necessary to irrigate from the top, either by flooding or with sprinklers. In large areas flooding is the best, as more can be irrigated than with sprinklers; though in small patches, say up to two acres, sprinklers can be used to advantage. The same method of cultivation as laid down for clovers also applies to lucerne, with the addition of grading the land, which is necessary to ensure even irrigation. If the ground is not too uneven a good plan is to make a triangle to suit the conditions of the soil and number of horses available to drag it. Three horses will work one about 12ft. wide made of jarrah or gum, about 6in. by 5in., and the implement is simply dragged over the ploughed land, when the ridges, hills, etc., will be dragged off and left in the hollow places. About 12lbs. or 13lbs. of seed is required per acre. It can be sown either in spring or in autumn, but in autumn it is a good plan to sow it with a cover crop to protect the young plants from frost. During our residence in this district I have tried over 20 different kinds of grasses, some with good but mostly with poor results, Paspalum being foremost as regards results, though I cannot say I am over keen on it. Stock do not relish it; in fact with us they had to be forced before they would take to it at all. However, as a standby it answered really well. During the recent hot summer we had it about 2ft. high and quite green, without irrigation. Unlike most grasses it will stand extreme cold as well as heat. The trouble we have experienced with this plant is in the germination, as it requires three weeks warm moist weather for it to germinate. I find that spring is the best time to sow it, although experts from New South Wales, which is the adopted home of the Paspalum, say autumn is the proper time. We have had no success with it sown in autumn. About 10lbs. of seed is required per acre. Where it was sown as a mixture, cattle kept it eaten down, but where it was sown by itself they had to be starved to it. Among other kinds tried was Yorkshire fog, which did better than most. Some authorities say that this is not fattening, but only keeps stock alive. For the accuracy of that statement I cannot vouch, but I have seen it used in conjunction with rye grass very extensively in the Millicent district, which is similar to our own. I have also tried rye grass, but with poor results, but as everyone knows it is one of the best for a cool district like this. I have seen it used extensively both in Mount Gambier and Millicent districts with splendid results. Where it is grown on loose soils it is not advisable to stock it with cattle, as they pull it up roots and all, but sheep and horses do no harm, as they bite it off. The horse paddock at Mount Graham Station was as good as ever it was 20 years after sowing. Cocksfoot is another good grass, though I have had no experience with it personally, but have seen it used as a mixture with rye grass and Yorkshire fog, the mixture used being 20lbs. of rye gras sand 5lbs. each of fog and cocksfoot. One more fodder that I have found good is Melilotus, but this is hardly suitable for dairy cows, as it has a tendency to taint the milk. Where the soil is loose it is a good plan to sow it after a burn as early after January as possible, as the seed has a waxy case which requires to be melted to ensure germination. It is an annual, but if allowed to run to seed it will come up thicker the second year than the first. It should be burned off after shedding the seed. This plant has a tendency to enrich the soil and will eventually kill out undergrowth. King's Island, the first place in Australia where Melilotus was grown, is now noted for it, though at one time it was a barren sandy patch in the ocean between the mainland and Tasmania. Melilotus could be grown to advantage in this district in scrubby land, especially the sandy parts. All that is necessary is to cut down the scrub, burn it when dry, and sow the seed at the rate of about 10lbs. to 12lbs. per acre. I have tried rib grass; it grows well, but cattle do not relish it, and I have not tried sheep on it. If sown it should be as a mixture. I have also tried Rhodes grass, sheep's burnet, crimson and Bokhara clover, and several others with little or no results regarding germination, so cannot say anything about them. Those mentioned above are what I know to be good, if properly cultivated; but proper cultivation is just as necessary for introduced grasses as for wheat or hay. In this district, with its assured rainfall and mild summer, land that is now practically useless could be made to carry up to two, and in some cases more, sheep per acre. Some may think that the quantity of seed advocated is excessive, but that is the quantity that I have found most suitable, and when one comes to consider that grass has a tendency to ripen very unevenly, it will be found that a few pounds more per acre are better than a few less. It will also pay to manure grasses, especially permanent kinds, both at the time of sowing and every autumn. When farmers realise what grasses mean to them, both they and the district will greatly benefit; but while natural grasses only are depended on the farmer and district will make little progress. My advice to the farmer and grazier is to try a patch every year until the whole holding is sown down, but bear in mind that 'what's worth doing is worth doing well.'" Mr. Stephenson mentioned that some Paspalum seed, which he had soaked for 24 hours, germinated 11 days after sowing, whilst unsoaked seed did not germinate until 20 days had elapsed. The Chairman (Mr. G. Hunt) said stock would soon eat out prairie grass. Ribbed grass made good sheep food. Members were agreed as to the value of cow grass.

NARRUNG (Average annual rainfall, 17in. to 18in.).

May 9th.—Present: 11 members and 10 visitors.

Afforestation.—A paper was read by Mr. G. G. Hackett. He said—"To encourage a system of tree-planting (which has become an absolute necessity, owing to the immense demand for timber), the Government has established nurseries for the distribution of young trees, and large areas are reserved and planted to increase the forest lands. The manufacture of paper alone requires some hundred thousand of acres or more of timber every year, and when one considers the thousand and one uses of timber one can readily understand the possibility of its becoming exhausted. The purpose of this paper is to stimulate discussion on the subject and its great advantages, and also to urge the individual, as far as possible, to supplement the national examples. The tree inhales through its leaves carbonic acid gas, and purifies the surrounding atmosphere. The writer has for many years used a shady tree for hanging meat under, and this has proved an unqualified success. For this purpose alone a tree or two in the vicinity of a homestead is invaluable. The deodorising power of trees is akin to that of the ocean, and residence in the forests at the proper times and season is as invigorating as a sojourn by the seaside. Trees add fertility to the soil, the natural decay adds vegetable mould, which is essential to the growth of plant life. The general appearance of this country prior to its early occupation led one to assume that trees were due to a more fertile soil, whereas, in fact, the fertility of the soil is the result of the growth of trees. The writer, after many years of observation, concludes that the evolution of vegetation in this locality was first heath and mallee, followed by trees, then grass and herbage. I am referring more particularly to the higher and inferior lands. I could point out many a little fertile oasis of from five to 20 acres, where I have noted the development as stated in the scrub country, which a generation since was heath and mallee. Mr. W. Mincham, in a paper read before the Meningie Agricultural Bureau, dwelt on the value of sheaoak (which is the chief timber of the district) as a fodder in bad seasons. He could have mentioned that its value as a fertiliser is even greater, the timber containing 6 per cent. or 7 per cent. of potash, which is one of the essentials for the growth of plant life. Trees have an important bearing on climatic conditions. Though one does not claim that trees produce rain, one has every reason to believe they have a strong influence in its conservation. The shaded temperature mellows the sun's powerful rays and materially checks evaporation. Trees also are a necessity for bird protection. It has been said that if all birds disappeared, in the space of a generation human ingenuity could not cope with the insect pest, and famine would overspread the land. There is also the utility and value of trees. Plots planted, in the course of 10 or

12 years, produce timber for all requirements on the farm, and I estimate its value at from £25 to £50 per acre at 10 years' growth. The value of shade for stock in the summer and shelter in the winter cannot be estimated, and when the timber is used up the soil has added fertility and is more fit for cultivation. Then again, how beautifying are the effects of trees in all surroundings, but more especially in rural localities. How pleasing to the eye are clumps of trees dotted here and there among the homesteads, and to the children born in such surroundings they become friends, and pleasant memories that last through life. There is an Arab saying, that he who digs a well and plants a tree leaves after him an imperishable record, for the wayfarer quenching his thirst at the well and availing himself of the shade of the tree will gratefully call blessings on the name of the benefactor; and as with the individual. so with the nation and community, posterity in due time will honor those who before them wisely and thoughtfully provide for those following, and leave an example that should endure as long as the world exists."

URAIDLA AND SUMMERTOWN (Average annual rainfall, 44·35in.).

May 5th.—Present: 11 members.

Onion-Growing.—Mr. G. Collett read the following paper:—"In the first place I would recommend growing both early soft and late keeping varieties, as the early sort will usually yield a better crop and can be marketed right off the land, and the keeping sort may be stored till later in the season. The best time for planting the seed in this district is about the middle of March. If left later the winter generally sets in before the plants get a good start, and the wet and cold weather checks their growth. I prefer having the plants grown in a warmer district, and if this is done the middle of April is the best time for sowing the seed. It should be put in drills, say, 6in. apart, as the plants are then much more easily cleaned than if broadcast. If care is given good plants should be assured. Give early attention to the cultivation and preparation of the land. I recommend growing a crop of potatoes with a heavy dressing of stable manure the year previous, as this assures the land being in good heart, and there will not be as many weeds to contend with as would be the case if the stable manure were put in with the onion crop. The land should be kept as clean as possible through the winter, and for this purpose I favor the scarifier after having ploughed once. When the time comes for planting I would give the ground a good deep ploughing, as this encourages the roots downwards and so helps them through the dry weather. Having ploughed the ground, before harrowing I would spread the artificial manure I intended for the crop, then harrow well and rake and drill ready for the plants. Having grown the plants and prepared the land the next requirement is the transplanting, which should be done in September if possible, because if we have a good spring the plants are a good size before the hot weather sets in. I would use a 10in. drill and plant soft onions 4in., and keeping varieties 3in. apart. As far as irrigating is concerned, I think that onions should have a good soaking once a week, but of course this greatly depends on the nature of the land. Keep the crop as free from weeds as possible, as every weed robs the crop of a certain amount of moisture. In saving onions for seed purposes, I would save the early sort for cropping qualities and appearance, and the late sorts for cropping and keeping qualities. It is well to put by twice as many as are required so that a second selection can be made." Mr. Hart advised gardeners to grow their own plants and transplant them as required. When early varieties were grown another good crop of vegetables could be secured from the land.

Waste Produce in the Garden.—At the previous meeting a paper was read by Mr. H. F. Johnston. He advised orchardists to run a few sheep in their holdings. These would destroy such growth as blackberries suckers, and sorrel, as well as consume windfall and codlin moth infested fruit, thus keeping the fruit pests in check. These animals could also run on the garden after such summer crops as potatoes and cabbages had been taken out. An iron post and wire netting fence could easily be erected to form an enclosure. Sheep, he thought, would be much more satisfactory in this connection than pigs, which were generally kept. They should not be given access to young trees. but to the older trees they would do more good than harm by eating the lower limbs, In some of the larger apple-growing districts sheep were run in the orchards for nine months of the year, being taken out in the winter when the land was ploughed in May. They ate down the grass in spring, and the cultivator could then be used with advantage in the early summer. In this district the spring food could be eaten by the sheep, and the land then gone over with a cultivator or duckfoot harrow. Fencing, which would cost about £16 per mile, could be of netting, or four barbed wires 6in. apart would be cheaper, although this has a tendency to tear out the wool, and was dangerous to other stock. Mr. Stacey did not think it wise to run sheep in an orchard—he preferred cultivating the land.

WOODSIDE (Average annual rainfall, 31·95in.).

May 6th.—Present: nine members and one visitor.

Compulsory Spraying of Fruit Trees.—Mr. R. R. Keddie read a paper as follows:—"I do not consider the present system of inspection a success, and with the most effective system of inspection for compulsory spraying, I do not think that the codlin moth will ever be eradicated. It is contended by some that by regular and frequent spraying now, in a few years only one spraying will be required. Allowing such to be the case, why make it compulsory? My experience this season with one apple and one pear tree which were only sprayed once, showed that they were as free from moth as those which had been sprayed three times. The fruit grower who sprays his trees will have clean fruit of good value, while the grower who neglects the spraying will have fruit that will be of little or no value. In cases that have come under my notice lately, the moth has received encouragement rather than otherwise—bandages being put round the trees and not removed once for the year. One of the effects of complying with the regulations under the Act in regard to cottage or small gardens being owned or occupied by working men, or those of small means, is, that rather than go to the expense of spraying, they are in many cases destroying the trees, which I consider a most undesirable action, as in a great many instances they are unable to buy fruit. It is admitted that spraying if properly done is effective, but why make it compulsory? I consider the most effective way to deal with the matter is to prohibit the distribution of moth-infested fruit. An inspector could deal with the fruit at all markets and places of distribution to the advantage of the seller and buyer." The majority of members were opposed to Mr. Keddie's views, but were unanimous in the opinion that the present state of compulsory spraying was the most effective way of eradicating the moth. [This paper was referred to the Chief Inspector of Fruit (Mr. Geo. Quinn), who comments as follows:—"The grounds upon which the compulsory spraying of small or large gardens is based, is that utter neglect of adjoining apple trees will make the owner who is willing to spray his orchard spend more in spraying to keep his fruit reasonably free from codlin moth. The cost of a small spraying outfit suitable for small gardens is about 30s., and the materials cost a mere fraction each year. Scores of small garden owners do spray their few trees, and these should be protected against their neighbors who are not disposed to do so."—Ed.]

FOREST RANGE, May 7th.—**Storing Wet Apples.**—In a discussion on this subject Mr. A. Green said apples would not deteriorate if stored when wet. Mr. J. Vickers stored scabby apples, which after a time became covered with mildew. Apples stored wet, he thought, always lost their glossy appearance. Mr. F. Green preferred storing dry apples, but dew did no harm. Apples wet with rain generated too much heat.

Onion-Planting.—Mr. E. Green favored planting onion seed in drills about 4in. wide. Mr. Vickers had obtained the best crops by planting in drills about 8in. wide. The wider the drill the more the plants sheltered one another. Mr. F. Green patted the ground down before sowing the seed, then covering it with stable manure to prevent caking. Mr. McLaren would not use stable manure for onions because of the weeds.

Pruning Apples.—Mr. Vickers did not favor early pruning, as this might cause the bark to split, offering a good opportunity for woolly aphis to gain a hold. Mr. Rowly thought the early pruned limb was more apt to die back from the cut.

Sulphate of Ammonia.—Mr. E. Green thought August the best time to apply sulphate of ammonia. He had used it in November and the results were not so good. An application of 3lbs. or 4lbs. was sufficient, and it should only be used occasionally. Mr. Vickers thought it had a more lasting effect if applied in August. In his opinion the fruit was more likely to contract bitter pit if the tree were dressed with this fertiliser. Both the tree and the fruit appeared greener.

LONGWOOD, May 9th.—The meeting was held at the homestead of Mr. J. Roebuck. The garden, which was irrigated by means of gravitation, was planted to turnips, swedes, radishes, rhubarb, and celery, the latter being planted about August in rows 18in. x 8in. A 6in. galvanized pipe, about 16in. long, was placed over each plant. The onion seed bed was prepared by growing and ploughing under a crop of oats. Twenty-four varieties of apples and seven varieties of pears were tabled.

MOUNT PLEASANT, May 9th.—Mr. Thompson contributed a short paper with regard to the introduction of lads as farm apprentices.

PORT ELLIOT.—Mr. P. R. Cudmore gave a very interesting account of a trip through Tasmania, describing many features connected with the fruit and hop growing industries, etc.

SOUTH-EAST DISTRICT.

KYBYBOLITE (Average annual rainfall, 22in.).

May 7th.—Present: eight members.

Fertility of Wheat Lands.—The Hon.-Secretary (Mr. E. C. H. Schinckel) read a paper on "The Fertility of Wheat Lands,' reprinted from the Victorian *Agricultural Journal*. "Fallowing is an excellent means of storing up soil moisture and cleaning the land, and on this account it pays for doing. But in the long run the wheat, fallow, wheat system can only be reviewed as a temporary expedient. Where it is well done the soil is seriously depleted of organic matter by fallowing. In California the conditions somewhat closely resemble those of our northern areas, but cultivation is of older date, and the experience of California, therefore, is for us fully significant. The subject is dealt with in an exhaustive bulletin (211) issued by the State University—'Continued grain culture under shallow preparation over a long period has seriously affected the naturally low humus supply of the grain lands of California. This condition has been rendered worse by the burning of the straw, and biennial culture necessitated by a limited rainfall. Humus in ample quantity means success · its lack means disaster, and this is particularly true in dry land farming.' The bulletin quotes a number of experiments, showing the excellent effects of ploughing in green manures as a preparation for wheat, and states that the wheat yield of California can be doubled by following this system, coupled with deeper cultivation.. As ploughing-in crops, rye is recommended as a start, to be followed later by an admixture of rye and peas, or vetches, when a foundation has been laid. Rye has been found the surest. Whatever crop is used it should be seeded as soon as it is possible to shallow-plough or disc the land in autumn, and the crop should be turned under in early spring, before the land is too dry for deep ploughing, and while it is still moist enough to start humification, or decay of the material ploughed in.'"

MOUNT GAMBIER (Average annual rainfall, 32in.).

May 9th.—Present: 18 members.

Lincoln Sheep and Wool.—Mr. W. J. Sutton read a paper from *The Pastoralists' Review*. In discussing the subject, Mr. A. J. Wedd said the Lincoln-Merino cross was the best for wool for this district. Mr. G. H. Kilsby also advised this cross. Mr. E. F. Crouch observed that in New Zealand the broad-locked Lincoln was a better constitutioned sheep than the narrow-locked. About three years ago he visited a station where they put a number of Merino ewes with Romney Marsh rams, and some with Lincoln rams. All the lambs ran in one paddock, and had equal opportunity. The Lincoln cross gave between half to three-quarters more wool than the Romney cross, but the latter brought ½d. per pound more for the wool, so the results were about equal. What they would do on richer land like that around Mount Gambier would make all the difference in the world. To grow Lincolns successfully they had to put a lot down their throats. Everyone had to run sheep to suit his country.

Miscellaneous Matters.—The President (Mr. J. Wedd) had purchased a couple of tools lately that, he thought, might be of use to members who were troubled with rabbits. They were narrow spades, such as were used for laying tiles for drains. They would be useful in putting down netting to keep rabbits from crawling through, as it would obviate the worker shifting an unnecessary amount of earth. Another spade had a very long handle and a sort of goose-neck on it, which enabled a man to dig out a deep narrow trench. It would be very good for digging out rabbit burrows. Mr. Holloway had found that rape dressed with superphosphate, sowed broadcast, became immune to aphis. Mr. Crouch read an extract showing the value of lime and super. applied to the land with an interval of several days between.

NARACOORTE (Average annual rainfall, 22·60in.).

May 9th.—Present: seven members.

Rivalry Among Agriculturists.—An interesting paper under this heading was read by Mr. S. H. Schinckel. Healthy competition among sheepbreeders, he said, was largely responsible for the large-framed Merino sheep of South Australia. The same applied to improvements in horses, cattle, poultry, &c. Every farmer should strive to accomplish more than his neighbor in the way of quality of his crops, cultivation, &c. For the sake of economy most stables and sheds were built of rough material, and rightly rightly so, too; but only too often the builders paid little attention to neatness and convenience. Stable manure was frequently neglected. This should be regularly carted to a site selected, and not left about the stables and yards. Farm machinery should be kept under cover when not being used, the wood work being kept painted. No stock should be allowed to camp under the machinery sheds. Harness should also receive due attention, and fences be kept in repair. Rabbits and suchlike pests should be kept in check. A small flower garden was much more attractive in the front of a house than star thistles, &c. A healthy rivalry amongst farmers to excel in matters of this nature would work for the general good of the farming community. Mr. W. H. Smith mentioned cases where he had noticed improvements on farms which he had visited, and had adopted them on his own holding. It was decided to fully discuss the paper at the next meeting.

KEITH, May 9th.—Members thought fallow should be worked well to destroy weeds and secure a fine seed bed. On wheat land Scotch thistles should be destroyed, but they would soon die out if the land were not cultivated. Mr. Makin advised cutting shoots at the end of March or April, putting them on the stumps, and then burning. Seed should not be drilled too deeply.

THE JOURNAL OF AGRICULTURE

Published Monthly.

Subscription, 1s. per annum to residents in South Australia, and 2s. 6d. per annum elsewhere, including postage.

Circulation, 6,800 Monthly.

The Journal contains information of an official character relating to the Agricultural Lands, Stock, and Produce Export Departments. Illustrated articles and paragraphs by Government experts dealing with all branches of agriculture, horticulture, viticulture, pastoral matters, dairying, stock diseases, poultry, etc., are published regularly.

The results of experiments in connection with methods of agriculture, etc., stock and poultry diseases, insect and fungoid pests in South Australia and other lands are recorded, as well as the results of work at Roseworthy Agricultural College.

The experience of members of the Agricultural Bureau is made available to subscribers by the publication of reports of meetings of the Branches, including the more important papers and the discussion on them.

The Inquiry Department of the Journal furnishes replies by Government experts to all questions sent in, and advice is given to beginners in agricultural industries.

The Reference Library of the Department of Agriculture, which contains so many valuable works on agricultural subjects and thousands of bulletins issued by Departments of Intelligence in all parts of the world, is at the disposal of subscribers during office hours.

Applications for enrolment on the subscribers' list should be addressed to the Department of Agriculture, Victoria Buildings, Victoria Square, Adelaide.

T. PASCOE,

Minister of Agriculture.

POINTS FOR PRODUCERS.

The Social Phase of Work of Agricultural Bureau.

Speaking at a highly successful gathering held by the Blackwood Branch of the Agricultural Bureau on Monday evening, June 15th, the Minister of Agriculture (Hon. T. Pascoe, M.L.C.) expressed his gratification that the Branches of the Bureau were fostering the social phase of their work to a greater extent than had been the case. "It was a good thing," he continued, "to get wives and daughters interested in the work of the institution which had not only materially assisted farmers to overcome their difficulties, but had taught them to express their ideas in an intelligent and forceful manner, so much so that the South Australian farmer was often quite capable of holding his own in discussion with trained scientific men, and, therefore, the better able to reap the full benefit from lectures and debates generally." A report of the proceedings is included in the section of this *Journal* devoted to meetings of the Branches of the Bureau.

Farmers' Conferences.

The annual conferences of the Eyre Peninsula and the Pinnaroo District Branches will be held in August. The former will take place at Cleve on Tuesday, August 4th, with sessions in the morning, afternoon, and evening; and the latter at Lameroo on Friday and Saturday of the same week. The first session at Lameroo will be at 3·15 p.m. on August 7th, and followed by an evening session at 7·30; there will also be a morning session on the 8th, prior to the departure of the train to Adelaide. Members of the Advisory Board and officers of the Department of Agriculture will be present at these conferences, and papers of a practical nature will be submitted and discussed by representatives of the Branches in the districts. The usual concession of excursion fares on the railways will be available to *bona fide* members of the Agricultural Bureau upon application to the Secretary Advisory Board of Agriculture, Adelaide.

Synthetic Milk.

At a recent meeting of the Central and Associated Chambers of Agriculture, held in London, it was resolved that the Government should be urged to take legislative action to prevent synthetic milk, manufactured from soya beans and other materials, being sold as milk or under any adaptation of that name.

Sheep in the United States.

An authority in the *Pacific Rural Press* reports that there is a serious decrease in the number of sheep being raised in the United States. The decrease in the principal sheep States is given as follows :—Montana, about 40 per cent. ; Idaho, about 10 per cent. ; Utah, about 15 per cent. ; and Oregon, about 10 per cent. It is estimated that there will be a decrease of about 25,000,000lbs. in the 1914 clip.

Size in Cattle.

It is much the same in our modern markets with cattle as with sheep, in both of which coarseness is a thing to be avoided, and breeders must recognise the consumers' demands for small joints and breed accordingly. The butcher is a keen admirer of high breeding in cattle. He has experienced all sorts and sizes, and is sharp to recognise what pedigree brings and pays by results. The market, says the *Agricultural Gazette*, is the final court of judgment for all the bovine race, and that is the place to convince any doubter of the value of pure breeding. In one respect there is a great difference between sheep and cattle as regards the standard of quality. With regard to dairy cows, it is true that town dairymen and many dairy farmers still connect great size with great value, but it is extremely doubtful if they are wise in so doing. The larger the frame the more food is required, while the yield of milk is not necessarily more abundant.

Sunflower Culture.

Hitherto sufficient attention has not been paid to the commercial advantages of the sunflower. It is extensively grown in Russia, the United States, and other parts of the globe, but not so much in this country. This mammoth flower flourishes in a damp situation in a moderately strong soil. The seed is usually sown from 3ft. to 3½ft. apart, and from 2in. to 3in. deep. The young plants are generally thinned out so as to be from 12in. to 18in. apart. The quantity of seed required per acre is about 7lbs. The heads are gathered before they are quite ripe. In America quantities of seed are cultivated for poultry purposes. The chickens like the seed, and fatten quickly upon it, owing to the rich oil it contains. Small holders who have odd corners of land unsuitable for ordinary cultivation will be well advised in experimenting in sunflower cultivation. The stalks may be burnt, and the ashes returned to the soil as a fertiliser. Besides its value for poultry, sunflower seed is useful for feeding cattle and horses. For cattle a cake made of the seed is on the market. This is used for cattle in the same way as linseed cake ; 4lbs. of good sunflower cake is reckoned as equalling 3lbs. of linseed cake. The best cake contains from 10 per cent. to 11 per cent. of oil. Sheep also thrive on the cake, this being substituted for other kinds of seed cake. For pigs it is best used in conjunction with beans, peas, and barley meal. It is estimated that an ordinary field crop yields from 50bush. to 60bush. of seed to the acre. The usual price in the United Kingdom of sunflower seed for feeding purposes is about 15s. per cwt., as against 13s. 8d. per cwt. for Indian linseed. The price for nutted sunflower cake is generally from £6 5s. to £6 15s. per ton.—*Horticultural Review.*

Length of German Working Days.

In a recent German agricultural paper the details of the working day throughout the year are given for an estate in Posen. During January and February the day's work begins at 7·30 in the morning, during March at 6, while from April to September work starts at 5·30. In October the working day begins at 6, in November at 7, and in December at 7·30. During the months from April to September there is a half-hour rest period, with lunch served in the field, from 8 to 8·30 in the morning. There is an hour for the noonday meal throughout the year, from 12 to 1. In the afternoon there is a half-hour rest period with lunch, from 4 to 4·30, during the summer months, from April to August. The end of the day's work comes at 4 in December and January, 4·30 in February, 5·30 in March, 7 in April, 7·30 in May, 8·30 in June and July, 8 in August, 7 in September, 6·30 in October, and at 5 in November. The hours of work per day, inclusive of rest periods, for the various months are as follows:—January, 7½; February, 8; March, 10½; April, 11½; May, 12; June and July, 13; August, 12½; September, 12; October, 10½; November, 9; and December, 7½. The average length of the working day for the whole year is 10 hours and 35 minutes.—*Agricultural Gazette.*

Pure Milk Supply.

The Pure Food and Health Society of Great Britain have issued a proposed set of rules relating to the sale of milk right from its source, various sections being concerned with the conditions under which it is produced and stored at the farm, with its treatment in the town dairies, and with its supply to customers. Farmers and dairymen who agree to these rules will be permitted to use the society's pure milk seal, though this, says the *Mark Lane Express*, is not to be taken as a guarantee of purity, but merely as an indication that the precautions indicated have been carried out. The producer who desires to sell milk under this seal has to agree to periodical examination of his cows by a veterinary surgeon and by tuberculin tests. All milk is to be strained at the farm, and provision is to be made for cooling it immediately after milking. Detailed rules deal with the drainage and general cleanliness of cow sheds, the isolation of sick and newly-bought animals, the water supply, and the manner of milking. The milkers are to be under periodical medical inspection, and have to give an undertaking to report any form of sickness at their houses. Any addition to or abstraction from milk, whether coloring or any substance or liquid, is to be absolutely prohibited, and various milkings are not to be mixed. In town dairies the society requires a certificate as to proper drainage, and insists upon the most extreme cleanliness in every part of the building. Milk is to be sold only in glass bottles, which must be sealed before leaving the dairy, and not merely plugged with pulp covers. All pasteurised, sterilised, or separated milk must be so labelled, and dairies treating milk by those processes must be required to subscribe to additional conditions.

Selling Cattle by Live Weight.

In view of the discussions which have at various times taken place in regard to the inauguration in South Australia of the practice of selling cattle by live weight, it is interesting to note that when cattle are forwarded to the San Francisco market, where this practice is in vogue, it is the custom for butchers to hold them for 24 hours without feed or water before they are weighed. "If this were not done," says the *Pacific Rura Press*, "the sellers would very often fill the stock up with water and feed during the last 24 hours, with a resultant loss to the buyer when the cattle were butchered."

Imports and Exports of Fruits, Plants, Etc.

During the month of June, 1914, 1,111bush. of fresh fruits, 11,106bush. of bananas, 7,037 bags of potatoes, and 160pkgs. of seeds, plants, bulbs, and trees were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Acts of 1885 and 1910. Of these, 660bush. of bananas, 35pkgs. of plants, and 36pkgs. of trees, were fumigated, and 146bush. of bananas were destroyed (over-ripe). Under the Federal Commerce Act, 2,445bush. of fresh fruits, 2,624pkgs. of dried fruits, 12pkgs. of honey, 16pkgs. of seeds, and 18pkgs. of plants were exported to oversea markets during the same period. These were distributed as follows:—For London, 1,213pkgs. of dried fruits, 539bush. of oranges, and 1,040bush. of apples; for South Africa, 16pkgs. seeds, 296pkgs. of dried fruits, 12pkgs. honey, 3pkgs. of plants, and 9bush. of apples; for India, 280bush. of apples; for Canada, 400pkgs. of dried fruits; for Vancouver, 50pkgs. of dried fruits; for New Zealand, 15pkgs. plants, 665pkgs. of dried fruits, 480bush. of lemons, and 97bush. of oranges. Under the Federal Quarantine Act, 11,409pkgs. of plants, seeds, bulbs, nuts, &c., were examined and admitted from oversea markets.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.)

"E. N. H.," Eurelia, had a five-year-old mare which became stiff, and after three days got down, could not rise, and had to be shot. The mare was stable-fed, and did not appear to be in pain. At date of writing a gelding was developing similar symptoms.

Reply.—The symptoms are of toxæmic paralysis. It would be of interest to know the color of the patients and to see samples of the feed. Treatment.—Entirely change feed, giving bran and oats with a little linseed or olive oil in each feed, say a tablespoonful. Purge with a pint and a half of raw linseed oil or half a pint of castor oil. Give twice daily a tablespoon of Fowler's solution of arsenic and a teaspoonful of sulphate of quinine; if the animal is eating it will take them in the food; if not, mix with a little molasses and put into the mouth. It would be well in similar cases to communicate with the Chief Inspector of Stock, who would probably send a veterinary surgeon.

"P. H. R.," Balaklava, has a black mare who slipped a foal and had some difficulty with the afterbirth. Three weeks afterwards she became stiff, could not rise, had to be slung. She received Fowler's solution of arsenic and sulphate of quinine. She has a difficulty in urinating.

Reply.—It is difficult to determine from the symptoms whether this is a case of laminitis or of toxæmic paralysis, but probably the latter. It would be well to stimulate her hindquarters with a blister or liniment and continue the treatment; but try an entire change of food and purge with half a pint of castor oil.

"J. A. L." asks cause of death of horse which one day after working was noticed to be breathing heavily, the breath being very foul. The animal became worse and died in three days.

Reply.—The horse had inflammation of the lungs before being noticed; he should not have been worked when ill. Should others go the same way notify the Chief Inspector of Stock at once, and a veterinary surgeon will attend. Do not work; steam with only one teaspoonful of eucalyptus or turps. Give iodide of arsenic 4 grains, sugar of milk 10 grains, twice a day on tongue.

A member of the Coorabie Agricultural Bureau asks—What is a fair feeding ration for a working horse?

Reply.—The answer to this must be that it depends on individuals and circumstances; but certainly horses can be overfed and lose flesh on that account. The bulletins of the Roseworthy chaff-feeding experiments will give valuable information; also a little book, "The Economics of Feeding Horses," by Prof. Woodruff, now of Melbourne. Theoretically the nitrogenous ratio should be about 1-6. A horse weighing 1,000lbs. requires—For body maintenance, 6·5lbs. digestible starch with 0·65 protein; for work, 8·5lbs. digestible starch with 0·85 protein; total, 15lbs. digestible starch with 1·5 protein. Then age, weight, conditions of work, weather, balance of nutrient substances, and other conditions have to be calculated. Speaking generally, the feed of South Australian farm horses is deficient in fat and protein, and the energy expended in getting the nutrition out of it is greater than the nutriment obtained; hence horses fall away while getting large quantities. A mixed ration always gives better results than a plain one. Probably, for practical purposes, 40lbs. chaff, 6lbs. oats, 1lb. peas, 5lbs. hay (at night) would be quite sufficient for a big horse. On Sundays 4lbs. bran would take the place of oats and peas.

"H. G.," Waikerie, asks treatment for horse which had a swollen sore throat, with heavy breathing; when drinking water ran back through nose.

Reply.—Probably a chill and bronchitis. Steam with a teaspoonful of eucalyptus and give a teaspoonful of saltpetre twice a day in bran for a few days. A little Stockholm tar on teeth will also help.

Members of Goode Agricultural Bureau ask information concerning (1) mare dropping hips after foaling; (2) a cow, subject to fits—she bellows, rushes about and falls down, but in a little while fit passes off; (3) a horse which passes dung streaked with black clotted blood and of very bad smell.

Reply.—(1) The cause is failure of the bones of the pelvis to come together properly after birth. Prevention, keep mares at work; treatment, get in foal. Probably the bones will set right after the foal is dropped. (2) Probably tuberculosis of the brain, or worm cysts on the brain; possibly yacca has something to do with it. Feed and slaughter. If desired give nux vomica 1drm., sulphate of iron 1drm. in food twice daily for a fortnight. This will help if yacca is the cause. (3) Keep on with nux vomica, but also give arsenicum, 10 drops, three times a day. If these do not effect a cure, give a teaspoonful of sulphate of quinine once daily as well, in food. The trouble arises from bloodworms, the inner coat of the bowel having been destroyed by them.

"R. B.," Koppio, asks treatment for horse suffering from injury on inside near hind leg, 4in. above hock, possibly due to kick. The horse is in great pain, but there is very little swelling or discharge.

Reply.—A kick in this position often causes a greenstick fracture of the tibia, which gives no more definite symptoms than those described, but sometimes weeks after the bone breaks in two. Treatment—A good dab of Stockholm tar and rest in a small paddock.

"J. P.," Tarcowie, seeks advice as to treatment for mare whose udder swells when foal is being weaned.

Reply.—Wean gradually. When foal is off, rub udder with a warm solution of alum, a teaspoonful to a pint of water, and follow by hot lard or soapsuds. Give a little cooling medicine, such as an ounce of Epsom salts three times a day in feed or drinking water for a few days. Feed on long hay only, and not much of it.

"McG.," Whyte-Yarcowie, asks information concerning gelding which became ill 6·30 a.m. and died 12 hours later. The stomach was found ruptured and parts very frail. Numbers of small white worms like fine sewing cotton were found.

Reply.—The part of the stomach received is affected with an abscess caused by the fine worms described (*Habronema equi*), which find their way into the stomach from stable and house flies, with the result named. There are no definite symptoms, but sometimes the horse hiccoughs and draws his chin in to his breast. In such case a heaped teaspoonful of baking soda daily in the food will upset the worms when at work forming the abscess.

"J. R. C.," Longwood, asks whether cows would be likely to be injured if allowed to eat wattle leaves.

The Dairy Expert (Mr. P. H. Suter) replies—Wattle leaves would upset the digestive system, thus reducing the milk yield, and the milk secreted would have a taint which would also be communicated to the butter.

"H. S.," Macclesfield, has a gelding 9 years, which scours badly and, therefore, is in poor condition. He has given the animal aloes and nux vomica, as recommended, but without any improvement.

Reply—Trouble probably arises from systemic weakness of the bowels or a cancer growth in them. Never water before work and keep supply short. Give twice daily, in food, a powder containing chalk, 2 drams; catechu, 1 dram; cinnamon, 1 dram.

"H. F. J. H." had cow which calved and was cleaned properly; 48 hours later she became paralysed and died. He asks cause, as several other cows in district have died from apparently same trouble.

Reply—Probably milk fever. Treatment—Fill udder with air; keep cow on breast and warm; do not drench.

"S. B.," Murat Bay, had horse, 15 years, which became sanded; was successfully treated with honey and put in another paddock. Later, horse appeared filled with wind and suffered very acute pain and died. *Post mortem* showed that bowel had burst and some bots were found.

Reply—The bowels burst on account of the distension by gas, a condition which frequently follows change of feed in old horses. The bots were not responsible, neither was the drenching, for, if so, the horse would have remained standing for two or three weeks. When a horse cannot pass wind well rub the flanks and put 4ozs. glycerine in the enema. Give as a drench one-quarter pint gin, 25 drops ess. peppermint in half-pint warm water. This condition is usually termed stoppage of the water, which it is not. Horses hold their water because of the pain in their bowels.

"W. H. G." asks advice concerning 6-year-old mare. Her coat is sleek but she is low in condition, a very slow feeder, and slobbers and wets the nosebag through. Teeth have been looked at and seem all right.

Reply—The mare has abscesses in her stomach caused by minute worms. Give her a heaped teaspoonful of baking soda twice a day in her food for a month, and once a day in her food give her two tablespoons of Fowler's solution of arsenic for a fortnight.

"J. L.," asks treatment for cows which fail about a fortnight after calving, lose appetite, and yield milk which smells badly.

Reply—Probably the cows do not clean properly, and it would be well to give a few hours after calving a drench made of Epsom salts, 1lb.; sulphur, 1oz.; ginger, 1oz., dissolved in a quart of warm beer.

"A. E. C.," Crystal Brook, requires advice concerning cow, 10½ years, which used to give 14lbs. butter a week. Front right quarter became hard, milk fell off, rubbing and vaseline did not improve matters; two hindquarters have gone same way.

Reply—Inflammation of udder, probably arising from the attack of the germ which produces the contagious form; but in the case of a valuable cow it would be well to have a veterinary surgeon to see her, as there is a possibility of tuberculosis or actinomycosis. In the meantime, dissolve a teaspoonful of boracic acid in a pint of warm water and inject a quarter of the quantity into each teat once a day for a few days after milking, rub the udder well with hot soapsuds also, and give twice a day, in a little molasses on the tongue, 10 drops of tr. phytolacca for a fortnight or so. Treat it as if contagious and handle her last, washing the hands after doing so. Do not milk on to the ground. Destroy milk.

"F. R. F." seeks advice concerning young cow carrying third calf which is languid and mopes about near water all day. The brisket is swelled very much. A previous one, showing similar symptoms, had a clear jelly-like fluid in the swelling.

Reply—The symptoms are those of inflammation of the heartbag or pericarditis, which arises sometimes from a chill or foreign body in the chest such as a piece of wire ; or hydatids, which are very probably the cause in this case ; other parasites such as flukes may cause it. It would probably be most economic to shoot the cow, in which case any strange substances might be wrapped in a cloth soaked in strong brine or 4 per cent. formalin and sent to the Veterinary Lecturer for examination. If treatment is decided on, 10 drops of tr. digitalis three times a day for a fortnight might be tried.

"K.," Wepowie, asks the effect of molasses on the teeth of horses.

Reply—Molasses are not necessarily destructive to teeth, but if fed in greater quantities than 5 per cent. of the bulk of food set up acid indigestion, which eventually will react on the teeth.

Members of the Mount Remarkable Agricultural Bureau inquire treatment for sand crack on hoof of horse, which has become very painful and with offensive discharge.

Reply—Pare to bottom of crack to allow drainage ; remove all pressure at bottom by cutting away wall on each side of crack ; keep wrapped in cloth soaked in tr. arnica 1 part, glycerine 10 parts, for a few days, afterwards fill crack with wax or similar substance ; coat over with tyre solution ; and shoe so that no bearing comes on bottom of crack. Repeat treatment when necessary.

HORTICULTURE.

"E. P." asks what varieties of pears and Japanese plums should be planted on Bay of Biscay badly-drained soil, also for rotation of peach trees.

The Horticultural Instructor (Mr. Geo. Quinn) replies—I cannot recommend planting any kind of pear on very undrained soil. The Glou Morceau on quince stock may succeed, but would suggest the drainage be improved, and then any kind of pear or pear seedling stock would succeed. The favorite varieties of pears at the present time appear to be Beurre Bosc, Beurre Diel, Beurre Clairgeau, Clapp's Favorite, Doyenne du Comice, Glou Morceau, Harrington's Victoria, Josephine de Malines, Madam Cole, Packham's Triumph, Passuns de Portugal, William's Bon Chretien, Vicar of Winkfield. Of all these, though much despised, the lastnamed is probably the heaviest cropper, and carries to Europe most consistently. The above remark respecting the soil also applies to Japanese plums. Of these, Climax, Burbank, Federation, Formosa, Rubio, Wickson, and Wright's Early are probably the best; but I do not advise planting these in any number, as at present they appear to possess a value as fresh fruit only. A rotation of peaches is comprised as under:—*High's Early Canada, Ulatis, *Triumph, *Hale's Early, Ruby Red, Wiggins, *Peregrine, Louis Grognet, *Mountain Rose, *Early Crawford, *Elberta, Lovell, Red Shanghai, *Belle of Georgia, *Finlayson's Seedling, *Lady Palmerston, *Salwey, *Pullar's Clingstone, Red Italian Clingstone. A smaller selected list of these is marked *.

ANTHRACNOSE ON GRAPE VINES.

"Fruitgrower," Clare, asks for information respecting the remedies found most acceptable in Europe and elsewhere in the treatment of anthracnose on grape vines.

Mr. Quinn replies—Owing to the limited amount of local data, I have consulted the work of E. Bourcart, D.Sc., "Insecticides, Fungicides, and Weed Killers," published in 1911, for information respecting the above.

Sulphuric Acid.

On page 86, in discussing the use of sulphuric acid as a remedy, he states, "*Gleosporium ampelophagum, Sacc.*" (so-called Grape Rot). "To combat this disease the utility of the acid was found empirically. It is not, it must be understood, a question of treating this disease during the growing period, for sulphuric acid, or even the acid mixtures, would have a deplorable action on the stocks. The acid is used exclusively in winter to cauterise the spots hollowed out of the young wood, sorts of canker produced by the anthracnose containing spores which should be considered as hotbeds of infection. The remedy most generally used is a 50 per cent. green vitriol (sulphate of iron) solution; but to intensify its action it is associated with sulphuric acid in the proportion of 1 per cent. to 2 per cent. Fifty kilogrammes (110lbs.) of green vitriol are taken and 1 litre (say, 4lbs.) of sulphuric acid are poured on to it, and the whole dissolved in 100 litres (22galls.) of hot water.

"However, many vinegrowers limit themselves to sulphuric acid and regard it as sufficient to circumscribe the disease. Bouchard, Debray, Belese, and McAlpine are unanimous in eulogising the good results of this method, which, according to McAlpine, is in current use in Australia. It is certain that it kills not only the spores of this disease, but also those of oidium. It is important to operate before budding time, so as not to injure the growth. It is necessary to imbibe the stems, the runners, and all the wood, and even the eyes. The latter, owing to this treatment, blossom, it is true, some days later than non-treated vines, but this, in many cases, is an advantage. The coat may be applied with a brush or a woollen mop rag (on a handle)."

Sulphate of Iron.

Under the heading of "Green Vitriol," page 185, we find the statement respecting the treatment of the same disease. "Sulphuring and treating the vine with cupric bouillies (copper mixtures and compounds such as Bordeaux and Burgundy mixtures) have not circumscribed this disease at the same time as the oidium and mildew. Anthracnose must be treated by itself, and only winter treatment with green vitriol has proved entirely satisfactory. Schnorf was the first to advise the use of 50 per cent. solutions of green vitriol to contend against this disease, and Skawinski was the first to add to these solutions a small amount of sulphuric acid to render the solutions more corrosive. This last has given perfect results. Studied in different countries, this mixture has undergone some alterations of importance. Sorauer advises a 40 per cent. solution ; Tomé, a 35 per cent. ; Ghirardi, from 0·52 per cent for young shoots to avoid scorching by stronger doses ; Bolley advises 50 per cent. of green vitriol and 5 per cent. sulphuric acid ; Galloway, 6 per cent. of green vitriol and 5 per cent. of sulphuric acid ; Scribner, 23·6 per cent. of green vitriol, 6·6 per cent. of blue vitriol (bluestone or copper sulphate), and 1·9 per cent. of sulphuric acid ; Thomas, 20 per cent. green vitriol, 14 per cent. blue vitriol, and 12 per cent. of fat lime ; finally, Orillard, 25 per cent. of green vitriol and 10 per cent. of blue vitriol. Contrary to the opinion of Berlese, who attributes the success of these mixtures to their (free) sulphuric acid content, alone capable, in his opinion, of sterilising the cankers produced by anthracnose, green vitriol (iron sulphate) employed pure is perfectly capable of giving excellent results ; moreover, it has the advantage over 10 per cent. sulphuric acid solutions of not scorching the buds and only retarding their unfolding slightly. If the addition of blue vitriol (copper sulphate) be not injurious, and if mixtures containing this product have given excellent results in the Haute Garonne, this salt (*i.e.*, blue vitriol) is not indispensable and adds to the cost of the treatment. To-day, 50 per cent. solutions of green vitriol acidulated by sulphuric acid are in constant use in the Bordelais ; they are included in the annual treatment of vines in Medoc and in districts which suffer from anthracnose. The green vitriol solutions are made thus—50 kilogrammes, equalling 110lbs. of green vitriol (iron sulphate), are placed in a wooden or stoneware vat, then mixed with 1 litre (4lbs.) sulphuric acid of 53 B (commercial sulphate acid). Whilst stirring with a stick, 100 litres (22galls.) of hot water are run into the receiver. The precaution of first mixing the green vitriol crystals with the sulphuric acid is necessary to avoid projection (spurting) of the corrosive liquid. The solution is applied hot to prevent crystallisation on cooling. . . . . It is necessary to coat (the vines) from below, upwards, so as not to scorch the buds ; it is also preferable to unbark the stock (take off loose dry bark of the vine) before using this corrosive liquid." In bad cases, Dr. Bourcart advises "Two applications at an interval of 15 days, and the last operation should not take place within 15 days of the opening of the leaf; after coating the wood becomes black. When anthracnose is developed during plant growth it is contended against by mixtures of sulphur and green vitriol in powder form (powdered bluestone and flowers of sulphur). This treatment stops the development of the spores; but it should be renewed several times to protect the vine. It is, in fact, a preventive rather than a curative method."

It would appear from the above that the iron sulphate and sulphuric acid compound is favored as against the simple sulphuric acid solution by this writer. The exact percentage of sulphuric acid, when used alone, is not clearly indicated, but from the general context strengths varying from 1 per cent. to 10 per cent. appear to have been tried. These percentages are evidently calculated from weight. Our commercial sulphuric acids weigh about 1·83 times as heavy as water, volume for volume.

"A. Y.," Owen, has forwarded twigs of orange trees asking for the name of the disease affecting same, and also stating that his 7-year old trees were looking pale and unhealthy.

Mr. Quinn replies—The leaves and shoots are affected by the black scale (*Lecanium oleae*)), which is in the immature stage, and may be found readily as small oval-shaped, brown-colored, limpet-like creatures upon these twigs and leaves. The surfaces of the leaves and shoots are covered with 'sooty mould,' which is a fungus found growing upon the sweet liquid excrements of the scale, which have been spread over them as a film by the dew or rain or by water you have applied in hosing the trees. This fungus is not a parasite upon the plant, but, of course, obstructs the passage of light to its leaf surfaces. The remedy consists in destroying the scale insects which are the primary cause of the trouble. This may be done by spraying the trees occasionally—seeing that all parts are coated—with kerosine emulsion made by dissolving ½lb. soap in 1gall. of water by boiling, and whilst boiling hot pour into it the kerosine and churn it with a syringe or spray pump from one bucket to another into a creamy substance from which the kerosine oil does not come to the surface. This will take about half an hour's vigorous churning as described. For use, you put one part of this stock solution into about 14 parts of water—preferably warm water—and keep it stirred whilst being sprayed on to the tree. Do not use the stock solution if the kerosine separates at all freely after standing, but re-agitate the whole thing over again. In respect to the pale color of your trees, I suggest you sprinkle about 1lb. sulphate of ammonia and 1lb. sulphate of potash upon the soil around each tree, starting just under the foliage and making a circle extending 2ft. or 3ft. farther out. You may sow these together and dig them in with a fork so as to mix them with the soil. These manures will cost you about 6d. per tree to apply, and will, I think, cause them to take on a healthy green appearance as the spring time comes around.

"S. L. G.," Ardrossan, wishes to know the most suitable varieties of nectarines, peaches, and apricots for his district.

Reply—The following are recommended :—Nectarines, Dr. Chisholm, Goldmine, Stanwick; peaches, High's Early Canada, Mountain Rose, Lady Palmerston ; apricots, Newcastle Early, Oullin's Early, Moorpark. These are placed in their order of ripening.

A New South Wales correspondent, who states that he has read with interest Mr. Quinn's work on pruning and Mr. H. E. Laffer's contributions to the *Journal*, asks—(1) The name of earliest ripening grape in South Australia ; (2) the remedy for curl leaf on peaches ; (3) a description of Black Malaga vine ; and (4) best remedy for anthracnose.

Reply—(1) The earliest ripening grape grown here is Green's Early, which is never ready when grown outdoors before the first or second week in January. (2) The best remedy tried here for curl leaf in the peach and nectarine is a spray made by dissolving 1¼lbs. washing soda and 1lb. bluestone in separate vessels, each holding, say, 5galls. of water, and then mixing the contents so as to make 10galls. of spray. This is applied when the flower buds are opening in the spring ; but in wet districts it is necessary to give two dressings, one about a fortnight before the buds open, and the second as they expand. (3) The Black Malaga variety of grape vine, as grown here, has smooth, large, light-green foliage, borne on thick, brown, barked shoots, which often fail to ripen at the extremities. The bunches are large and long, and the black berries are loosely clustered in the bunch. The skin of the fruit is red before turning black, and it is a very firm, tough-skinned, oval-shaped berry of average sweetness, ripening about the latest of all the varieties grown here. It is sometimes called Malaga Muscat, but it has no muscat flavor. (4) The best remedy for anthracnose in the grape is, after burning all prunings, to take 56lbs. sulphate of iron, put it in a wooden vessel, and pour over it 2lbs. of commercial sulphuric acid ; then pour in 11galls. of boiling water and stir it into a solution. Mop this over all parts of the vine, more particularly the rods and spurs saved from last season's growth. This is very corrosive and should not be allowed to touch the skin or clothing of the person applying it.

POULTRY.

"R. B.," Wirrabara, asks treatment for fowls which lose use of legs and become very mopy ; the comb is pale, droppings thin and green and white color. About 12 have died. There is no sign of tick, and birds run at large.

The Poultry Expert (Mr. D. F. Laurie) replies—Your birds are probably suffering from the effects of intestinal worms, which have been very much in evidence this year. As the birds run about you will have some difficulty in dealing with them. However, obtain a supply of Bickford's worm paste and use as directed. You will need some bran and pollard to make a mash, and I should treat the whole flock.

SUPERPHOSPHATE.

The Maitland Agricultural Bureau inquires—(1) If superphosphate loses 140lbs. in each ton by evaporation, what percentage is required to bring the remaining manure to the standard ? (2) Seeing that it is known that superphosphate loses weight by evaporation, should not the manufacturers give a certain amount of overweight to allow for same ? (3) Does the Government analyse manures free of charge in cases of dispute ?

The Inspector of Fertilisers, Mr. G. Quinn, replies—(1) The loss due to evaporation by superphosphate is that of moisture only, so that the sample which has lost 140lbs. weight to the ton has become that much more concentrated, and if tested for phosphate of lime or phosphoric acid would simply be increased in percentage. The quality of the article has not in any way deteriorated, because the whole of the valuable constituent purchased is still there. In using superphosphate of the condition stated, 105lbs. would contain as much phosphoric acid as 1cwt. did in the first place, as only moisture has been lost, so that the adjustment is simple, and instead of adding anything to bring it up to the former condition, simply a lesser weight should be applied per acre. (2) Does not appeal as warranting any reply, unless, of course, the buyer is anxious to pay more for cartage and railage than is necessary. (3) The Government has not undertaken to analyse manures free of cost in case of dispute, but any person may have a sample of superphosphate tested for water soluble phosphate of lime at a fee of 10s. 6d. This amount is also charged for each determination of a constituent in any other fertiliser.

The Yadnarie Agricultural Bureau asks what guarantee the public have that super. purchased is up to standard.

Mr. Quinn replies—The guarantee received by the public that superphosphate and other fertilisers are up to the standard is given in the form of an invoice by the vendor, which the purchaser should demand in every instance. The guarantee contained in this invoice must coincide with that declared and registered with the Inspector of Fertilisers in Adelaide. The Fertilisers Inspector procures samples whenever possible from the consignments or manufactured lots, and has them analysed to see that the guarantee is maintained. If the purchaser suspects the fertiliser to be inferior to the guarantee he should take a sample and seal it in the presence of the seller and forward it along with the invoice containing the guarantee to the Government Analyst, or some other competent analyst, who usually determines the water soluble phosphatic content for 10s. 6d. In special cases, the Inspector of Fertilisers has tested samples from disputed lots, but unless a duly appointed inspector takes them in the presence of the vendor or his representative, the Government can take no legal action, but the private buyer has legal redress if he wishes to obtain it.

DEPARTMENT OF AGRICULTURE.

IMPORTANT CHANGES IN STAFF.

PROFESSOR PERKINS APPOINTED DIRECTOR.

Consequent on the resignation of Mr. Wm. Lowrie, M.A., B.Sc., from the position of Director of Agriculture, the Government have made some important changes in the official staff of the Department of Agriculture. Professor A. J. Perkins, who for 22 years has been connected with the department, for the last 10 years as Principal of Roseworthy College, has been appointed to the position of Director of Agriculture. Mr. W. J. Colebatch, B.Sc. (Agriculture), M.R.C.V.S. (Superintendent of Agriculture in the South-East and Manager of Kybybolite Experiment Farm), succeeds Professor Perkins as Principal of Roseworthy College ; and Mr. W. J. Spafford (Assistant Lecturer and Demonstrator of Agriculture and Assistant Experimentalist at Roseworthy College) has been appointed to the new position of Superintendent of Agricultural Experimental Work.

In the course of a statement to the press the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), commenting on the new appointments, said—" In dealing with the rearrangement of the staff the Government was very reluctant to remove Professor Perkins from Roseworthy College, where he has done such good work, or to transfer Mr. Colebatch from the South-East after he has obtained a good grasp of many of the problems confronting the producers in that part of the State. The Ministry felt, however, that there was no one in South Australia more competent than Professor Perkins to supervise and direct the agricultural experiment work, and that he could not give that work the attention it deserves, and at the same time, even with additional assistance, do justice to Roseworthy College. For those reasons, therefore, it was decided to appoint him Director of Agriculture. As such he will be chief technical adviser to the Minister, and will be responsible to the Minister for the whole of the technical staff of the department. He will also be responsible for the general experimental work and management of the Government farms throughout the State, with the exception of the Roseworthy Agricultural College, the immediate responsibility for which will be entrusted to the Principal in co-operation with the Director.

" In view of Professor Perkins' promotion, Mr. Colebatch, the next senior agricultural officer in the department, has been appointed Principal of the

Roseworthy College. During Professor Perkins' absence in Europe, three years ago, Mr. Colebatch was Acting Principal for 12 months, and the Minister and Professor Perkins are confident that he will be successful in maintaining the high standard of efficiency of the institution. The Minister realises that much of the value that should have been obtained from the experimental work conducted by the department outside the experimental farms has been lost through the want of proper supervision and the keeping of records. As it is intended to do a good deal in that direction in various parts of the State, Mr. W. J. Spafford, who has been assistant to Professor Perkins in the experimental operations at Roseworthy, has been appointed Superintendent of Experimental Work, and will, under the instructions of the Director, personally supervise this outside work. The Director of Agriculture will be responsible for the South-Eastern experimental work, and in this will have the benefit of Mr. Colebatch's experience. Applications will shortly be called for the post of Manager of the Kybybolite Experimental Farm.

"While the various technical officers will remain under the general supervision of the Director, the policy previously outlined in respect to their work will be adhered to. In the course of their duties both the Director of Agriculture and the Superintendent of Experimental Work will naturally visit the various parts of the State, particularly those where experimental centres are situated, and, with the co-operation of the Agricultural Bureau, arrangements will be made for them to deliver lectures. The Director, where possible, will attend country conferences of the Agricultural Bureau, in order to keep the members in touch with what the department is doing in their respective districts. A number of minor appointments are involved in these changes, and they will mostly be filled by officers already in the department, as the Government is of opinion that opportunity should be given to promising young officers with local training to justify the confidence reposed in them by their superior officers. Steps are being taken to select a suitable area of land beyond Minnipa Hill, on the route of the Minnipa to Cape Thevenard railway, for an experimental farm."

It is understood that Mr. Wm. Lowrie has purchased the Battunga Estate, near Macclesfield, and that he intends devoting his energies to mixed farming. Those acquainted with his great services to agriculture in this State will welcome the announcement that he intends to remain in South Australia, and will wish him the very best of success in his new undertaking.

ROSEWORTHY AGRICULTURAL COLLEGE.

FIFTH REPORT ON THE PERMANENT EXPERIMENT FIELD, 1905-1914.

By **Arthur J. Perkins**, Principal Roseworthy Agricultural College, and W. J. **Spafford**, Assistant Experimentalist.

INTRODUCTORY.

Experimental work bearing on manures, rotations, &c., has absorbed much of the activities of the staff of the Roseworthy Agricultural College Farm ever since its inception in 1883 ; but whereas, in earlier years, it had been customary to make work of this kind fit in with the ordinary farm cropping, in 1904 it was thought advisable to set apart for this purpose a special block of land, to which the name of " Permanent Experiment Field " was given. Agricultural experimental work generally can never present that definiteness in results that characterises those obtainable in a chemical or physical laboratory; there are, as a rule, too many more or less capricious factors which have to be taken into consideration. Of these the chief is, of course, the weather. Doubtless, with sufficient experience of any given locality, we are able, as a rule, to define its average weather conditions ; on the other hand, the existence of a normal average implies the presence on either side of it of opposing extremes, which may rule a season when we least expect it. It follows, therefore, that single year experiments are as a rule without practical value, since the results derived from them will hold good only under similar seasonal conditions. The value, therefore, of the solution to any agricultural problem will depend mainly on the extent to which it can be proved to correspond to the normal average weather conditions of any district; and, in our view, the only feasible way to secure results of this kind consists in patiently accumulating year after year data bearing on the same subject in the same way that weather data are accumulated. In the course of time the means of these data will offer the most accurate solution to any agricultural problem that may have been taken up. In other words, the practical value of agricultural experimental work depends very largely on its continuity; and this, perhaps, is the chief claim that can be put forward in favor of the innovation introduced for the first time in 1904.

PREVIOUS REPORTS.

Four reports bearing on results secured in the Permanent Experiment Field have already been published in the pages of the *Journal of Agriculture,* and subsequently in pamphlet form. The first report appeared in 1906, the second in 1907, the third in 1909, and the fourth in 1911.

Although in the main the original scheme of work outlined in 1904 has been adhered to throughout, necessity and experience have from time to time led to various modifications, which have been duly noted in earlier reports, and to which further notice will not be made. Some of the experiments originally undertaken, for instance, have been definitely closed and finally reported upon in the earlier reports ; those desirous of further information on the subject are therefore referred to what has already been published on these points.

THE PERMANENT EXPERIMENT FIELD.

Originally the Permanent Experiment Field consisted of 122 acres, divided up into 61 two-acre plots. In 1911 another 10 plots were added to the original ones, making the area of the field about 142 acres. The soil of this large field is on the whole fairly uniform in character; it consists of tolerably strong loam, which originally carried scattered groups of Murray box (*Eucalyptus largiflorens*), and may be looked upon as typically good wheat land. The only noticeable irregularity in the character of the soil of this field is met with in three or four of the plots, in which are to be found slight rises of travertine limestone, with its characteristic covering of loose, light soil ; soil of this kind carries mallee (*Eucalyptus dumosa, oleosa, &c.*) in the way of natural vegetation. The areas concerned are, however, too small to exercise any appreciable influence over the results we shall have to record.

Apart from this field, but immediately to the north-west of it, 15 new plots, 2·82 acres in area each, were set out in 1909. These plots are known as the Grainger Superphosphate Plots, and, as they cover similar work to that done in the Permanent Experiment Field, results derived from them will be considered in this report.

ANALYSIS OF THE NINE SEASONS UNDER CONSIDERATION.

We shall have to consider the results of nine consecutive seasons—1905-1913 ; it is essential, therefore, that we should from the outset have a brief account of the salient features of the individual seasons concerned. We append, in the first place in Table I., a full account of the yearly rainfalls comparatively with the means of the 30 years of which we have local record.

TABLE I.—*Showing the Yearly Rainfall, Month by Month,* 1905-1913, *comparatively with the Means of* 30 *years,* 1883-1913.

December	1·44	0·92	1·16	0·74	0·78
Totals	13·69	14·97	15·66	17·94	17·64

A comparison of the mean total rainfall for the nine years concerned—1905-1913—with that of the 30 years covered by our records—1883-1913—shows that the total yearly rainfall over this period has been fairly normal, at all events in so far as the mean yearly quantities of rain received are concerned. It may be noted, too, that the results referred to in this report concern five years in which the total rainfall was below the normal average, viz., 1905, 1907, 1911, 1912, and 1913 ; three years in which the total rainfall was above the normal average, viz., 1906, 1909, and 1910 ; and one year in which the total rainfall was almost exactly normal, viz., 1908.

From the point of view of crop growth, however, "distribution" in the matter of rainfall is of far greater importance than the mere yearly total. We have, therefore, summarised in Table II. what may be termed "useful" rain from the point of view of cereal crops, for the nine seasons in which we are concerned comparatively with the mean distribution of the previous 30 years.

TABLE II.—*Showing Distribution of "Useful" Rain,* 1905-1913, *comparatively with Mean Distribution of* 30 *years,* 1883-1913.

Years.	Seeding Rain (April-May)	Winter Rain (June-July)	Spring Rain (Aug.-Oct.)	Early Summer Rain (Nov.)	Total "Useful" (April-Nov.)	Rain without Influence on Cereals.
	Inches.	Inches.	Inches.	Inches.	Inches.	Inches.
1905	4·34	4·65	4·99	0·25	14·23	2·48
1906	1·44	4·83	7·77	2·26	16·30	3·42
1907	4·75	2·72	4·55	1·86	13·88	1·17
1908	4·12	4·31	7·03	0·07	15·53	2·21
1909	4·80	5·64	8·63	2·08	21·15	1·90
1910	3·43	5·67	6·51	1·18	16·79	7·08
1911	2·12	3·89	3·41	0·04	9·46	4·23
1912	1·10	3·55	6·56	1·84	13·05	1·92
1913	0·62	0·91	8·08	1·21	10·82	4·84
Means—						
1905–13	2·97	4·02	6·39	1·20	14·58	3·36
1883-1913	3·54	4·56	5·48	1·04	14·62	3·02

If again, we compare the means of the nine years that concern us—1905-13—with those of the 30 years of which we have record—1883-1913—we shall see that the mean total "useful" rain during these years was practically normal. In the matter of distribution we may note that, whilst the seeding and winter rains (April-July) were below the normal means (a little over an inch), the spring rains (August-October) by their greater copiousness compensated the winter shortage.

Finally, there remains for consideration what may be termed "fallow" rains, *i.e.*, rains of the preceding season falling on the land whilst it lay in the state of bare fallow between the months of August of one year and of March in the succeeding year. Data concerning these "fallow" rains have been summarised below in Table III. :—

TABLE III.—*Showing "Fallow" Rains—August 1st of one year to March 31st of succeeding year*—1905-13—*comparatively with mean of* 30 *years*—1883-1913.

		Inches.			Inches.
Season	1904–05	7·18	Season	1910–11—	11·41
"	1905–06	7·96	"	1911–12	5·89
"	1906–07	11·26	"	1912–13	13·00
"	1907–08	8·96			
"	1908–09	9·51	Mean	1904–1913	10·30
"	1909–10	17·56	"	1883–1913	9·54

All that need be noted for the present in this connection is that over the period of nine years, between 1905 and 1913, crops sown on bare fallow had the advantage of slightly more "fallow" rain than is usually the case in the district.

GENERAL CHARACTERISTICS OF THE NINE SEASONS.

Finally, we summarise briefly the general characteristics of the nine seasons concerned.

Season 1905-06 was characterised by very favorable seeding weather ; by a cold wet winter, without, however, much frost ; by a late cold spring ; and finally by very favorable ripening weather. Both hay and grain yields were exceptionally heavy and of excellent quality. The general College Farm yield of hay was represented in this season by 3 tons 5cwts. 67lbs. to the acre, and the general wheat yield by 24bush. 11lbs. to the acre.

Season 1906-07 opened with unfavorable seeding weather, followed by a very dry, though mild, winter. The spring months were on the whole unusually moist; unfortunately high temperatures accompanied by severe northerly winds set in rather suddenly, and blighted off many of the crops. The hay crops, although bulky in appearance, did not weigh well, and were poorer in quality, whilst much of the grain was shrivelled and inferior. The general College Farm hay average was represented by 2 tons 11cwts. 90lbs., and the wheat average 14bush. 30lbs. to the acre.

Season 1907-08 opened with favorable seeding weather, succeeded, however, by a very cold dry winter ; 18 heavy frosts were recorded this winter. Spring months were both dry and hot, and both hay and grain yields were light, although of good quality. The general hay average on the College Farm was represented by 1 ton 15cwts. 108lbs., and the general wheat average by 13bush. 20lbs. to the acre.

Season 1908-09 opened with favorable seeding weather, followed again by a cold dry winter, amply compensated for, however, by copious September and October rains. Ripening weather, too, was very favorable ; and in the end both hay and grain crops both heavy in yield and of excellent quality. The general hay average on the College Farm was represented by 2 tons 7cwts. 5lbs. to the acre, and the wheat average by 22bush. 14lbs. to the acre.

Season 1909-10 again opened with favorable seeding weather, albeit at times somewhat wet for field operations. The winter months were exceptionally wet, and many crops in the district were under water for several weeks, much to their detriment. Spring months were very moist and favorable, and all crops were most promising in appearance until early summer, when some of the most forward were slightly blighted off by hot weather. In the end both hay and grain crops were very heavy and of exceptional quality. The general hay average on the College Farm was 2 tons 15cwts. 68lbs. to the acre, and the wheat average 25bush. 5lbs. to the acre—the highest grain average hitherto recorded on the College Farm.

Season 1910-11 was characterised chiefly by unfavorable seeding weather, followed by exceptionally wet winter and spring months. The ripening period was favorable. Eventually hay crops were very heavy, but grain crops rather light and poor in quality. The general hay average on the College Farm was represented by 2 tons 7cwts. 31lbs. to the acre, and the grain average 17bush. 26lbs.

Season 1911-12 was remarkable for the general shortage of the rainfall ; seeding rains, winter rains, spring rains, and early summer rains were one and all below the normal average of the district, moreover seeding rains did not reach us until the middle of May. Finally, November was unduly hot and hindered the ripening off of the grain crops. Our hay crops were of fair quality and averaged on the farm 1 ton 8cwts. 6lbs. to the acre, whilst the farm wheat crops averaged 14bush. 17lbs. to the acre.

Season 1912-13 was again a season of low rainfall. There were practically no seeding rains ; rain sufficient to bring about the germination of sown crops did not come until the last week in June. Winter rains were fair, although still below the normal mean, whilst spring and early summer rains were exceedingly copious and well timed. Towards mid October College crops promised to be exceptionally heavy ; unfortunately the latter end of the month proved very dry and hot, and the crops experienced a rather severe set back. The average hay yield on the College Farm was 1 ton 14cwts. 90lbs. to the acre, and the average wheat yield 19bush. 36lbs. to the acre.

Season 1913-14 can claim the distinction of standing out as the worst season in our records. We have to note for this season almost complete absence of both seeding rains and winter rains, with the result that crops that had been sown in April and May did not germinate until the beginning of August ; spring rains, on the other hand, were abnormally heavy. These late germinating crops made rather rank growth in the spring, and ultimately succumbed to red rust and untimely hot north winds. The College Farm hay and wheat yields were the lowest on our records, viz., for hay, 16cwts. 7lbs. to the acre, and for wheat 6bush. 32lbs. to the acre.

AVERAGE YIELDS OF THE PERMANENT EXPERIMENT FIELD, 1905-1911.

Now that we have defined briefly the characteristics of the seasons with which we are concerned, it should prove of some interest, in the first instance, to endeavor to trace out their exact influence on the average yields of the plots of the Permanent Experiment Field. A careful examination of this question should enable us to determine the relative importance of individual climatic factors on cereal growing in the district in which we are placed.

In this connection, however, we are not in a position to group together in a general average the yields of all the plots of the Permanent Experiment Field, and this because, during the nine years that concern us, variations have from time to time arisen in the general treatment of some of the plots. We have, however, 15 pairs of plots scattered over the field, and representing an area of about 30 acres, the treatment of which has never varied since 1905. All these plots represent wheat preceded regularly by one year's bare fallow ; in 11 of the plots the land comes under wheat regularly in alternate years ; and in four of them every third year, a year of ordinary pasture intervening between the last wheat crop and the bare fallow. Thirteen of these plots are variously manured, whilst two of them have remained permanently unmanured since 1904.

Throughout these nine years the same variety of wheat, viz., King's White, has been used on all the plots, with the exception of 1906, when Gluyas wheat was used instead. The average yields of these plots, therefore, are strictly comparable one with the other from year to year, and may be taken to represent fairly accurately the average yields of this field for wheat grown after bare fallow.

We have summarised below in Table IV. the average yields of these plots between 1905 and 1913 :—

Table IV.—*Showing Average Yields of* 15 *Typical Plots of Wheat preceded by Bare Fallow in the Permanent Experiment Field.*

Season.	Average Total Produce Yield.			Average Grain Yield.	
	Tons	cwts.	lbs.	Bush.	lbs.
1905	2	11	77	28	41
1906	2	2	97	19	52
1907	1	1	70	15	50
1908	2	8	25	29	50
1909	2	12	94	29	5
1910	2	6	78	20	52
1911	1	12	4	16	23
1912	1	7	105	18	1
1913	0	11	79	5	19
Means	1	17	33	20	26

By way of emphasising the importance of the results set out in Table IV. the following facts will be recalled :—

(1) The figures given represent the average yields of 30 acres of the same field over nine successive seasons.

(2) In all the plots included in this area the wheat crop was in each season preceded by one year's bare fallow.

(3) Throughout the period under consideration the various plots represented received identically the same treatment from season to season.

(4) With the exception of 1906, throughout these nine years the same variety of wheat has been availed of, viz., King's White—a variety particularly well adapted to local conditions.

From a consideration of these facts it may be gathered that the results indicated in Table IV. set out in very sharp outline the purely seasonal influences controlling the yield of wheat grown on bare fallow in this district. That this seasonal influence is very considerable may be gauged by the fact that whilst in one season the average yield of wheat is close on 30bush. to the acre in another it is only slightly in excess of 5bush. to the acre. Before endeavoring to trace out the influence on yields of individual seasonal factors, we may note that the average grain yield for the nine seasons is about 20½bush. to the acre. This average we take to represent fairly accurately the possibilities of the district, wherever careful farming practices are followed. It is perfectly true, of course, that the College general farm average does not attain to this figure—our 10-year average (1904-13) is about 17½bush. to the acre. In this connection, however, it should be stated that this general average includes the yields of numerous varieties, more or less well adapted to local conditions, which for purely experimental purposes we are compelled to grow year after year on the College Farm, and which always exercise a depressing influence on the general average.

Again, for the nine years under consideration the average yield of total produce is shown to have been 1 ton 17cwts. 33lbs. to the acre. We shall frequently have occasion in the course of this report to make use of the term "total produce," and it is perhaps as well that we should from the outset define clearly its special significance. By "total produce" we understand the total weight of the crop—straw, chaff, and grain—as it is being carted from the field to the threshing machine. We have hitherto assumed that total produce yield represented roughly what would have been the hay yield of the crop had it been cut earlier for hay purposes. We had, however, occasion in two successive years to investigate various questions bearing on the cutting stage of wheaten hay, which were reported on in earlier numbers of the *Journal*; among other things these investigations showed very clearly that between the hay-dry weight of a wheat crop cut when the grain is about to leave the milky stage, and the hay-dry weight of the same crop cut when the grain was practically ripe, there was a difference in yield in favor of the earlier cut of about 18 per cent. In these circumstances an average yield of ripe total produce to the acre of 1 ton 17cwts. 33lbs. would correspond to an average hay yield of 2 tons 5cwts. 54lbs. to the acre; and this figure we take to represent very fairly the average hay capabilities of the district under good farming practices. It corresponds fairly closely to the College general farm average for the past 10 years, which is 2 tons 3cwts. 38lbs. to the acre.

THE INFLUENCE ON YIELDS OF INDIVIDUAL SEASONAL FACTORS.

We now propose endeavoring to trace out the special influence on yields of individual seasonal factors. In any given district what may be termed average local climatic conditions represent as a rule a special combination of seasonal factors which, according to circumstances, are liable to undergo favorable or unfavorable modifications, reflected in the field by yields that are either above or below the usual average. And whilst we believe that consistently successful farming depends very largely on the extent to which general practice is made to conform to this recognised combination of seasonal factors, we cannot overlook the fact that the importance in this direction of individual factors frequently altogether overshadows the influence of other members of the combination; and it is this point which we propose eliciting for this district in the light of our nine years' records.

An examination of Table IV. will show that in three of the seasons—1905, 1908, and 1909—the average yields were considerably above the normal; in two of them—1906 and 1910—the average yields were just about normal; in three others—1907, 1911, and 1912—the average yields were below the normal; and finally in one season—1913—the average yield was very considerably below the normal. With a view to facilitating a discussion of the apparent influence of individual seasonal factors we have summarised below in Table V. the various rainfall data, distributing the seasons in accordance to the value of their respective yields.

TABLE V.—*Showing the Influence of Rainfall Distribution on Grain Yields.*

Season.	Seeding Rains (April-May). In.	Winter Rains (June-July). In.	Spring Rains (August-October). In.	Early Summer Rain (Novem.). In.	"Useful" Rain (April-November). In.	Total Rainfall. In.	Grain Yields. B. lbs.
			YIELDS MUCH ABOVE THE AVERAGE.				
1908	4·18	4·31	7·03	0·07	15·53	17·74	29 50
1909	4·80	5·64	8·63	2·08	21·15	23·05	29 5

			YIELDS NORMAL.				
1910	3·43	5·67	6·51	1·18	16·79	23·87	20 52
1906	1·44	4·83	7·77	2·26	16·30	19·72	19 52
			YIELDS BELOW THE AVERAGE.				
1912	1·10	3·55	6·56	1·84	13·05	14·97	18 1
1911	2·12	3·89	3·41	0·04	9·46	13·69	16 23
1907	4·75	2·72	4·55	1·86	13·88	15·05	15 50
			YIELD VERY MUCH BELOW THE AVERAGE.				
1913	0·62	0·91	8·08	1·21	10·82	15·66	5 19
Means 1883-1913	3·54	4·56	5·48	1·04	14·62	17·64	—

A single glance at Table V. will suffice to show that in this district maximum yields are not necessarily dependent upon unusually heavy rainfall; indeed the heaviest average yield recorded—close on 30bush. to the acre—was secured in 1908, a year in which the the total rainfall almost exactly equalled the 30 years' mean for the district. On the other hand, in 1910, with a rainfall of about 6in. above the mean, the average yield was only slightly above the normal.

We may assume in a general way that, other things being equal, maximum yields are for the most part the result of an unusually favorable combination of seasonal factors; and if we concentrate our attention on the three years in which yields were very much above the average we may be able to discover what this special combination is, in so far as this district is concerned.

In the first place we shall notice that the total rainfall was almost exactly normal in 1908, an inch below normal in 1905, and about 6½in. above normal in 1909. Next, "useful" rain—April-November—was about normal in 1905, an inch above normal in 1908, and about 6½in. above normal in 1909. If, further, we look into details of rainfall distribution we shall see that each of these three seasons opened under favorable seeding conditions and with the advantage of seeding rains appreciably in excess of the normal average, whilst winter rains were normal in 1908 and 1905, and an inch above normal in 1909. Spring rains, on the other hand, were considerably above normal in 1908 and 1909, and about ½in. below normal in 1905. Finally, with the exception of 1909, November rains were too slight to carry any special influence.

On these data it would seem that of the three seasons, 1909 should eventually have shown up much to best advantage, and, but for one seasonal mishap, such undoubtedly would have been the case. Both 1905 and 1908 were free from early hot dry weather, while in 1909 a few days of unexpectedly sudden heat was sufficient to blight off the ears of many a promising crop—a misfortune which had the effect of appreciably depressing yields.

We may conclude that in this district maximum grain yields may be said to depend, other things being equal, upon the following combination of seasonal factors: First, rain between April and November slightly in excess of the normal, probably not less than 15in.; secondly, an early and favorable seeding season, with not less than a well distributed 4in. over April and May; thirdly, normal winter rains, *i.e.*, between 4½in. and 5in. in June and July; finally, the spring rains must be copious and well distributed, not less than 5½in. to 6in. between August and October. Generally speaking, with a good earlier distribution of rain, November rains are not of much value in this district. In the end, however, the most ideal of rainfall distributions may fail to lift yields above average if unexpected and sudden bouts of hot weather set in whilst the plants are still more or less soft and sappy. We are aware, of course, that it is sometimes customary to attribute unsatisfactory yields to the action of frosts whilst the wheat plants are in bloom; we find it difficult to accept this view, for this district at all events. We are certainly exposed to occasional hoar frosts in September and October; it is exceedingly rare, however, that these frosts are of sufficient intensity to affect wheat 4ft. or 5ft. from the ground.

If next we look for those seasonal factors which lead to grain yields below the average, we must note in the first place a total yearly rainfall appreciably below the normal, and particularly a low "useful" rain between April and November. In the matter of rainfall distribution, we think that a shortage in the seeding rains, such as obtained in 1906, 1911, 1912, and 1913, is the most potent factor in depressing the grain yields of wheat, and this chiefly because it generally leads to late and unsatisfactory germination which but rarely allows wheat plants to ripen off normally. If low seeding rains are followed up by a dry and cold winter the evil is much accentuated, and as a rule no amount of spring rains can lift the yields above mediocrity. We had good evidence of this in 1911 and 1912, but particularly in 1913. Finally, it may be noted that late germinated crops that are whipped along by spring warmth and copious spring rains continue soft and sappy at a late period in the year, and are always open to easy blighting by moderately hot weather and are quite powerless against red rust.

CONCLUSIONS.

Before closing this portion of the report we shall summarise below what appear to be the conclusions derivable therefrom :—

(1) In the Roseworthy district, and those similarly situated, we may look upon 20bush. of wheat, or 2½ tons of hay, as representing average yields well within the reach of those who know how to adapt farming practice to the requirements of local conditions.

(2) In the same districts 15in. to 16in. of rain well distributed over the growing period of cereals—April to November—render possible yields of 28bush. to 30bush. of wheat or 3 tons to 3½ tons of hay.

(3) In the same districts the most favorable rain distribution for maximum crops is represented by good early seeding rains aggregating 4in. to 5in. in April and May, followed by 4in. to 5in. in June and July, and by 6in. to 7in. between August 1st and October 31st. November rains are, as a rule, without significance in seasons that are otherwise favorable.

(4) In these districts the seasonal factors exercising most powerfully a depressing influence on yields, whether of grain or of hay, are as follows, in order of relative importance :—(*a*) Unduly late seeding rains ; (*b*) a shortage of seeding rains followed by a dry winter ; (*c*) a shortage of spring rains following on an unfavorable winter ; (*d*) unseasonably sudden hot weather accompanied by northerly winds in October or even in November ; and (*e*) moist warm weather in October and November leading to attacks of red rust.

ROTATION PLOTS.

Whilst in this field rotation plots have from the outset been a special feature of the work we have had in hand, circumstances have from time to time compelled us to modify both their scope and their incidence. We have had in fact to grope about in search of rotations likely to be of some practical value to the district ; nor, so far as the search is concerned, can it be said that we have as yet emerged from the purely experimental stage of the work. Various forms of rotation have been tested and, for a variety of reasons, discarded ; these have already been reported upon in earlier reports on the Permanent Experiment Field, and need not occupy us here. We shall confine our attention, therefore, to those rotations that are still retained in the present arrangements of the various plots. In this connection we shall have to consider the following types :—

(1) Two special modifications of the old Norfolk four-course rotation, viz. :—

	A		B
First year	Turnips	..	Kale
Second year	Barley	..	Oats
Third year	Pease	..	Vetches
Fourth year	Wheat	..	Wheat

(2) Two common local rotations which will serve as standards of comparison in determining the value of other rotations, viz. :—

	A		B
First year	Bare fallow	..	Bare fallow
Second year	Wheat	..	Wheat
Third year	—	..	Pasture

(3) A slight modification in the above rotations occasionally met with in local practice, and involving the introduction of summer crop, viz. :—

First year	Sorghum
Second year	Wheat

(4) A rotation including two cereal crops in succession to a year of bare fallow, viz. :—

First year	Bare fallow
Second year	Wheat
Third year	Barley

(5) A more complicated rotation, in which one year's bare fallow is made to figure only once in five years, viz. :—

First year	Bare fallow
Second year	Wheat
Third year	Leguminous fodder crop
Fourth year	Wheat
Fifth year	Barley

We have other forms of rotation in view which will be dealt with, however, in later reports.

Bare Fallow–Wheat Rotation.

(*Plots* 10 *and* 11.)

In this rotation the land comes under wheat regularly every other year, and is treated as bare fallow in the alternate years ; it is a form of rotation commonly availed of in the district, and in many other portions of the State that are similarly situated. We propose making it a standard of comparison for other forms of rotation tested, and shall therefore open the discussion with a full account of this rotation. Full details concerning results recorded between 1905 and 1913 for the two plots concerned in this rotation are shown in Table VI. :

Table VI.—*Showing* 1905-1913 *Harvest Returns from Wheat Grown continuously after Bare Fallow, with* 1*cwt. Superphosphate to the Acre.* (*Plots* 10 *and* 11.)

Year.	Total Produce per Acre.			Grain per Acre.		Straw to 60lbs. of Grain.	Bushel Weight.
	Tons	cwts.	lbs.	Bush.	lbs.	lbs.	lbs.
1905	2	11	54	28	56	139	62½
1906	2	8	100	23	43	171	58½
1907	1	8	88	20	31	97	62½
1908	2	11	26	32	46	115	64½
1909	2	7	61	29	54	118	62½
1910	2	5	98	19	49	199	64¼
1911	1	8	9	14	7	163	63¼
1912	1	6	32	18	11	102	65¾
1913	1	10	19	5	4	165	60
Means	1	17	67	21	27	141	62½

We see, therefore, from the above that land carrying wheat dressed with 1cwt. of superphosphate in every other year, and treated as bare fallow in alternate years, yielded in nine years an average of 21bush. 27lbs. to the acre. If we assume the average price of wheat to have been 3s. 6d. a bushel, this represents a gross return per two acres of £3 15s. 1d. per annum; if we assume further the rental value of the land to be 10s. an acre, and the cost of preparing the land, putting in, taking off, and marketing the crop to be 25s. an acre, this leaves a net profit of £1 10s. 1d. for two acres, or 15s. 0½d. per acre per annum.

If we look at these average returns from the point of view of hay crops we must recollect that total produce at harvest time does not represent more than 82 per cent. of the hay weight had the crop been cut at an earlier stage. Hence an average total produce yield of 1 ton 17cwts. 67lbs. represents about 2 tons 5cwts. 95lbs. of hay to the acre. The price of hay is subject to far more frequent and violent fluctuations than is the case with wheat, and introduces a speculative element in farming practice; hence, perhaps, the secret of the popularity of hay growing. In the circumstances it is not easy to get at the average gross returns of a hay crop in the district; if however we assume 35s. a ton to represent a fair average price, the average hay crop will have a gross value of £4 0s. 3d., *i.e.*, slightly more than the corresponding wheat crop. Rent, of course, remains the same, whilst the cost of handling the hay crop is not far different from that already indicated for the wheat crop; hence the average net profit for the hay crop works out to about 17s. 8½d. per acre per annum, *i.e.*, about 2s. 8d. above that of the wheat crop. It should not be forgotten, however, that these figures must vary with whatever market prices are offering for saleable produce.

It is, of course, true that even land that comes regularly in alternate years under bare fallow and wheat respectively offers a certain amount of grazing which might be made to contribute towards the gross revenues of the farm. There is, for instance, a fair amount of stubble grazing between the months of

December and March ; in certain seasons quite appreciable grazing in the early autumn and winter months before fallowing operations are completed; and finally, according to the seasons, fallow grazing is more or less plentiful. At the same time the farmer who makes it a regular practice to crop one half of his arable land and to fallow the other half is hardly likely to keep sheep, or indeed livestock of any kind other than working horses, unless there be attached to the farm a suitable proportion of rough land that cannot come under the plough. In the great majority of cases, therefore, what grazing is in the circumstances available will be utilised by the working horses, and to that extent reduce general expenses.

In the case of the two plots illustrating this form of rotation—plots 10 and 11—we have kept a record of the value of the grazing available, and have summarised the results below in Table VII. :—

TABLE VII.—*Showing the Grazing Capacity of Land treated alternately as Wheat and Bare Fallow* (*Plots* 10 *and* 11).

	Stubble Grazing—		Winter Grazing before Fallowing—	
Year.	Sheep per Acre December-March.	Gross Returns at 15s. per sheep per annum. s. d.	Equivalent Sheep per Acre per annum.	Gross Returns at 15s. per sheep per annum. s. d.
1907	—	—	0·03	13 11½
1908	—	—	0·46	6 11
1909	1·27	6 4	0·15	2 3
1910	0·76	3 9½	0·54	8 1
1911	1·08	5 5	0·49	7 4
1912	1·99	9 11½	0·00	—
1913	0·64	3 2½	—	—
Means	1·15	5 9	0·37	5 6

We see, therefore, that between 1909 and 1913 the grazing capacity of the stubbles of these plots had a value of 1·15 sheep per acre for four months (December-March), representing 5s. 9d. per acre, if we assume a ewe to yield gross revenue to the extent of 15s. per annum. These figures are on the whole below those of our general farm average, which, in "The Sheep Carrying Capacity of a Lower North Farm," were shown to be, between 1906 and 1913, 1·55 sheep per acre for the four months of stubble grazing.

Early winter grazing available before fallowing operations are completed is entirely dependent on early rains ; if these rains fail us, as was the case in 1912 and in 1913, there is no grazing available ; if the reverse is the case quite useful grazing will be available. The mean value of this form of grazing between 1907 and 1913 was represented on these plots by the equivalent of 0·37 sheep per acre per annum, having a gross money value of 5s. 6d.

The grazing value of bare fallow varies very considerably from year to year according to the character of the seasons, nor is it easy to estimate accurately on relatively small areas. We shall have to content ourselves, therefore, with the average figure indicated in "The Sheep Carrying Capacity of a Lower

North Farm" for the College farm between 1907 and 1913, viz., the equivalent of 0·25 sheep per acre per annum, representing a money value of 3s. 9d. per acre.

These several values — 5s. 9d. for stubble grazing, 5s. 6d. for early winter grazing, and 3s. 9d. for fallow grazing—are available only in alternate years, and must therefore be divided in two before they can be added to the yearly gross returns of the form of rotation under consideration. In the aggregate they will represent, therefore, an additional 7s. 6d. per acre per annum in the way of gross returns.

In conclusion, therefore, if we assume its grazing capacity to be utilised to the utmost, land coming alternately under wheat and bare-fallow will yield gross returns £4 10s. 1d. in alternate years; after deduction of rent and cost of production this becomes £2 5s. 1d., or a net profit of £1 2s. 6d. per acre per annum. Whilst at ruling rates, if hay takes the place of wheat, the figures would become £4 15s. 3d. for gross returns and £1 5s. 2d. for net profit per acre per annum.

BARE FALLOW-WHEAT-PASTURE ROTATION.

(*Plots* 17, 18, *and* 19.)

This is a form of rotation that is common enough on those farms on which sheep are kept; the wheat crop that had been preceded by one year of bare fallow, is succeeded by one year's pasture. In the majority of cases nothing is sown on pasture land of this character, and livestock are made dependent on the spontaneous vegetation that springs up on the stubbles; occasionally, however, a catch crop of rape, or some other similar crop, is roughly put in with the object of improving the stock-carrying capacity of the land. In the plots under consideration practice has varied with years; in 1906 and 1907 the plot out of cultivation was left as ordinary pasture, in 1908 it was sown to vetches, and from 1909 to 1913 to rape.

We have had several series of plots grown under this type of rotation. For purposes of comparison, however, we have thought it fairer in the present instance to take into consideration only those plots dressed with 1cwt. of superphosphate whenever they came under wheat. The harvest returns from these plots between 1908 and 1913—the only years that can be used in this connection—are shown below in Table VIII.

TABLE VIII.—*Showing* 1908-1913 *Harvest Returns from Land coming under Wheat once in three years, and dressed regularly with* 1*cwt. of Superphosphate.*

Year.	Total Produce per Acre. Tons	cwts.	lbs.	Grain per Acre. Bush.	lbs.	Straw to 60lbs. of Grain. lbs.	Bushel Weight. lbs.
1908	2	11	55	29	1	139	63¾
1909	2	10	56	26	37	152	62¼
1910	2	10	71	19	2	238	63¼
1911	1	17	69	17	51	176	61¾
1912	1	11	93	20	54	111	65
1913	0	11	48	6	8	149	60½
Means	1	18	103	19	56	161	62¾

Thus, then, over the six seasons extending between 1908 and 1913 the yield of wheat preceded by bare fallow and followed by pasture was represented by 19bush. 56lbs. of grain and 1 ton 18cwts. 103lbs. of total produce. This last figure represents about 2 tons 7cwts. 52lbs. of hay to the acre.

Over the same period of six years the yield of wheat from land alternatively under wheat and bare fallow, and treated with the same dressing of superphosphate, was 19bush. 59lbs. to the acre, and 1 ton 17cwts. 67lbs. of total produce, corresponding to 2 tons 2cwts. 58lbs.

We may conclude, therefore, in the first instance, that to leave the land out of cultivation once in three years does not, in the limited period of our observations, appear to have influenced the grain yield of the wheat crop, when compared with the yield of land coming under wheat regularly in alternate years. The calculated hay yield, on the other hand, shows an improvement of about 12 per cent.

Let us next consider what were the grazing returns from land under this form of rotation. The grazing returns during the pasture year, *i.e.*, the 12 months immediately following the wheat crop are shown below for each season in Table IX.

TABLE IX.—*Showing Sheep-carrying Capacity of Land left out of Cultivation and following Wheat dressed with* 1*cwt. of Superphosphate.*

1906–07	2·47 sheep per acre per annum.
1907–08	2·19 " "
1908–09	2·54 " "
1909–10	1·99 " "
1910–11	1·20 " "
1911–12	1·11 " "
1912–13	1·27 " "
1913–14	0·62 " "
Mean 1906–13	1·67 sheep per acre per annum.

Thus, then, in spite of the fact that the last four seasons were very unfavorable grass years, the sheep-carrying capacity of land out of cultivation between 1906 and 1913 was represented by one and two-thirds sheep per acre per annum, which represents £1 5s. 0½d. in gross returns, on the basis of 15s. per sheep.

There remains to be considered the grazing available in the years when the land comes respectively under wheat and under bare fallow. These returns are shown in Table X.

TABLE X.—*Showing Grazing available on Land coming under Wheat once in three years and dressed with 1cwt. of Superphosphate in the Wheat and Bare Fallow Years.*

Year.	Stubble Grazing.		Winter Grazing before Fallowing.		Fallow Grazing.	
	Sheep per Acre per Annum.	Gross Returns at 15s. per Sheep. *s. d.*	Sheep per Acre per Annum.	Gross Returns at 15s. per Sheep. *s. d.*	Sheep per Acre per Annum.	Gross Returns at 15s. per Sheep. *s. d.*
1907	—	—	0·87	—	—	—
1908	—	—	0·19	—	—	—
1909	0·84	—	0·51	—	—	—
1910	0·21	—	1·02	—	—	—
1911	0·14	—	0·57	—	—	—
1912	0·66	—	0·00	—	—	—
1913	0·76	—	0·00	—	—	—
1914	0·23	—	—	—	—	—
Means.......	0·47	7 0½	0·45	6 9	0·25	3 9

If, therefore, we combine the results in Table IX. with those in Table X. we see that in the course of a year the average sheep-carrying capacity of land coming under wheat once in three years was represented by 2·84 sheep for three acres, representing gross returns to the amount of £2 2s. 7d. at the rate of 15s. per sheep. It may be remarked that these figures represent close on a sheep to the acre for the whole of the arable area of a farm worked on these principles.

We are now in a position to compare the net returns of this form of rotation with those previously indicated for land coming in regular alternation under bare fallow and wheat. In the first place it must be stated that the figures for the two-course rotation must be recalculated so as to make them correspond to the six seasons of which we have record for the three-course rotation, viz., 1908-1913. We append below in Table XI. a statement to that effect (1) for the crop taken as grain, and (2) for the crop taken as hay.

TABLE XI.—*Showing Calculated Receipts and Expenditure for Wheat grown in regular alternation with Bare Fallow,* 1908-1913.

WHEAT CROP CUT FOR GRAIN.	£ *s.* *d.*	£ *s.* *d.*
Receipts—		
Grain crop..	3 9 11

Two years' expenditure	2 5 0	
Six years' expenditure	—	6 15 0
Balance of receipts over expenditure per acre for six years	—	**£5 19 10½**
Balance of receipts over expenditure per acre per annum	—	**£0 19 3¼**

Wheat Crop Cut for Hay.

	£	s.	d.	£	s.	d.
Receipts—						
Hay crop	3	14	5			
Grazing	0	15	0½			
Two years' receipts	4	9	5½			
Six years' receipts		—		13	8	4½
Expenditure—						
Two years' rent	1	0	0			
Cost of production	1	5	0			
Two years' expenditure	2	5	0			
Six years' expenditure		—		6	15	0
Balance of receipts over expenditure per acre for six years		—		£6	13	4½
Balance of receipts over expenditure per acre per annum		—		£1	2	6¾

In Table XII. below we have summarised, on similar lines, receipts and expenditure from land carrying wheat once in three years.

Table XII.—*Showing Calculated Receipts and Expenditure from Land carrying Wheat preceded by Bare Fallow once in three years,* 1908-1913.

Wheat Crop Cut for Grain.

	£	s.	d.	£	s.	d.
Receipts—						
Grain crop	3	9	9			
Grazing	2	2	7			
Three years' receipts	5	12	4			
Six years' receipts		—		11	4	8
Expenditure—						
Three years' rent	1	10	0			
Cost of production	1	5	0			
Three years' expenditure	2	15	0			
Six years' expenditure		—		5	10	0
Balance of receipts over expenditure per acre for six years		—		£5	14	8
Balance of receipts over expenditure per acre per annum		—		£0	19	1¼

Wheat Crop Cut for Hay.

	£	s.	d.	£	s.	d.
Receipts—						
Hay crop	4	3	1			
Grazing	2	2	7			
Three years' receipts	6	5	8			
Six years' receipts		—		12	11	4
Expenditure—						
Three years' rent	1	10	0			
Cost of production	1	5	0			
Three years' expenditure	2	15	0			
Six years' expenditure		—		5	10	0
Balance of receipts over expenditure per acre for six years		—		£7	1	4
Balance of receipts over expenditure per acre per annum		—		£1	3	7

A comparison of these two statements—Tables XI. and XII.—will show that, even when full allowance is made for the grazing capacity of land on which wheat is made to alternate regularly with bare fallow, there is practically no difference between the balance of receipts over expenditure of this rotation, per acre per annum, when compared with that of land carrying wheat once in three years and grazed every third year. Indeed, when the wheat crop is cut for hay there would appear to be 1s. per acre per annum to the advantage of the latter practice. We are, of course, quite prepared to admit that the figures given represent no more than average estimates, liable to vary very widely with circumstances. It is, at the same time, satisfactory to note that to miss one year's cropping in six does not necessarily involve one in pecuniary loss. It should be added, too, that we have dealt with the results of six successive seasons only. We quite anticipate that in the course of time the advantage in favor of grazing will become more marked, since whilst on the one hand organic matter will be accumulating in the land, on the other it will gradually be wasting away under the influence of oft recurring years of bare fallow, much to the detriment of the mechanical condition of the land, and ultimately of its fertility too.

In the examples that we have considered we have dealt with land dressed regularly with 1cwt. of superphosphate every time it came under wheat. We shall have occasion to show that this dressing is not advantageous from the grazing point of view; and had we made our comparisons between plots dressed with 2cwts. of superphosphate instead of with 1cwt., results would have been even more strikingly in favor of the practice of leaving land out for grazing every third year.

(*To be continued.*)

Haymaking

INTER-STATE CONFERENCE OF MINISTERS OF AGRICULTURE.

SUMMARY OF PROCEEDINGS.

The annual inter-State conference of Ministers of Agriculture, one of the most noteworthy events connected with the primary producing interests in Australia, was held in Brisbane on May 19th and 20th. With the exception of Western Australia, all the States were represented by the respective Ministers and some of their principal departmental officers.

In the course of the proceedings numerous questions of importance were discussed, and decisions which, in many cases, will tend to facilitate the inter-State trade in various agricultural products, necessarily subject to inspection in order to prevent the introduction of disease, were arrived at. Particular attention was given to the restrictions imposed by Western Australia on the importation of potatoes, and the heavy inspection fees charged, amounting to 15s. a ton. This is a severe tax on the Tasmanian and Victorian exporters, and was regarded in the nature of an import duty rather than a fee to cover the necessary cost of inspection. In the other States the fee varies from 6d. to 1s. a ton, and it was, therefore, decided to bring the matter under the notice of the Federal Government in the hope that more reasonable provisions could be secured.

Fruit Nomenclature and Export.

In view of the confusion caused in the local market and in the export trade, as well as among purchasers of fruit trees, it was resolved that a fruit nomenclature committee, consisting of representatives of each State, should be appointed to investigate and report on the correct names to be used for the different varieties of fruit. It was decided, at the instance of New South Wales, that in connection with the inter-State trade second-hand cases might be used for forwarding fruit direct to jam-makers, on condition that the manufacturers entered into a bond to treat all such second-hand cases in such manner as might be prescribed by regulation. As in the eastern States there exist a number of diseases which are not present in South Australia, the Minister of Agriculture for South Australia intimated that he would be unable to give effect to this resolution.

It was determined to recommend to the various States the adoption in the list of Australian standard fruit cases an improved Canadian case, which the

New South Wales representatives mentioned had been modified to suit Australian conditions. It now measures 20in. by 10in. by 11½in. inside, and has been accepted not only by Canadian shippers, but also by the Italian exporters of citrus fruits. Considering the large quantities of American apples and Italian citrus fruits imported into the eastern States, it was considered desirable to adopt this case in order to avoid the necessity for repacking the fruit when sold on the local market. The New South Wales Fruit Expert was also strongly in favor of it for local use.

In a report Mr. Crowe (Victorian Superintendent of Exports) suggested for export use a box measuring 18in. by 14¾in. by 10in. inside measurements. This is a slightly different shape to the present standard export case, and 25 of these will go to the ton instead of 23, and sometimes 24, of the present boxes. The saving in freight alone by the adoption of this case Mr. Crowe estimated at £10,000 to £15,000 on the Commonwealth oversea export for the current year. The case was carefully inspected by the experts from the other States, some of whom were of opinion that the ¼in. wood used for the sides, top, and bottom was too weak, and that further the timber would not be cut in general trade work sufficiently accurate to make the saving in space possible. It was pointed out that by the slight alterations effected during the past two years most of the shipments from South Australia were now going 24 cases to the ton, instead of 23, as in former years. It was resolved that the matter should be further investigated by the respective States.

Reports were submitted by Victoria and South Australia on the question of the decay of fruit in cold storage and in transit to market, and it was decided that each State should be asked to record the data received from the various Agents-General or Trade Commissioners in respect to the carriage of fruit to Great Britain, the condition of the fruit when it arrived, and any particulars concerning the causes of injury.

The proposals of two citrus growers in Italy regarding the treatment of citrus trees to cause them to produce fruit during the warm weather instead of during the winter months was referred to the experts of the various departments to make investigations and experiments in connection with the possibility of doing this. It was admitted that it would be of immense value to Australia if, instead of oranges and lemons ripening in the winter, when there was relatively little demand for them, the fruit could be made to mature in the warm weather, as was claimed to be possible by the Italian growers. Mr. Allen (fruit expert of New South Wales), who recently returned from a visit to Europe, stated that the desired result had been accomplished by some lemon growers of Sicily.

It was resolved to approach the various shipping companies and ask for certain alterations in respect to the loading and stacking of fruit in order to prevent much injury which now occurs.

STANDARD FOR FUNGICIDES.

The conference recommended that all the States, which had not already done so, should be urged to pass legislation to provide for the adoption of standards for fungicides and insecticides, and for the protection of purchasers of such goods. It was also decided that the agricultural chemists of the various States should, in the meantime, confer and draw up a set of standards to be incorporated in the regulations under such legislation. It was pointed out that it was essential that each State should, so far as possible, adopt the same standards as to what might or might not be included in insecticides and fungicides known under certain names, as it would be impossible for manufacturers to carry out their business satisfactorily if they had to adopt a different formula for the different States.

WHEAT STANDARD COMMITTEE.

At the instance of Victoria and New South Wales the conference resolved :—"That a wheat standard committee be appointed in each State by the Government for the purpose of fixing the f.a.q. standard sample each year, and that such committee consist of seven members, three representing the wheat exporters, two representing the wheat growers, and one the milling trade, with the Minister of Agriculture, or an officer deputed by him, as chairman."

EXPORT BUTTER.

Reports were submitted by the Ministers of Agriculture for Victoria and South Australia on matters connected with the sale of butter in Great Britain. Resolutions were carried affirming (1) the desirableness of compulsory grading of butter for export ; (2) the principle of compulsory grading of creamery and factory butter for inter-State trade ; (3) that all cream purchased by factories should be paid for according to quality ; (4) that butter for export graded as superfine and first grade should have the grade stamped on the boxes, and that the factory should be compelled to grade its butter, and pack it under registered brands representing such grades ; (5) that all cream graders and testers at the butter and cheese factories should be required to pass an examination, such certificates of competency, issued by the respective departments, to be inter changeable between the States ; (6) that the representatives of each State in London should meet periodically, and consult with each other with a view to report to their respective Governments on the best method of distributing butter in the United Kingdom ; (7) that the temperature at which butter is shipped should, so far as possible, be reduced from 30° F. to 20° F., and the carrying temperature from 15° to 10°, it having been demonstrated that the butter carried better at the lower temperature.

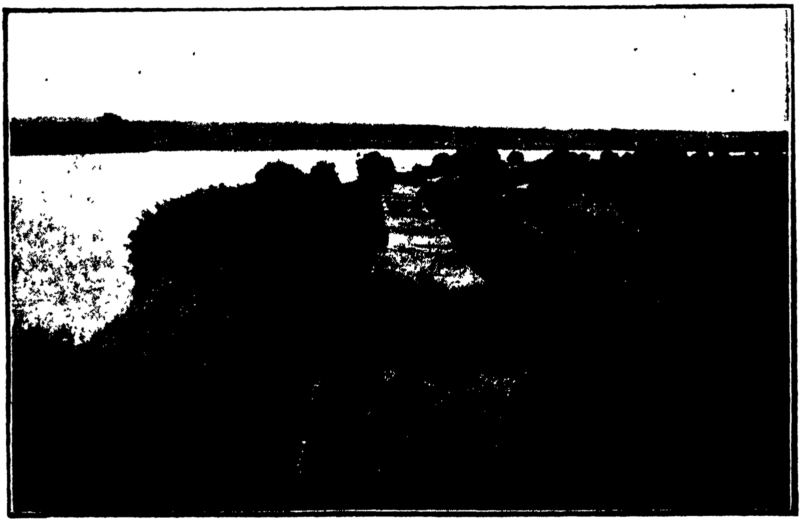
In respect to the question of coloring matter in margarine it was explained that in the eastern States the sale of margarine containing coloring matter is prohibited, but owing to there being no prohibition in South Australia, colored margarine is being manufactured in both New South Wales and Victorian factories, and shipped to South Australia. The Ministers were unanimously of opinion that the addition of coloring opened the way to fraud on the consumers, and was also dangerous to the dairying industry, and in view of this fact it was resolved that the Governments of the various States should be urged to refuse to adopt the recommendation of the pure foods standards committee that the coloring of margarine should be permitted.

SEA CARRIAGE OF PRODUCE.

The conference recommended the joint purchase of 10 thermographs, of the standard adopted and tested by the Canadian Government, for installation, with the consent of the steamship companies, in vessels engaged in carrying perishable produce overseas, to secure a reliable record of the temperature prevailing in the hold during the voyage, and the condition under which the produce carried at such temperatures arrived in Great Britain.

BRANDING HIDES.

At the instance of Victoria it was decided that efforts should be made by the departments in the different States to ascertain the best methods of utilising the least valuable portions of the hides of cattle for branding purposes, as the estimated loss by the present system of branding on the loins, rump, and ribs amounts to more than £400,000 per annum.



River Murray Reclamation Works.

THE PRINCIPLES AND PRACTICE OF PRUNING.

Address by Mr. GEO. QUINN, Horticultural Instructor.

The following address on "The Principles and Practice of Pruning" was delivered by Mr. Geo. Quinn, Horticultural Instructor, on the occasion of the annual pruning competitions held under the auspices of the Clare Agricultural Bureau :—

"The theory of pruning may be summed up as the accumulated observations of the behavior of plants when subjected to certain operative treatments under known conditions of soil, climate, and general vegetative activities. Like every other subject involving the records of natural phenomena, it must at once be admitted that the sum of our knowledge of this art is not to be claimed as a discovery of any given age or generation of gardeners, but rather is it made up of gradual accretions, which have little by little dawned in upon our inquiring minds. In the more advanced stages of the study of the application of the art of pruning come in all those diversities of treatments arising from the great variety of trees and plants which are submitted to the processes of pruning. These, however, cannot be claimed to belong to the basic principles which underlie pruning. Again it is often stated that everyone prunes differently, and every pruner has a different idea or set of ideas upon what he deems to be the proper method. Whilst judged by results all of these may not be wholly wrong, it would be folly to claim that they are wholly right. It would seem to be an incontestable statement that all pruning must be based upon the fact that the plant upon which our operations are performed is a living organism endowed with certain physiological functions, and our pruning can only prove successful in so far as it is in keeping with a proper conception of those functions.

"Assuming that the conditions of soil and climate are such as may be deemed reasonably appropriate to the growth of the plants under treatment, I wish to draw your attention to a few observed facts in the growth of plants which appeal to me as containing some basic underlying principles which alone can guide the pruner into following correct practices :—(1) The value of foliage to the plant. (2) The advantages accruing to growths securing a vertical position. (3) The relative disadvantages of a procumbent position. (4) The mutual relationship between roots and branches. (5) The relation of vegetative activity to fruit production. (6) The primary natural object of fruit production.

"Under the first heading we know that the greater the area of the foliage spread out into the sunlight the more rapidly will the manufacture of those compounds which are known under the general term of elaborated sap take place. The solidified form of these compounds we view later as leaves, stems, and shoots. How very important this fact is to the pruner, when he wishes to restrict the growth of any plant or portion of a plant, can be readily seen. The second fact arises from an unvarying rule which prevails in the growth of the plants, whereby the sap flows with greatest vigor to the highest points, thus giving them increasing advantages over those less fortunately situated. Hence it is that the pruner strives to elevate the shoots of that tree which is naturally spindly and prone in habit, and *vice versa*, if it serves his purpose he will divert the shoots of the upright, and consequently strong variety, into more horizontal positions. Why these effects should be produced we will consider later. The converse of this is found in our third proposition where the wider the angle which the shoot makes with a vertical line the more diffused does the sap become, and consequently settles into the buds of any such limb more evenly, thus causing them to grow more in unison than would be the case were any of them raised to a distinctly higher point. This fact forms the basis of all permanently successful methods of trellising grape vines or fruit trees. This question of vertical or horizontal position has an important bearing upon deciding the fate of a shoot, determining whether it shall be a lateral or fruit spur on the one hand or a strong leader on the other. Our fourth proposition indicates the mutual dependence or interdependence of the root and shoot systems of a plant. Under normal conditions of growth the sap which has been elaborated in the leaves descends by general diffusion to the roots and to the stems, shoots, and twigs, resulting in a practically simultaneous extension of all parts. The roots increase in size and length, and the stems and limbs do likewise in perfect concert. The balance therefore is complete, and should a portion of the top be removed, or some of the roots be severed, the energies of the plant are set into motion in the direction of repairing or replacing the injured member. Hence we see that when portion of the top is removed in the dormant season, and the roots are left intact, the balance is in favor of the roots, and they are enabled to send up a volume of crude sap, which finding fewer outlets, are concentrated in those parts, and acting upon the buds cause increased vigor in them, beyond what would have been the case had there been more buds to supply. On the other hand, let the root system be curtailed and the top left intact, and a lessened supply of inorganic salts is sent up and the general vigor of the top is checked. In this we can see the effect of restriction of supply, just as we saw prevention of the fullest elaboration when leaves are removed. The value of this fact comes home to the pruner in dealing with young trees recently lifted from the nursery bed, in which much of the root system has been cut off and left behind. It also appeals to him when dealing with the weakened tree which needs a stimulant in the form of giving the balance over to the root system by reducing the top by winter pruning, thus concentrating what at first is a weak supply of crude sap in fewer channels or buds, Again, it appeals to him in the case of vigorous large trees which refuse to bear adequate crops. In such cases he reduces by root pruning their possibilities for gathering mineral salts in excess, thus steadying the sap-making powers of the top and forcing a slower diffusion of that which is manufactured. This last-named phrase brings us to our fifth proposition referring to the relationship noticeable between vegetative activity and fruit production. It has been observed that within certain limits the production of fruit, or more correctly seeds, diminishes with an increased degree of vigor of vegetation in the plants. Thus, of most fruiting plants the strong growing one of mature size fruits but sparsely, and then almost without exception is the fruit borne on the laterals or spurs, which, owing to their respective positions, are kept in a more or less stinted condition. The young tree full of the flush of its vigorous development makes no pretence to fruit, but its stunted sickly fellow, lagging behind in vegetative activity, turns to a fruiting habit all too prematurely to permit of it reaching profitable proportions. This is probably to the fruitgrower one of the most important of all observed facts in the growth of his trees, and every pruner should be fully seized of its significance. Any operative treatment which is conducive to stimulated growth in a tree of average healthy development may be expected to diminish the quantity of fruit yielded, whilst the effect of that stimulation is felt, and *vice versa*, anything which tends to check the vigor of an already strongly proportioned tree will in most instances tend towards the formation of those shoots and buds which are producers of fruit crops. Thus it is that we say that the fruit-bearing habit arises from a quiescent condition in the tree or branch. The final proposition relates to the natural objective of the plant in producing fruit. This we may safely assert is the formation of seeds for reproduction of its species, and the greater number of individual fruits indicate the contained seed germs as the final result. The pruner is seized of the fact that the limit of the tree's powers in seed production stretches beyond its ability to clothe each one in the large volume of pulp which in most sorts of fruits give the greatest value. In consequence he sets himself the task of reducing the number to induce or permit an increased volume of pulp cells being formed around each one. To this end he either reduces the flower buds whilst they are yet unopened, or he plucks the immature fruits to the subsequent gain of those retained.

WHY WE PRUNE.

"We will now turn to the effect of putting these precepts into practice, and begin by asking the pertinent question—why do we prune our trees? I take it our objective may be summed up as follows:—Pruning is practised for the purpose of securing more regular crops of fruit of high quality over the longest period of years. This is the ultimate result sought, but we have first to apply it to (1) modify the natural form of the plant; (2) to stimulate or reduce the production of branches; (3) to sustain a healthy condition in the plant.

" Beginning with the tree as it arrives from the nursery we remove all broken or dead roots before planting it in its permanent position. As previously remarked its balance of roots and branches has been broken, and we must reduce the limbs to correspond with the much curtailed root area. Let me digress here by saying that if we transplanted our trees in late autumn, while the ground is still warm, the lacerated root repairs largely the injuries received whilst being lifted from the nursery bed. The elaborated sap has not yet ceased to be diffused, and the flow towards the injured roots is undoubtedly augmented by those injuries. Hence it is that whilst the top has ceased to grow and the leaves are falling, or have fallen, the root activities go on awhile with much vigor. That this descent of elaborated sap should be encouraged from every available twig, the shortening back or balancing of top with root should not be too hastily performed after transplanting takes place, but rather left until mid-winter arrives, and the lowered temperature of the soil tells us of the full period of dormancy in the plant. It is then the pruner proceeds to reduce the branches to a fewer number of buds, so as to give the root system if possible the balance of power. The return of vitality in the plant shows an increased vigor in those individual buds, resulting in a strong growth of shoots, limited as yet in number. The next winter season will see the balance again given to the root system, with similar results in wood and leaf growth in summer. This regular order may be followed for several years more or less in accordance with the development of the individual trees. As a normal stature is attained the roots need not be further encouraged to hold the balance of power, but rather should the top be left untouched in winter or the leaf spread be reduced in summer to stay their absorptive and assimilative powers so that no longer is the rapid manufacture of tree-forming compounds encouraged. If the removal of foliage and the admission of sunlight do not check this vigor, the balance of power may be given to the top much more markedly by actually curtailing the roots and thus lessening the supply of crude food materials at both ends of the chain. Assuming the treatment results in the fruiting habit becoming established, and crops are obtained, the nourishing of which leaves a lessening amount of sap for the production of wood and foliage, the danger line of over-cropping is sooner or later approached, and again the question of increasing the vigor of the tree without unduly reducing its yield of fruit becomes the concern of the grower. To this end the pruner again steps in, and either reduces the number of shoots which may possibly bear fruits, or he reduces the fruits themselves whilst they are yet in a very immature condition, thus lightening the tree's burden to its vegetative advantage.

" We may thus sum up the principles of pruning by saying that under normal conditions any reduction of the top of a tree whilst it is in leaf tends to check its vitality or vigor of vegetation, and a checked condition of growth is conducive to the production of flower buds, and possibly fruits. On the contrary, any reduction of the top during the dormant period turns in the direction of giving the balance of power to the root system at the return of spring, and this, as it has been seen, results in an increased development of roots and shoots, and, if excessive, in a reduction of the number of flower buds formed during that and possibly succeeding seasons."

THE AGRICULTURAL BUREAU.

PRUNING COMPETITIONS AT CLARE.

An encouraging feature in connection with the important work of the Agricultural Bureau is the increased attention given to the conducting of experiments and demonstrations. Three years ago the Clare Branch inaugurated an annual pruning match, and the success which has attended the fixture, both as regards the number of competitors and spectators and the keen interest taken, affords incontestable proof of the general recognition of the benefits accruing from such object lessons.

This year's competition was held on Monday, June 8th, in the orchard and vineyard of Mr. W. Pattullo. At 9·30 a.m. about 150 persons had assembled, and shortly after the competitions were in full swing, class after class—except for a brief interval for lunch—following in rapid succession. At the conclusion of the contest the judges addressed the competitors and others, pointing out and demonstrating the faults and defects of the pruning. The Secretary of the Advisory Board (Mr. G. G. Nicholls), who also spoke, urged those present who were not members of the Agricultural Bureau to join that organisation and co-operate in its useful work, one exemplification of which they had witnessed that afternoon. Much credit for the success of the competition is due to the committee of management—Messrs. J. Dux (chairman), C. Jarman, R. Hunter, J. H. Knappstein, J. Berridge, W. Pattullo, and the joint secretaries, Messrs. M. L. Nolan and P. H. Knappstein.

THE CLASSES.

Included in the test were classes for apricots, apples, peaches, currants, sultanas, and wine grapes. A class was also provided for youths—15 years of age or under—for pruning one sultana and one currant vine each. The work done in this class was very creditable indeed, and many a man would find it hard to do better work than that accomplished by some of the lads. An innovation was made in the inclusion of championship prizes for apples and peaches in the form of gold medals to be awarded to the competitors in these classes who secure the highest total for three consecutive years. The judging will be in the hands of a committee of the Bureau, and will be based upon the actual weight of marketable fruit the trees are carrying in season, as well as upon points gained in the pruning competition. Each competitor will have the same tree to handle for the three years.

A VALUABLE CONTEST.

Commenting on the contest, the Horticultural Instructor (Mr. Quinn) remarked that he thought the pruning match should command the wholehearted support of all orchard and vineyard owners who employed labor, owing to the fact that the possession of a certificate signed by a competent judge that the workman had displayed in open competition the necessary ability, skill, and decision to effectively prune certain kinds of trees and vines, was the best recommendation that he was not likely to do any harm and needed little or no instruction as to how he should set to work. On the other hand the workmen who engaged in this type of work, by pruning in the competition were gaining a standard of excellence which would go a long way toward giving them that preference which the command of skill and the proper knowledge of the practice must bestow. Consequently they would benefit in securing the highest wages, and could rightly demand such, above those who were not possessed of such qualifications.

Mr. Quinn favorably contrasted the pruning match with those he had seen in other parts of the State, in so far that not only were the competitors exceedingly keen, but that they had first class material to work upon. For example, of the fruit trees the apricots and peaches were remarkably well grown and the apple trees were of fair average character.

Sufficient work was allotted each competitor to enable him to show very clearly his knowledge of the treatment which should be given to the kinds of fruits dealt with, and, of course, the competitors were informed of the variety of the tree in each instance.

Peaches were Red May, Early Crawford ; apricots, Moorpark ; and apples, Cleopatra and Jonathan—all well-known varieties involving treatment peculiar to each.

PRIZE AND CERTIFICATE LIST.

Apricots.—Judge, Mr. Geo. Quinn ; steward, Mr. C. J. Radford (14 competitors ; maximum points, 100).—C. Glaetzer, 85 points, 1st prize and certificate ; P. Dunstan, 83 points, 2nd prize and certificate ; W. Smith, 82 points, 3rd prize and certificate. Certificates—H. Bartlett, 81 points ; A. Burgess, 80 points ; J. Butler, 80 points ; T. Taylor, 80 points ; O. Dunstan, 80 points.

Apples.—Judge, Mr. J. Kempster; steward, Mr. C. Neate (28 competitors; maximum points, 100).—W. Foreman, 94 points, 1st prize and certificate; C. Glaetzer, 87 points, and A. Burgess, 87 points, tied for 2nd, divided 2nd and 3rd prizes. Certificates—H. Bartlett, 86 points; W. Millard, 86 points; F. Mutton, 85 points; W. Smith, 83 points; B. Burgess, 82 points; W. Baker, 80 points; O. Dunstan, 80 points; H. Stewart, 80 points; H. Baker, 80 points; A. Bartlett, 80 points; C. Barber, 80 points.

Currants.—Judge, Mr. A. P. Birks; steward, Mr. E. Victorsen (32 competitors; maximum points, 100).—W. Bond, 91 points, 1st prize and certificate; O. Dunstan, 90 points, 2nd prize and certificate; T. Taylor, 89 points, and C. Barber, 89 points, 3rd prize and certificate. Certificates.—O. Ward, 88 points; J. Butler, 85 points; H. Bartlett, 85 points; C. Glaetzer, 83 points; T. Webster, 83 points; J. Ward, 82 points; H. Stewart, 82 points; M. Barber, 82 points; A. Burgess, 81 points; B. Burgess, 81 points; A. Collins, 81 points; J. Miller, 80 points; F. L. Burgess, 80 points; C. Bray, 80 points; A. Ward, 80 points.

Sultanas.—Judge, Mr. C. T. Jarman; steward, Mr. B. Lloyd (24 competitors; maximum points, 100).—H. Bartlett, 91 points, 1st prize and certificate; W. Millard, 91 points, 2nd prize and certificate; C. Glaetzer, 90 points, 3rd prize and certificate. Certificates—P. Dunstan, 89 points; T. Taylor, 88 points; S. Hill, 88 points; B. Carroll, 88 points; H. Baker, 87 points; W. Baker, 87 points; W. Foreman, 87 points; W. Bond, 86 points; W. Smith, 86 points; F. L. Burgess, 85 points; F. Knappstein, 85 points; E. O. Wishart, 84 points; W. Maynard, 84; O. Ward, 83 points; T. Webster, 83 points; A. Collins, 83 points; H. Stewart, 83 points; J Ward, 81 points; A. Ward, 80 points; J. Butler, 80 points.

Wine Grapes.—Judge, Mr. E. O. Wishart; steward, Mr. P. R. Pascoe (19 competitors; maximum points, 100).—W. Baker, 87 points, 1st prize and certificate; W. Millard, 86 points, 2nd prize and certificate; C. Barber, 85 points, 3rd prize and certificate. Certificates—A. Bartlett, 84 points; W. Bond, 82 points.

Peaches.—Judges, Messrs. Geo. Quinn and J. T. Hague; stewards, Messrs. C. J. Radford and R. Hunter (21 competitors; maximum points, 100).—J. Butler, 86 points, 1st prize and certificate; J. Ward, 84 points, and A. Dunstan, 84 points, tie—2nd and 3rd prize divided. Certificates—W. Foreman, 83 points; F. G. Hicks, 83 points; B. Carroll, 81 points; P. Dunstan, 81 points; W. Smith, 80 points.

Juvenile class for boys 15 *years or under.*—Judge, Mr. W. G. Lewcock, jun.; steward, Mr. R. Hill (maximum points, 100).—R. Birks, 94 points, 1st prize and certificate; L. Dux and G. Pattullo tied for second place—divided 2nd and 3rd prizes; certificates to each.

TO DRENCH OR NOT TO DRENCH?

A QUESTION IN EVOLUTION.

By F. E. Place, B.V.Sc., M.R.C.V.S., Veterinary Lecturer.

A sick horse and something to pour inside him—a combination of circumstances which seems to have exercised men's minds for thousands of years. Homer tells us that outside the walls of Troy the arrows of Apollo fell thick and fast on man and beast, so that thousands died of the plague ; and an undiscovered manuscript is said to describe a scene where Achilles is in sad trouble over the sickness of his charger, and sends for Hipparchos, the priest and horse doctor, who comes and, with rich and varied ritual, prescribes and orders the administration of a drench for the suffering beast, which soon succumbs, as it cannot absorb through its lungs some quarts of burnt dog's liver suspended in thick Chian wine. Achilles seems to have his doubts as to the cause of death; which frame of mind Hipparchos deems most impious, and departs in dudgeon, warning the wrathful owner to sacrifice a cock to Aesculapius, and to be truly thankful for the skill bestowed on the operator, "For without my aid the horse might e'en have lived."

Some hundreds of years pass, and we are with Cæsar on the banks of the Rhone. The constant fording and refording have played havoc with the Roman cavalry ; the horses cough and run at the nose, and die of "Morbus." So the great commander sends for Eques Veterinarius, who, with prompt skill, holds a sick horse parade, and declares, with many mystic terms, that each patient must be drenched with 2 quarts of juice made from pounded fox lung mixed with eagle's dung. The disease is so virulent that even while being drenched the horses fall and die. Cæsar was evidently much annoyed, for he writes of the "loss of horses under that —— E. V." But later, with the calmness of a great general, he admits that, but for the quickness of the deaths following the drenching, the fodder might have been consumed and his chance of successful retreat much lessened, and so recommends E. V. for promotion, on the ground that he has been of great service to the State.

The scene changes to the Holy Land; and on the shore at Joppa, sickness and death decimate the chargers of Richard Cœur de Lion's knights; so Mareschal Knight, who is "cunning with horses and skilled withal," is consulted, specially with respect to the king's favorite Barbary charger. He prescribes large drenches of water from the Sea of Galilee, to fetch the which would mean penetrating the Saracen lines. The king is not charmed with the prospect, and hints that the horses already drenched have died more quickly and certainly than those which have not had the benefit of the valiant Mareschal's drenches; and, when night calls for truce, Richard consults one of Saladin's Arab officers, but cannot translate the word "drench." However, a Paynim Hakeem is sent for, who laughs outright at the idea, and gives the Frank a sweet-smelling gum, to be burned under the horse's nostrils, and a smooth paste to be put upon his tongue. Some days later Richard plays polo on the Barb, and in the evening the Mareschal descants at mess on the wondrous healing power of the waters of Galilee when given as a drench in large quantities, a view that is strongly upheld by the king's chirurgeon and his reverence the chaplain.

A few more centuries pass, and the Merry Monarch hands out the tinkling silver bells to the winner on Newmarket Heath; for already dour King Jamie's imported Barbs and Place's White Turk have formed the strain that later produces St. Simon and Carbine. But "the distemper," a legacy of the late unhappy wars, is spread from inn stable to farm, from farm to grange, from grange to castle, and post horses stagger on the last stage to die; the plough lies idle under the hedge. Farrier Smith is therefore in great demand, for who so clever as he at giving a drench? And that's a thing no unlearned person should attempt, for pouring oil of vitriol or spirits of salts down a horse's nostril is no lay matter. And, reader, mark the advance—now there is no hit or miss, pouring into the lungs *via* the mouth; no, with skilled attention it goes direct from nose to lungs, and the distemper troubles them no more. But one day, in the parlor of the Jolly Huntsman, Tom Ashley, who combined the lucrative trades of tanner and knacker, twitted his cousin the farrier on the fact that since he had grown too fat to drench with ease and drank too much to afford to use potent drugs, horse hides had become quite scarce; whereupon, with a round oath, the farrier gave his professional opinion that infernal drenching had killed more incarnadined horses than ever the glanders had; and who shall say he was wrong?

Yet, in the year of grace 1914, no sooner does the horse get the gripes than someone is sent galloping off for a drench, and probably for a drenching bit, for that will ensure the drench going down; yes, but where? Where the dog's liver and Chian wine went, where the fox lung juice went, where Farrier Smith's concoctions went—down the windpipe into the lungs. Why? Because the horse's nose is above his mouth and his windpipe below his gullet, and when he drinks his head is down, and his windpipe is protected by a trapdoor (the epiglottis), so that the liquid glides over it into the gullet down into the stomach. But when the patient sufferer falls into the hands of ministering angels with a drench, up goes his head, the muscles of his throat are stretched so that the trapdoor is forced open, and, being shaped like the lid of a jug, involuntarily catches the drench and tips it down the windpipe. And still the nose is used as a funnel, despite the fact that it is arranged to allow air, not liquid, to get into the windpipe; and if liquid is substituted for air it, too, has to go the wrong way after intensely irritating a very delicate organ ; and when a horse coughs he is bound to take the drench down his windpipe. Nowadays the active principles of all useful drugs can be obtained in concentrated form, and, mixed with molasses or pollard, can be put on the tongue or teeth, or tastelessly mixed with the food or drink, or inhaled in vapor form without harm; and the chorus that comes down the ages in an equine Esperanto, " Killed by drenching," will, *diminuendo pianissimo*, be lost to the ear, while the cheerful whinny of the grateful and restored patient will take its place if the question in the headline is answered in the negative.

THE "FRENLER" REMEDY FOR CODLIN MOTH.

By George Quinn (Chief Inspector under the Vine, Fruit, and Vegetable Protection Acts, 1885 and 1910).

During the past couple of seasons a proprietary compound known as " Frenler " has received some prominence in a neighboring State as a remedy against codlin moth. It consists of a pungent liquid which, after being placed in jars or receptacles, is hung in the apple and pear trees at the time the moths are actively depositing their eggs upon the fruits and foliage. It has been claimed that the codlin moths are attracted by the odor of the liquid, and becoming thus enticed into the jars, are subsequently drowned. In this State the law does not recognise any remedy for this pest other than those such as spraying with lead arsenate, bandaging, &c., as prescribed by regulations framed for the purpose.

Owing to numerous inquiries from orchardists, it was decided to give the compound a trial. Mr. G. L. Wishart, Inspector of Orchards for the Northern Districts, was asked to conduct a test at Angaston. The inspector now reports as follows:—

" An old tree of the Cleopatra variety, somewhat isolated, was selected for the test, and with the exception of an early spray of Bordeaux mixture, left unsprayed throughout the season. Two wide-mouthed glass jars containing the 'Frenler' mixture were hung in the branches on October 7th, and the usual bandage of sacking placed around the butt of the tree. On January 3rd the whole tree was carefully gone over, and all fruits showing signs of tunnelling picked off, examined, and counted. On April 20th the tree was stripped of its crop, the fruit being examined and counted as before. From time to time, as the 'Frenler' evaporated, the jars were kept refilled with fresh solution, a bottleful of the concentrated 'Frenler,' costing 4s., being used during the test. The following table shows the results of the examinations of the fruits, jars, and bandages in detail."

Table showing Results of Examinations of the Fruits, Jars, and Bandages in Detail.

Date.	Fruits—Sound.	Fruits attacked at—				
		Calyx.	Calyx End.	Stem.	Stem End.	Equator.

Totals—Codlin moths, 122; bees, 47; miscellaneous insects, 49 (including ants, beetles, flies, and small moths); codlin larvæ trapped in bandage, 179.

KYBYBOLITE AND GREEN PATCH.

CROPS AND CROPPING.

(Address by W. J. Colebatch, B.Sc. (Agric.), M.R.C.V.S.)

(Continued from page 1174.)

In districts that are liable to be short of natural feed both in the autumn and early summer, and where at the same time sown grasses are apt to prove disappointing, the practice of lambing down all the ewes in May and June is open to criticism. Where ample provision is made in the shape of late summer and autumn green feed there is less to be said against the system, but it is not always possible to arrange for such provision. During the last two seasons the months of March and April have been so dry that early sown grain did not germinate till well in to May, and most of the autumn lambs had been dropped two or three weeks before the feed was ready for grazing. Again, it should not be overlooked that the ewes tupped in December and January are asked to nourish and develop their lambs during a period that is usually marked by shortage of paddock feed. It is true that with spring lambs there is the danger of an early summer, with the consequent drying off of "milking" feed, and of course there is a little more bother at shearing, but where proper care is taken to have on hand a block of kale and sorghum the spring lambs will do well, and I am confident there will be a much lower proportion of stunted weaners in them than in those reared through the cold wet winter months. Furthermore, those intended for the fat market will come in better time for the new kale than those weaned in October. What I believe to be the best practice is to lamb one half of the flock in May and the other half in September. This will enable us to do the milking ewes better and to have more feed available for the lambs when asked to forage for themselves. Unfortunately the stubble feed on these ironstone soils does not last; in fact were it not for the presence of sorrel there would be little but dry feed in any of our stubbles. Hence, if we are to grow lamb or mutton we are compelled to raise green feed, for it is well known that the short benty pastures characteristic of our country will not fatten, though it will grow fine bright wool. It is obvious, then, that in considering the crops and scheme of cropping best suited to our conditions we must first of all recognise the fact that the importance of grazing crops to cereals is very much greater than in our wheat-growing areas.

Early Green-feed.

In February, whenever the opportunity offers of sowing under favorable circumstances, or at any rate in March, whether the rains come or not, it will pay on most of our holdings to turn over a hay stubble or pea stubble and drill in a big block of green feed. So far as our experience teaches rye is undoubtedly the best grain for early sowing. Barley is better than oats, but it will not stand a dry spell like rye nor does it grow as rapidly under light rainfall. Even in droughty years rye can always be depended on to grow a fair amount of feed, and if fed early and not allowed to run to head it will thicken up in the stand and last right into the spring. About September it begins to get thin and spindly, and at this season of the year is inferior to either oats or barley. Oats do not grow quickly enough in the autumn, but they continue to shoot much later in the spring than the other cereals. The question of palatability can hardly be said to come in, as sheep will take to any of the cereals very readily when the paddocks are bare. Our usual practice at Kybybolite is to sow 1½bush. of rye with 1cwt. 36-38 min. super. per acre as early as possible. This is then grazed back when 4in. or 5in. high, and if rains are delayed it is kept down. About the end of May, when the soil is soft, the field is harrowed, about 1½bush. of Algerian oats cross-drilled in and then reharrowed. In wet autumns the later sowings of green feed should consist of Cape barley and oats in equal amounts. After the winter the heavy harrows should be again run over to spread the manure and freshen up the surface.

Hay Crops.

Generally speaking the rubble country is better suited to oats than wheat, and consequently it will pay better to make oaten instead of wheaten hay. It is sometimes asked whether it would not be wiser to grow a mixture of the two, and where they can be relied upon to produce a heavy cut the practice has its advantages. In my experience, however, to attempt to grow a mixed crop on our land without drainage is to risk too much. In very wet years in the past neither oats nor wheat have made satisfactory growth, and when a mixed crop makes poor headway the opportunity of using the stripper instead of the binder is not presented. When the drains have been provided our districts may become more trustworthy as regards cropping, and the growing of mixed hay may then be reconsidered. I do not think one can do better than sow Algerian or Calcutta oats at the rate of 1¾bush. to 2bush. per acre, with the same quantity of manure as in the case of early green feed. One advantage in growing oaten hay is that the seed can be early sown without fear of malting. Our practice is to follow the green-feed grown on pea stubble with a hay crop. The land is ploughed up in March or April, whether ploughing rains fall or not. In April the seed is sown, and as soon as rains come in the water furrows are drawn. This enables a farmer to get on with his work a dry year, and so spare himself and his teams a lot of anxiety and rush later on.

WHEAT CROP.

On our light land the best wheat crops will almost invariably be found on fallow. Good crops have been raised on "green" ploughing, and sometimes even on cultivated stubble, but as the settlements grow in years I have little doubt that the conclusion arrived at will be that it pays to fallow up in the spring for the wheat crop. With regard to the time of seeding, I have no hesitation in saying that, in my opinion, May is unquestionably the month to sow wheat. We have seen as much as 10bush. per acre less on July as against May sowings of Gallant wheat, and that in a relatively dry year. In wet autumns June sowings are too late, and I think one would be well advised to confine wheat drilling as far as possible to the month of May. If there is land to sow after that it would be more judicious to sow oats or barley. From 60lbs. to 90lbs. per acre is found heavy enough at Kybybolite, but of course each man can readily discover his own requirements, both as to the quantity of seed and manure per acre.

WHEAT HARVEST RETURNS AT KYBYBOLITE.

The following table of yields obtained at Kybybolite will indicate the comparative merits of some of the more important varieties of wheat under our conditions :—

Variety.	1913.		1914.		1913-14.	
	bush.	lbs.	bush.	lbs.	bush.	lbs.
Lott's	30	20	31	33	30	56
Fan	—		29	41	—	
Yandilla King	28	16	30	47	29	31
Bayah	29	36	29	9	29	22
Clubhead	29	51	28	51	29	21
Talavera	27	5	31	20	29	18
White Tuscan S.	25	20	31	25	28	25
Dart's Imperial	27	1	29	45	28	23
Federation	33	29	23	16	28	22
Phyllis's Marvel	—		28	12	—	
Marshall's No. 3	24	45	29	33	27	9
Baroota Wonder	22	27	30	55	26	41
White Tuscan N.	27	32	24	41	26	6
Bordier	25	34	25	21	25	27
Majestic	26	16	23	16	24	46
Gallant	25	27	21	24	23	25
Farm Averages	22	54	26	44	24	49

In fairness to Federation it should be pointed out that the 1914 crop was not grown on fallowed land. Had it been grown in the same field as Lott's it would probably have yielded quite as well, if not better, than it did the year previous. The main point to note is that the mid-season and late wheats do better with us than the early types. Of the late varieties Bordier is one of the best. It has given a good account of itself in the last two dry years, and in 1912 it yielded 19bush. as against 15bush. from Federation. It stools well, and seems a likely wheat for wet years. Like most late varieties it should be sown early. The early kinds, such as Bunyip, Golden Drop, and King's, even when late sown, do not thrive as well as the hardier wheats.

OAT CROPS.

As soon as the wheat seeding is over the balance of the oat crop should be got in as quickly as possible, and every effort should be made to complete this work by the middle of June. Algerian and Calcutta oats are the best yielders for us, and they should be sown at the rate of 1½bush. per acre. The standard dressing for wheat, oats, and barley is 1cwt. per acre of min. sup., 36-38 grade. In order to keep down drake and barley clean seed should be obtained, and to combat the attacks of smut the seed should be pickled in a 2 per cent. bluestone solution every other year. At the end of the winter all the cereal crops on the Kybybolite Farm are thoroughly well harrowed, and this I believe to be a very beneficial practice. It is also customary with us to graze the crops up to the middle of August, but personal experience is the only safe guide in a matter of this kind.

PEASE.

On clean land pease may be sown as late as August, but where there is much sorrel it is better to get them established in the winter. We sow pease in June or July at the rate of 2bush. per acre in pairs of drills. The Early Dun variety has done best with us, but possibly if they could be got in earlier, say April, the Partridge variety would yield well also. The ironstone rubble land grows pease surprisingly well with but 1cwt. standard min. super. per acre, but they will not succeed if the seeding be too light. On no account sow less than 2bush. per acre.

BARLEY.

Barley may be sown in the autumn or late winter. If early sown it should be grazed back in June or July. It is usually more convenient, however, to defer barley-sowing till July or August. A fair sample of malting barley can be grown on our soils, but they are better suited for the production of the six-rowed variety; 2bush. of seed per acre will be found sufficient.

SUMMER CROPS.

Whilst the low rainfall years are generally those of high yields, yet they are also years of scarcity as regards summer paddock feed. The last two years have brought this right home to us, and more attention will need to be paid to the raising of such crops as kale, rape, sorghum, and lucerne. The pea crop also may be used as a summer grazing for fattening off, but every farmer should endeavor to save enough seed for himself, as the price of a good seed sample is rarely much under 5s. per bushel. With a 2bush. seeding this means 10s. an acre, as against 2s. to 3s. for rape or kale. Lucerne has done fairly well at the Government Farm, Kybybolite, but in dry years the summer growth is not as stout and vigorous as I should like to see it before recommending it strongly. Up to the present we have found kale and sorghum to be the most reliable and serviceable of summer grazing crops on the ironstone country. It is not possible to go very fully into the cultivation of these, but I will briefly indicate our methods of growing them.

Rape and kale will both flourish on buckshot soils, and they should be cultivated much more extensively. They are inexpensive crops to raise, and the work of seeding falls at a convenient season. Rape fattens more rapidly than kale, and where it can be grown to advantage it should be preferred for sheep. In my own district, however, we are more appreciative of thousand-headed kale, since it is only slightly affected by insect pests, whereas the rape crop may be completely devastated by them. When the caterpillars and plant lice first appear on rape the feed may be gained if fed at express speed, but when this is done the green keep is soon disposed of and the sheep driven back on to the failing grass land again. What is wanted on the Green Patch and Kybybolite farms is a more lasting green fodder, for we have not only to provide fattening crops for the marketing of our surplus but also nutritious sheep keep during the months of January, February, and March. Kale is, to my mind, the crop that suits our needs best in this respect, though I think it a wise plan for every man to try a few acres of both rape and kale for himself to test the matter on his own block. I have noticed on the coast an odd patch of stubble kale, but I have not observed any fields of kale grown as a principal crop. This I feel sure is a defect in your farming system which you will have to remedy. When sowing kale or rape in wet districts there is nothing against the practice of mixing the seed and manure immediately prior to drilling. For kale 1lb. to 1¼lbs. per acre, and of rape 3lbs. to 5lbs. will be ample. The former is better sown through every fourth hoe, so that horsehoeing may be given if necessary. We usually make a point of running a Planet Jr. up the rows as soon as the lines become distinct, but if the land be clean good crops may be grown without any inter-tillage. With rape it is better to sow a pound or two of white mustard and drill the mixture in through every other coulter.

Sorghum and Maize.—The various kinds of sorghums, kaffir corns, and millets have all been subjected to trials at Kybybolite, and the conclusion we have come to is that early amber sugar cane, sorghum saccharatum, and imphee are far the best for us in dry years. In moist summers maize can be grown to advantage and possibly on picked spots a proportion of it might be cultivated every season ; it will not stand the dry weather, however, and having no recuperative powers, when once fed down the field is left bare. Sorghum, on the other hand, keeps springing from the crown, and may be treated like pasture. It can either be grown in wide rows to admit of after working, or, as we prefer it, through every drill, to be grazed and kept grazed down like a grass field. We sow from 8lbs. to 10lbs. per acre in September or October, but in favorable summers it could be sown right up to Christmas.

FEDERAL FRUIT COMMISSION.

THE MAJORITY REPORT.

The majority report of the Federal Fruit Commission, signed by Mr. Frank Foster (Chairman), Senators Ready and Lynch, and Mr. W. F. Finlayson, M.H.R., was laid upon the table of the Senate on June 26th. The minority statement of Messrs. S. Sampson and J. Thomson, M's.H.R., will be submitted at a later date The following digest of the report is taken from *The Register* :—

" As a result of its investigations the majority has arrived at the conclusion that a few firms in Australia control the bulk of the oversea export trade. In Tasmania the exporting firms are said to be outwardly separate entities, each operating in its own particular sphere, but the Commission found that even these were controlled by a combination operating on lines similar to those of some of the American trusts.

" Dealing with transport, the Commission points out that the absence of suitable methods offers perhaps the most serious obstacle to satisfactory marketing, and that there is room for improvement in the method of handling the fruit is also indicated in no uncertain way. Commonwealth-owned steamers and a uniform railway gauge for Australia are among the remedies for existing evils which the Commissioners put forward.

The Dried Fruit Industry.

" Investigations into the dried fruit industry revealed interesting features. The Commission found that the production of currants, sultanas, and raisins had made such rapid progress that the Australian market is almost exclusively supplied from local sources. Repeated testimonies were given to the Commission as to the high commercial value of the Australian product, which is reputedly equal, and in many cases superior, to the imported goods. This position has been secured by a successful combination of growers and a strong association of packers, their united efforts having succeeded in stimulating production, regulating prices, and supplying the public with a satisfactory article. The report goes on to say—' There is, however, some objection to the operations of the Australian Dried Fruits Association, inasmuch as because of its control of production, marketing, and export (now that the average local demand has been overtaken) there is a tendency to maintain prices and profits by limiting production and restricting competition in distribution by exporting annually certain quantities, and dumping the balance into local distilleries at a greatly reduced price to the growers. Consequently, the law of supply and demand as popularly understood is suspended. Prices are maintained, irrespective of whether the crops are light or heavy, and are regulated according to the supply available in other countries, from which these fruits would otherwise be obtained. Australian consumers are therefore compulsorily more interested in conditions in Asia Minor than in the Commonwealth, and their interests are not safeguarded under the tariff incidence. The Commissioners are of opinion that there is a sufficiently wide margin of profit to justify a considerable reduction in the retail price to the public. This would encourage a greatly increased consumption, and promote the extension of the industry. An improved railway service between Mildura and Melbourne would also be advantageous to the growers by assisting them to market successfully their green fruit.'

RECOMMENDATIONS.

" There are 29 recommendations put forward by the majority, as follows :— 1. That the Government contract with steamship companies for the necessary refrigerated space for fruit exports and allot the same *pro rata* according to the requirements of growers in the several States. 2. That fruitgrowers be given an opportunity to secure refrigerated space for fruit for export within a few weeks of the time of shipment. 3. That an equitable proportion of refrigerated space be secured to each State in the case of subsidized steamers. 4. That refrigerated chambers of reasonable capacity be provided for the carriage of fruit in vessels engaged in the inter-State trade. 5. That self-registering thermometers be installed in the refrigerated chambers of all oversea vessels carrying fruit cargo. 6. That cool storage facilities be established in suitable centres under Government or co-operative control. 7. That a Commonwealth-owned line of oversea steamers be established. 8. That a Commonwealth-owned line of inter-State steamers be established. 9. That more effective arrangements be secured for the safe carriage of fruit in the inter-State trade, both on deck and under hatches. 10. That a sufficient supply of louvred vans be provided on the railways of each State. 11. That all carts, wagons, and cars used in the transport of fruit be periodically inspected and disinfected. 12. Co-operative marketing of fruit. 13. That produce departments controlling exports be established in all the States. 14. That inquiry be made abroad as to the possibility of securing more effective distribution of Australian fruit in the United Kingdom and on the Continent of Europe. 15. That an inquiry be made abroad into the charges and practices of selling and distributing, agents' methods of sale, handling, storage, and display of Australian fruit. 16. That the export of inferior and diseased fruit be prohibited. 17. That to ensure uniform grading and branding, central packing sheds be established in the fruit-growing districts. 18. That all cases used in the transport of fruit be of uniform capacity, the bushel to be the standard. 19. That a Commonwealth Trade Commissioner in London be appointed. 20. That all fruit agents and traders be licensed. 21. That the operations of the Commonwealth Bank be extended to permit the establishment of a credit-foncier system to enable advances to be made to fruitgrowers, and to provide necessary financial accommodation. 22. That voluntary co-operative societies among fruitgrowers be formed to carry out grading, packing, branding, &c., through central packing sheds, and to utilise State or Commonwealth control of transport by rail or boat, cool storage, and marketing, in order to eliminate the unnecessary middleman. 23. Effective organisation of growers and employés in the fruit industry. 24. That action be taken to discover the most effective method of preserving lemons. 25. That abandoned orchards be eradicated by the authorities. 26. That the controlling authorities be given power to combat orchard pests and diseases at the expense of growers who have failed to do so after due notice. 27. That all nurseries be registered and periodically inspected. 28. That a Commonwealth Bureau of Agriculture be established. 29. That the use of trays and walking planks be made compulsory."

"RUSTY" MANGOLDS.

Recently Mr. J. Spencer, of Clarendon, brought under the notice of the Agricultural Department the tops of some of his mangolds, which appeared to have been smitten by a rust, with the result that they wilted away almost to nothing. The specimens were forwarded to the Government Vegetable Pathologist (Professor Osborn), who sent to the Minister of Agriculture (Hon. T. Pascoe) the following interesting report:—"The mangolds are infected with *Uromyces betae*, the 'beet rust,' an introduced fungus that probably came with the seed from Europe, where the disease is of less importance. Nothing can be done to cure the infected plants, though there might be a lessening of virulence as the weather becomes hotter and drier. It is desirable to burn the diseased leaves, not to allow them to rot on the ground, and also not to grow beet or mangolds on the same land for at least two years. If any of the mangolds are running to seed, I shall be glad if the grower will send to me some heads to examine."

POULTRY NOTES.

By D. F. Laurie, Government Poultry Expert and Lecturer.

POULTRY AND AGRICULTURAL BUREAUX.

I am glad to notice that many papers on poultry breeding are included in the reports of the various Bureau meetings. There are a few points which arise, and may be considered.

Apathy of Farmers.

During many years I have visited numerous farms, and have discussed poultry breeding with both farmer and his wife. As a rule, poultry are to be found on the farms in this State, and it is rarely that any complaint is made that the venture is unprofitable. While there are many farmers who take an intelligent view of the question, there are more who are apathetic. These latter seem to have a grudge against poultry that is difficult to understand. As a rule such a farmer pays little attention to housing and breeding, although he may allow his wife sufficient wheat to feed the birds. Our South Australian farmers are justly proud of their high position among the farmers of the Commonwealth. Many of them, however, have yet to appreciate the fact that stock-dealing and wheat-growing are not the only points in farming worth considering.

Poultry on every Farm.

Every farmer should have a flock of modern commercial poultry, housed properly and fed on business lines. Few farmers are to be found who will deny that poultry on a farm are very profitable. There are some who are so wealthy that a hundred or two pounds a year is not worth considering. It is good for such that they live in such a wonderfully productive land where one need not work too hard. Then, again, many who agree with the poultry proposition do not house their birds properly. Yet there are scores of level-headed and successful farmers who have for years owned model poultry plants on their farms. Many farms are badly infested with poultry ticks, and this is a question which will have to be grappled with before long. The trouble is due to faulty methods of housing, to carelessness, and general apathy.

Pure versus Crossbreds or Mongrels.

In a report in the June *Journal* I see the time-worn statement that such and such speakers considered that crossbreds (mongrels) were hardier than pure breds. Many in this State have "crossing" on the brain; it is an obsession. There is no foundation for the statement that pure-bred poultry are more delicate or prone to disease than mongrels are. Throughout the world the successful poultry breeders breed pure stock only. If it were not so no one would be fool enough to continue a bad practice. As it is no sensible man would attempt commercial poultry breeding with other than pure stock of proved strain. It is a fact, however, than many farmers are keen buyers—they look upon a fowl as a fowl, and prefer one at a cheap price. The breeder who is known for the productiveness and strong constitution of his stock has always a ready sale at a good price. The incompetent breeder can, of course, sell his delicate useless stock at a low price. It is really worthless.

TESTING HENS FOR A SECOND OR THIRD YEAR.

Mr. Stevens, of Mount Barker Bureau, urges that there should be second-year and third-year tests at Parafield. I have discussed the egg production in the second and third year of certain breeds, with Mr. Stevens and many other breeders. A second-year test with White Leghorns is not warranted, and the only result that might accrue is what any breeder can achieve, viz., the discovery of material for building up a strain that would lay well in the second year. Wyandottes and Langshans, if well bred and carefully culled, are always worth keeping for a second year, and some of the hens even for a third year. With the all-round or general-purpose breeds the profits are general, and not from eggs only. I have always advised breeders to cull their pullets. I mean where a man has a number—be it 50 or 5,000—producing market eggs. He can at the close of the first year pick out a percentage worth keeping on, perhaps for six months only. This is especially necessary in order to keep up a supply of large eggs while the pullets are improving in that respect. There is this point, however, as regards competitions—how many breeders would consent to the innovation ? This year the heavy breeds—with the exception of two pens in Section I.—are being single tested. Any owner of a good layer will naturally require her for breeding. The matter has been kept in view for some years, and probably I shall communicate with the present competitors to ascertain how many are willing to compete for a further period.

LECTURES AT THE SCHOOL OF MINES.

A course of 12 lectures began on Wednesday evening, July 1st, and will continue on each Wednesday evening at 8 o'clock. Readers in the suburban area are invited to join this class, as it will save much letter-writing, telephoning, and personal interviews. The fee is nominal, only 5s.

OPERATIONS FOR JULY.

Time flies ! Here we are in the first month of the second half of the year. In the June number I covered a good deal of ground of a general nature, and applicable to July operations. July heralds a general application to the business of incubation. Judging by the advertisements, most of the leading incubators are to be purchased in Adelaide. I am often requested to express opinions as to this and that machine. On reflection it will be admitted that I could not do so, because other makers, or agents, would feel aggrieved. After all it is the man more than the machine. With one exception, I have never had a machine to try which was not capable of satisfactory work.

INCUBATOR THERMOMETERS.

Unless the thermometer is accurate the hatch will be more or less a failure. Never buy a cheap thermometer for use in an incubator. Even the best made thermometers are liable to damage which will cause serious error. The column of mercury may be broken, and a small portion of the mercury representing several degrees may become detached and lodged up in the vacuum space at the top of the tube. All thermometers should be tested. If you cannot compare with a standard, take your own temperature and that of a few other healthy persons as a check. In health this should be 98½°. If the thermometer is correct at this reading it would be strange if it were incorrect at 101° to 103°.

STUDY THE MAKER'S DIRECTIONS.

Most makers send explicit instructions with their machines, and these should be carefully observed. Different machines require special treatment, as described by the makers. If possible, build a special incubator room which will provide fairly constant temperatures. After placing the eggs in the drawer or egg tray, mark each with a lead pencil—not an indelible—and leave in the machine for 48 hours before turning them. Test for fertility on sixth or seventh day, and again on the fifteenth for hens, and twenty-second for ducks. Do not open the machine after the first egg "chips." Do not remove from machine until chicks, ducklings, &c., are dry. Do not feed for from 24 to 40 hours after removing from the machine.

BREEDS TO KEEP.

For Market Egg Production.—White Leghorns. If you are so desirous you may build up a good laying strain of Brown Leghorns or Minorcas. A good strain, if the birds are typical, would be very profitable.

For Eggs and Meat.—Just as a Clydesdale is not used for a flat racer, nor a racehorse for sand-carting, so no one breed will give a maximum of eggs and provide the very highest type of table bird. Our modern general purpose breeds are moderate to good layers, and the chickens make moderate to good table chickens. Looking at the entries in Section 4 of the Parafield Laying Competition, one gathers a fair idea of what the leading breeders here consider the best to breed.

White Orpingtons (four pens).—A breed which is making many friends, as the hens are good winter layers of fine eggs, and the chickens are plump, and have white skin, flesh, and legs. They are large, hardy, and handsome fowls.

Black Orpingtons (six pens).—This is a well-known favorite breed—large bodied, hardy, handsome, good layers. The chickens grow quickly, and have white flesh and skin ; legs black.

Buff Orpington (one pen).—The difficulties in breeding the correct shade of buff without mealiness or dark feathers is against this bird. As a rule the hens are not good layers. The chickens are excellent, and have white skin, flesh, and legs.

Silver Wyandottes (four pens).—A beautiful and popular breed, and one that has done big things in egg-production. Generally a good layer ; sometimes the eggs are small. Chickens quick growing, plump, splendid quality. Creamy flesh and skin, yellow legs.

White Wyandottes (two pens).—This variety is coming into public favor. It is less difficult to breed than the other varieties of Wyandotte. It should be the ideal farmers' fowl. Wyandottes are medium sized.

White Plymouth Rocks (three pens).—This variety is coming into much favor, and does not need double mating, as is the case with the barred variety. Some strains are good layers of fine eggs, and the chickens are excellent, quick growing. Skin and flesh creamy-white, legs yellow. This breed won in the table section General Purposes Society March Show.

Barred Rocks.—This breed is similar to the foregoing in utility. Separate matings, however, are required for breeding standard males and females. Plymouth Rocks are large fowls.

Langshan (one pen).—This good old breed deserved better representation. The hens are good layers of the nicest brown eggs ; the chickens are excellent for table.

Indian Game.—Splendid table birds, the breast meat is phenomenal. The chicks are always plump. As layers the hens do not shine.

Rhode Island Reds.—A breed comparatively new to Australia. Hens fair layers ; chickens very hardy and easy to rear, quick growers ; quality of meat good, skin and flesh creamy, legs yellow.

Faverolles are not in the test, but the breed is one of the best. The hens are good layers, and the chickens, when well fattened, are of the very highest quality.

Old English Game.—The hens are excellent layers of standard eggs, and the chickens make small but most beautiful tablebirds of the very highest quality.

Sussex, Red, Speckled, Light.—The Reds have made some stir in Victoria, and have been bred here by one or two people. Speckleds are now to hand, and also, it is said, some Light Sussex, but I have not seen them. The Sussex is an old breed remarkable for its table qualities ; the hens are fair layers. The various sorts have yet to be proved in this State.

PARAFIELD POULTRY STATION.

EGG-LAYING COMPETITION, 1914-15.

[Started April 1st, 1914, to terminate March 31st, 1915.]

Competitor.	Eggs Laid for Month ended June 30th.	Total Eggs Laid from April 1st, 1914, to June 30th, 1914.

PARAFIELD EGG-LAYING COMPETITION.

REPORT FOR JUNE.

Health.—The general health of the birds has been good. Birds which were previously recorded as sick have either recovered or have been replaced. In Section 1—Open Class—one bird in pen 38 was removed owing to leg weakness. In pen 27 a hen died from malignant growths at base of the tail. In Section 3, Single Test, Light Breeds, the health of the birds is normal. In Section 4, Single Test, General Purpose Breeds, hen No. $\genfrac{}{}{0pt}{}{6}{7}$ was suffering from leg weakness, and was treated. One bird died, No. $\genfrac{}{}{0pt}{}{8}{5}$, evidently through choking at feeding time, as she otherwise appeared healthy.

Moulting.—This year the moult has been a long and slow process. But although the birds are looking fit, there seems to be some condition which reacts. In former years as soon as the new feathers grew the laying rapidly increased ; but it is not so this year. From all quarters reports from breeders have been received telling of similar conditions. There is no doubt the unseasonable weather does not suit the fowls.

The weather has been spring-like, with five frosty mornings. Rain, very light, was recorded on five occasions—only 34 points for the month, or 2·50in. below the average. The warm days and cold nights are not conducive to the best results.

Egg Production.—There has been fair all-round improvement ; the total eggs laid has increased by about 2,000 eggs more than were laid during May.

Broodiness.—There were three cases recorded in pen 51, and one in pen 50, Section 1.

Greenfood is abundant, and the birds have ample supplies in variety, principally lucerne and barley.

Visitors.—Seventy-eight persons visited the Poultry Station during the month—total to date 1,176.

D. F. Laurie, Poultry Expert.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, June 10th, there being present Messrs. G. R. Laffer, M.P. (Chairman), A. M. Dawkins, F. Coleman, C. E. Birks, J. Miller, G. Jeffrey, C. J. Valentine, Col. Rowell, and G. G. Nicholls (Secretary).

Combined Drill and Cultivator.—A reply was received from the Secretary of the Royal Agricultural Society as follows, in response to an inquiry regarding the wisdom of adopting a suggestion made by the Willowie Branch, that steps should be taken to induce the Government to encourage the manufacturing of a combined cultivator and seed drill, by offering prizes at the Royal Agricultural Society's shows, and by other means :—" Although such a combined implement has been on the market for a considerable number of years, the fact that there has been little demand for it shows that it does not commend itself to farmers generally. The function of the society is largely educational, and it is felt that such a method of seeding as by a combined cultivator and drill should not receive encouragement, as by the use of such an implement neither operation could be efficiently performed."

Forestry Lectures.—Respecting a suggestion made at the preceding meeting that arrangements might be made for the Lecturer in Forestry to give addresses before the Branches of the Bureau, the Secretary to the Minister of Agriculture wrote that the Commissioner of Crown Lands advised that the instructor had very little time for public lecturing, owing to University duties, and he questioned whether it was wise to call upon him or upon the Conservator, except possibly when a general congress was being held. The Minister was generally in accord with this view, and would endeavor to arrange for forestry matters to be dealt with at some of the annual conferences.

Branding of Manure Bags.—Mr. Coleman said that for years the bags containing superphosphate were branded distinctly, but during the last 12 months more than one firm had been sending out fertilizers in bags which carried merely a label or tag indicating the character of the contents. That was highly undesirable, because the unmarked bags were almost certain to be utilised for other purposes, including the conveyance and storage of wheat. The Fertilizers Act merely required that certain particulars should be " durably affixed to every sack." That should be struck out, and it should be made obligatory upon those who sold or offered manure for sale to brand the bags themselves. With a view to that end, he proposed that the matter should be brought under the notice of the Minister of Agriculture, and added that he had heard that the farmers were "rushing the super. distributed in the unmarked bags in order to get the sacks cheaply." Mr. Jeffrey seconded the proposition, which was agreed to.

Postal Carriage of Fruit.—With reference to a request received some time ago from the Longwood Branch in relation to the facilities for the conveyance of fruit through the post, the Secretary reported that he had written to the Deputy Postmaster-General, who had replied to the effect that "parcels of fruit, cut flowers, vegetables, and eggs are accepted for transmission through and to all parcel post offices in Australia, the limit of weight being 11lbs. where the service is by railway, coach, or steamboat, and 3lbs. where other means of conveyance are employed. The articles mentioned must be specially marked 'fragile' or 'perishable' as the case may be. No arrangement similar to the New Zealand 'Order coupon for the supply of fruit' is at present in existence in any of the States, but on July 1st, 1914, it is intended to initiate in Victoria a scheme by which agricultural produce will be carried at reduced rates by the Railways Commissioner and delivered in Melbourne by the Postal Department."

The Fruit Industry.—Mr. Birks desired to be informed whether there was any justification for a feeling of pessimism regarding the prospects for the currant and fresh fruit industry. The Chairman (a large fruitgrower) pointed out that, although the latest apple crop locally had suffered through the lack of moisture, it was noteworthy that during the last couple of seasons good fruit had brought higher prices than probably ever before. Personally he saw no reason for alarm or despondency, and emphasized the fact that new world markets were constantly being opened up, and what in the fruit line was once regarded as a luxury was now being looked upon as a necessity, all of which augured well for an increasing demand for fruit. Growers, however, must realise that it was essential properly to grade their fruit, and place it on the market in uniform lots, by which means only could they hope to absolutely win the confidence of the buyers. The Tasmanian orchardists were in no way pessimistic, a fact which was eloquently proved by the large areas they were putting under trees every year.

Indian "Gram."—A fodder known as gram was brought under the notice of the Board by the Secretary, who explained that, having seen references to it by Capt. H. Parsons (Secretary of the Inman Valley Branch of the Bureau), he had written to that gentleman and obtained the seeds and dried plants produced. These members inspected with much interest. The following report on the fodder had been courteously prepared and furnished by the Government Veterinary Lecturer (Mr. F. E. Place), who had spent many years in India :—" Gram (*Cicer arictinum*) is a legume, practically a pea bearing two seeds in a pod. The plant is deep rooting, bushy, and spreading, with purple flowers, and reddish-brown or yellowish seed. It is extensively grown in

India, where it is the chief fodder and grain for horses. It attracted the notice of Capt. Parsons, when he was at Sialkete on duty with the 17th Lancers, and he brought a few seeds home and grew them at Inman Valley. The sample of seed was of decidedly poor quality. In the parts of India where the temperature and rainfall approximate to the conditions in the north of this State, gram usually follows a green crop such as mustard, and is sown after the rains in September, and ripens for harvest in April and May. The South Australian conditions would probably be—seeding in July and August, and harvesting in December or January. The Indian system is too crude for adoption in South Australia, where the crop would be treated, as regards tillage and seeding, in the same way as peas. A 10-bush. crop is good in India, but Capt. Parsons estimates, from his own experience, that quite double that yield would be obtained under favorable conditions in South Australia. The accompanying analysis of the gram shows that it has a very high feeding value, being rich in fat, which food component is notably lacking in South Australian fodders, and the presence of which is so necessary to ward off paralysis, dry bible, and diseases of similar character. When gram is described as a badly-balanced food the condemnation is rather in its favor, because of its high nitrogen content. The feeding ratio, however, may be easily balanced by giving hay with it, or, if used as a green fodder, adopting the Indian plan of growing a mixed crop of gram and barley, wheat, or oats. No doubt the custom of mixing the crop facilitates harvesting by keeping the plant upright. The percentage composition of gram is—Water, 10·86 ; proteids, 21·17 ; fat, 4·47 ; carbohydrates, 69·11 ; salts, 3·39. A draught horse would do well on 8·10lbs. of gram, and 20lbs. to 25lbs. hay daily. Capt. Parsons has favored me with the following notes :—' Land prepared as for peas, the best results would be from land that had been fallowed the spring or summer before. Soil—light loam or sandy soil gave best results with the little experimented with. While in India I noticed that where gram was planted alone, it grew in loamy or sandy soils better than on heavy land. Of course this may have been on account of the crude mode of ploughing in India, with a wooden plough to a depth of only 2in. or 3in., and as the plant is a deep rooter, it has a better chance of rooting in light soil. Land for cultivation must be kept free from weeds. Drill in as for peas about 2bush. per acre, and use about 80lbs. guano super. What I experimented with I drilled in by hand, with a little fowl manure from the poultry house. For feeding off as a growing crop I would advocate planting mixed either with barley, rye, or oats. If planted early it runs over the ground, and does not stand up until about to blossom. Therefore, a mixture of barley or rye would keep it up, as with vetches. But for grain I would advocate planting in August in a district like Inman Valley. Last year I planted gram in September, and it was in blossom the same time as some planted on March 20th. Gram of quick growth is most palatable to stock ; in fact, when in blossom, it is like lucerne, much harder to digest and less attractive.'" The Board decided to send the report to the Hon. the Minister.

Branches.—The Secretary reported that the Branch at Friedrichswalde had been closed. Approval to a new Branch at Carrow was given, with the following gentlemen as members :—Messrs. W. J. M. Cowley, T. Burt, J. E. Matthews, C. Storrie, F. Beare, jun., T. Beare, sen., H. A. Freeman, J. McBride, W. Umhauff, W. D. Chalmers, L. F. Byrne, H. Lovelock, F. J. Anear, B. Gobelt, sen., G. M. Begg.

New Members.—Monarto South—A. Bormann ; Wilkawatt—A. B. Neville ; Crystal Brook—J. R. R. Cornish, J. Forgan, R. F. Harding, H. C. Heath, A. G. Head, S. H. Marshall ; Clare—C. H. Cichon ; Roberts and Verran—A. J. Drayton ; Utera Plains—F. H. Hill ; MacGillivray—J. G. Johnston ; North Bundaleer—J. P. Maloney, C. Pearce ; Mount Remarkable—T. Willington ; Two Wells—J. R. THE WHEAT MARKET.

Commenting on the wheat position *Beerbohm's Corn Trade List* under date London, June 5th, states :—" Much may happen to the crops during the next two or three months, but there are already indications that, on the one hand, the requirements of importing countries will be larger than in any previous year, and, on the other hand, that, with ordinary climatic conditions in the future, exporting countries will be in a position to ship more wheat than ever before. Apart from Italy and France together probably needing more wheat than in the present season, Austria-Hungary, which usually grows sufficient wheat for its own consumption, is expected to be a very large importer. The crop in Hungary promises to give such a very poor yield that the minimum requirements of foreign wheat are put at 5,000,000 quarters, while some of the estimates are for a much larger quantity. In all probability by far the larger proportion of any surplus that Roumania may have to spare will be taken by Hungary, and only a comparatively small quantity will be available for other European countries. If Russia has an average crop this year (present prospects are favorable), that country will have a large surplus for export, as, in view of the continued large exports for the time of year, it would appear pretty certain that there are still large reserves left over from the last crop. With America almost certain to be a larger exporter than ever before, it would, however, still require moderate shipments from the Argentine, Australia, and India, and a large export from Canada. to satisfy the requirements of importing countries in the coming season. There have been a good many complaints from time to time as to the poor quality of much of last year's wheat, this being given as the reason why the quantity of foreign wheat required has been larger than estimated early in the season. It is quite possible that this year's wheat will be of better quality, and import requirements modified to some extent.

" Meanwhile it does not appear at all probable that supplies of wheat in the last two months of the present season will be in any way excessive. At the same time, if ordinary climatic conditions obtain during this month and next, and the European wheat crops be harvested at the usual time, consumers will most likely confine their purchases to the satisfying of actual requirements, unless there should even now be some serious mishap to the American crop."

THE WORLD'S VISIBLE WHEAT SUPPLY ON JUNE 1.

Steamer Freights.—(July 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, 17s. 6d. per ton (5⅝d. per bushel) ; to South Africa, 17s. 6d. per ton (5⅝d. per bushel). Parcels, Port Adelaide to London-Liverpool, or Continent, 20s. per ton (6⅜d. per bushel) ; Port Adelaide to Melbourne, 12s. per ton (3⅞d. per bushel) ; to Sydney, 14s. 6d. per ton (4⅝d. per bushel).

Sailer Freights.—From South Australia to United Kingdom-Continent, 20s. per ton (6⅜d. per bushel) ; South Africa, 17s. 6d. per ton (5⅝d. per bushel).

DAIRY AND FARM PRODUCE MARKETS.

A. W. Sandford & Co., Limited, report on July 1st—

Butter.—The local increase has been very light, and importations continue from the eastern States to fill up the shortage. Values all round have improved to the extent of a penny per pound, prices being ruled from outside markets. "Alfa" is selling at 1s. 4d.; "Primus," 1s. 3d.; choice separators and dairies, 1s. 1d. to 1s. 2d.; store and collectors', 11d. to 11¾d. per pound.

Eggs.—The mild weather has brought along larger quantities, and quite a record drop has been established, chiefly owing to Western Australia being self-supplying. The easing during the month was 9d. per dozen. A cold snap of weather would, however, cut off supplies and the market would improve. Hen eggs, 10½d. per dozen; duck, 11d.

Cheese is meeting with a very good turnover, no doubt the high prices ruling for fresh meat causing a heavier consumption in this line. Present quotations are from 8¼d. to 8¾d. per pound for large to loaf.

Honey.—The inquiry has been much better this month, purchasers operating with more freedom. Prime clear extracted is selling at 3d. per round; beeswax, 1s. 3d. per pound.

Almonds.—Competition has been very keen, and all parcels readily taken up, both for local and export. Brandis, 7½d.; mixed softshells, 6½d.; hardshells, 3½d.; kernels, 1s. 5d. per pound.

Bacon.—Prices are unaltered, and although local supplies have increased they are not sufficient to fill the demand, and importations have been necessary. Best factory-cured sides are selling at 9½d. to 10½d.; hams, 9d. to 11d.; lard in skins, 8d.; bulk, 7d. per pound.

Live Poultry.—Good rates continue to rule for all classes, and although the catalogues have shown a marked increase the demand has been quite equal to it, and good clearances have been effected. Heavy weight table roosters, 2s. 9d. to 3s. 3d. each; nice conditioned cockerels, 2s. to 2s. 6d.; hens, 1s. 6d. to 2s. (light sorts lower); ducks, 2s. to 2s. 9d.; geese 3s. 9d. to 4s. 9d.; pigeons, 5¼d. to 6d.; turkeys, from 7d. to 9d. per pound live weight for fair to good table birds.

Potatoes and Onions.—Potatoes have arrived freely from the Mount Gambier and Millicent districts, and a fair quantity has also come to hand from Victorian centres, the result being prices have eased a little. Onions—Local supplies have nearly cut out, and the consequent additional draw on the South-East crops has resulted in decidedly better rates. Present quotations—Potatoes, £4 7s. 6d. to £5 per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 5s. to 7s. per cwt. in the market. Onions—£7 10s. per ton of 2,240lbs. on trucks Mile End or Port Adelaide; 8s. 6d. to 9s. per cwt. in the market.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall for the month of and to the end of June, 1914, also the average precipitation to the end of June, and the average annual rainfall.

Station.	For June, 1914.	To end June, 1914.	Av'ge. to end June.	Av'ge. Annual Rainfall

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

July 15th and August 12th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by George G. Nicholls, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

AMYTON (Average annual rainfall, 11·82in.).

Present: seven members and three visitors.

Wool-Growing *versus* Lamb-Raising.—In a paper dealing with this subject, Mr. J. J. McCormack said—"Outside of Goyder's line of rainfall, and within what is commonly known as the fringe country, it is imperative for the landholders to go in for a system of mixed farming, such as wheat cultivation and dairying, or sheep-raising. The chief drawback with which the average Northern farmer has to contend is that for mixed farming his holding is too small. With the average holding consisting of about 1,000 acres, it behoves the farmer to get the best possible return from the pasture at his command. He should avoid bareing his pasture grasses to the roots, causing the best of his soil to drift. From experience of both dairying and sheep, I find the latter most profitable. I have been keeping sheep since 1904. I was informed that breeding ewes and lambs was the most profitable undertaking. This is the first mistake I made, for I obtained my information from a farmer situated in a far more favorable district as regards rainfall. I purchased 400 four-tooth Merino ewes and mated them with good Merino rams. The result was a lambing of 70 per cent., *i.e.*, 280 lambs. Owing to the absence of greenfeed in the autumn, 1905, the ewes did not have sufficient milk, hence the lambs were stunted. A favorable season followed. Only 120 of these were suitable for freezers. This left me to carry over the summer, 1905, in addition to my breeding ewes, 160 lambs, making a total of 560. I again mated the ewes with good rams, but owing to carrying so many sheep through the summer months I was left with no surplus feed at lambing time. Rain held off until May, and the result was the loss of 30 per cent. of the ewes and 70 per cent. of the lambs. If a farmer intends to rear lambs the market is no place for him to purchase his ewes or rams, as, with very rare exceptions, he will secure a considerable number of inferior ewes, the result of culling off shears. It pays the farmer many times over to purchase a good strain of breeding ewes privately from such stations, for instance, as Bungaree, Canowie, or Carriewerloo. The same applies to the selection of rams. A ram costing five guineas will be much cheaper to the purchaser than a ram costing, say, 30s. It does not pay to keep inferior ewes and rams. On the local plains, however, I have noted, during the past three years in particular, farmers who had incurred big expense in procuring a good type of ewes with high-priced rams have been compelled to sell them at a sacrifice. For this reason I advocate keeping dry sheep. My objections to ewes and lambs are—they involve a big outlay in purchasing good quality young ewes and rams, with a great risk, owing to the uncertainty of the rainfall. The farmer cannot take advantage of weather conditions, as lambs must be dropped in April to ensure their being ripe in September, and also on account of the grass seeds. There are too many reject lambs unsuitable for freezers, which necessitates the owner carrying them over till the following year. This requires a considerable quantity of feed and reserve paddocks, which the average farmer cannot spare; also a reserve of fodder as well, in the event of

it being necessary to hand feed. In the event of a dry season a farmer is much handicapped in travelling his ewes and lambs to fresh fields. Dry sheep are better for the following reasons :—The farmer can easily ascertain just the number of sheep to graze on his paddocks, and they will improve in condition under much less favorable circumstances than the ewes and lambs. He has the option of selling his sheep fat in the wool, or if not fat he can shear them, when they will fatten off shears. Butchers' sheep are always in demand. He can sell out at the beginning of the summer months and re-stock in the autumn, thus giving his pasture a chance of a good seeding—a most important point which is often overlooked. He can travel his sheep long distances in the event of a shortage of feed, without inconvenience." Members agreed in general with the statements of the writer of the paper.

ARDEN VALE AND WYACCA (Average annual rainfall, 16·65in.).

June 8th.—Present : five members and three visitors.

Horses.—Mr. O. Eckert read a paper. It did not pay the farmer with a holding of about 800 acres in the North, he said, to breed horses for filling up gaps in the team. Rather than feed young stock, when feed was plentiful he would cut and stack it. Mr. M. Eckert would only keep one extra animal to replace any losses in a team of eight horses. The Chairman (Mr. J. H. Willis) and the Hon. Secretary (Mr. O. E. Hannemann) did not approve of the "one-team" system of farming, as in the event of rain holding off, it became very necessary to get the work done quickly

MOUNT REMARKABLE (Average annual rainfall, 23·04in.).

June 3rd.—Present : 17 members.

Breeding Pigs.—The Hon. Secretary read a paper recently written and read by Mr. P. T. Bowker at a meeting of Laura Branch (see page 1186, June, 1914, issue). Members were well pleased with the paper, but noticed that in his statement of profits, Mr. Bowker had not accounted for initial cost of pigs, nor for the cost of labor given in attendance on the animals. With respect to floors—some had had success with cement floors, others with stone-paved floors. It was mentioned that in the south farmers used slab or woodblock floors exclusively, as stone and cement tended to cause cramp and rheumatics. Mr. Giles stated that, in mixing concrete for the floors, he found it saved much hard work to thoroughly mix the other ingredients before adding the broken stone. The meeting also agreed that the Berkshire pig had few equals, though Yorkshire and English Black were very fine. Jerusalem artichokes were noted as good pig fodder. The pigs could be turned into the artichoke bed, except at such time as was necessary for the plant to re-establish its growth. Mention was made that pigs would root up and destroy soursob, but some said that the animals were not persistent and thorough enough to do much good. Mr. G. Yates, jun., spoke of his success in killing soursob by covering it with wheat chaff to a depth of 6in.

WEPOWIE (Average annual rainfall, 13in. to 14in.).

June 2nd.—Present : seven members and three visitors.

Sheep.—A paper dealing with sheep breeding was read by Mr. J. Burns. He thought the Merino the best all-round breed of sheep, and described the particular points of the Merino ram. He thought it better to breed with two-tooth rams or ewes, except in cold wet districts, than to keep the ewes for an extra 12 months, returning nothing but their wool. Whilst the two-tooth ewes would not make such good mothers as the older sheep, if given plenty of feed and water during lambing, they would give good results. Lambs should be dropped in April or May ; early lambs were best. The period of gestation in the ewe was 21 weeks three days, and a careful note should be made of the date on which the rams were put with the flock. They should be left with the ewes for eight or nine weeks. One ram was necessary for each 50 ewes ; 3 per cent. would be even better. About four weeks after they were dropped the lambs should be tailed and earmarked, and the ram lambs castrated. For tailing, it was best to use a knife, which should be dipped in a warm 5 per cent. solution of washing soda after each two or three lambs had been treated. In grass country it was necessary to cut the wool away from the sheep's eyes twice or three time during the year. Three weeks or a month before lambing the ewes should be breeched. They should not be caught by the legs, but carefully picked up in the arms, and set down again. A clean cut 3in. or 4in. wide should be made from the udder to the anus, and then on both sides to the root of the tail. A good clean water supply was of the utmost importance, therefore watering from troughs was preferable to dams,

WILLOWIE (Average annual rainfall, 11·90in.).

June 12th.—Present: seven members.

Farm Harness.—Mr. W. B. Bull read a paper on the treatment of farm harness. He mentioned that the quality of the leather used in the manufacture of harness at present was not so good as it had been in the past. Harness should be washed and dressed with the best neatsfoot oil two or three times a year. It should be protected from the ammonia fumes which arose from manure in the stables. The straw-stuffed pipe collar was best, and judgment should be used in regulating the draught. Bridles should have double buckles on the cheeks, the face band being in one strip. Messrs. Gray and D. McCallum preferred to have the harness hung in the stables. Mr. Hawke demonstrated a method of relieving pressure on the points of the shoulder of a horse doing cart work.

WILMINGTON (Average annual rainfall, 18·26in.).

June 3rd.—Present: 11 members.

Care of Harness.—In a paper dealing with this subject Mr. Benier said that as the farm harness frequently represented an outlay of up to £150 it should receive due care and attention. He advised the use of the piped collar. This should fit neatly and firmly on the shoulders, and each horse should have its own. A collar that was flat, or otherwise out of shape, should be restuffed. Sweat and dirt should be removed regularly. The draught on the hames would very frequently be found responsible for sore shoulders. When the animals' shoulder galled the lining of the collar should be depressed to prevent it bearing on the sore part. The substitution of a breastplate might overcome the difficulty. Large-sized wagon saddles were best. When working teams winkers were preferable to the open bridle, as the latter enabled a lazy animal to slacken off if the driver's attention were diverted. Heavy harness should be dressed with neatsfoot oil: lighter harness should be thoroughly washed with soft soap and water, and dressed when dry with harness composition. A repair outfit should always be at hand. Members agreed, and thought neatsfoot oil mixed with lard a good dressing for all kinds of harness. Too much oil, however, would cause the leather to rot.

WIRRABARA (Average annual rainfall, 18·91in.).

June 6th.—Present: 16 members.

Fodder Plants.—Mr. P. J. Curnow read the following paper:—"In a comparatively dry part like Wirrabara and surrounding districts it is a matter for surprise that farmers and dairymen have not taken up the question of laying down experimental blocks of fodder plants other than lucerne. There are many plants worthy of trial, that do well in other parts of this and other States. In some seasons, such as the present one, there are no rains early enough to enable farmers to plough their land in time to get in early feed for stock, which is a serious difficulty, especially where cows are kept. Where permanent pastures are possible this difficulty can be overcome, as once a fodder, suitable to the district, is laid down it does not require much rain to start new growth. In this way it provides, at least, early pickings, which help cattle over a period when the natural grasses have not yet come up, and when there is so little to assist in the production of milk. For summer feed the sorghums, millet, and maize are the most suitable. These are annual, and give a cutting after each rain before frosts appear. Early Amber cane is the best for horses, although some seasons it is difficult to get them to eat it. For cattle any of the sorghum family are good, and do well, when once started, in the spring with occasional showers. Quite a number of grasses do well during the summer if irrigation is available; but where water supplies are highly mineralised, and irrigation is impracticable, only such fodder plants as will stand the dry weather without water will suit most local farmers. One variety of grass that does well on flats, in good soil, is *Paspalum dilatatum.* It grows about 3ft. high, and is relished by cattle, and can be cut several times during the summer, and will last for years. A variety, well spoken of as a summer fodder in Queensland, is the New South Wales Rhodes grass, and it is one worthy of attention here. It withstands drought, and provides excellent fodder in dry weather. Such other grasses as Meadow Foxtail grass, Mitchell's grass, cocksfoot, crested dogstail, prairie, meadow fescue, Chuerney's fescue, perennial rye, and Yorkshire fog grass are worth a trial. For early winter feed, *Phalaris commutata*, millet grass, annual meadow grass, Texas blue grass, and Kentucky blue grass should be grown. Among the clovers for early winter feed these varieties are worthy of mention:—*Trifolium subterraneum*, Berseem or Egyptian clover, and Italian crimson clover. Berseem has done well at Roseworthy, and is a quick grower. The above varieties of grasses and clovers should help stock owners to solve the ever-present difficulty of providing early winter and summer feed, for in our variable climate a variety is needed. In the writer's opinion, it is a mistake to pin one's faith to one or two fodders to produce feed for large quantities of stock." A lengthy discussion followed, and several members intimated their intention of testing different varieties of introduced grasses.

QUORN, June 6th.—It was decided to issue a suggestion that farmers in these areas should sow small plots of kale, rape, and lucerne as feed for cows and poultry on the farm.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

BEAUFORT.

June 4th.—Present: nine members and two visitors.

Sheep on the Farm.—Dealing with this subject in a paper Mr. C. Wilson said farmers should rear sufficient sheep to provide for the requirements of the homestead, and not be dependent on purchasing stores. The class of animals he recommended was the progeny of the Merino ewe crossed with the Dorset Horn ram. The skins would then be saleable at a good price; with the Comeback ewe and the Shropshire ram this was not so, as the wool was dark edged. The skins should be hung neck downwards and extended with two spreaders. Mr. A. Gard advised purchasing fat sheep rather than stores on account of the uncertainty of grass being available. Merinos were most payable. Mr. J. Sampson mentioned that tick and lice would not thrive on sheep in this district. Mr. W. W. Mugford (the Chairman) said the farmer must keep a few sheep if he would work his land economically. These should be bred on the farm, and the Merino would be found most suitable. Dipping was beneficial to the sheep. Mr. P. H. H. Underwood agreed and favored the Merino. At shearing time aged sheep could be culled, fattened, and sold. Generally members recommended the Merino, and agreed that it was advisable to paint the skins with a wash to preserve them.

BELALIE NORTH (Average annual rainfall, 16in. to 17in.).

May 10th.—Present: 10 members and five visitors.

Preparations for Seeding.—In initiating a discussion on this subject Mr. I. Gullidge recommended crossing the ploughing with the cultivator, and then harrowing. The drilling should then be across the cultivating. Harrowing before the drill ensured the seed being buried to an even depth. He pickled his seed about one week before sowing when the ground was dry. Mr. O'Leary agreed that it was best to cross-work the land. He attached a harrows to the cultivator. Mr. Smart and Mr. Bradtke also agreed. Mr. Hall pickled his seed by dipping a bag at a time, but Mr. Warner expressed the view that the inside grain was not properly treated when this was done. The grain should be in butts. Graded seed should be sown, with which opinion Mr. Fox concurred.

BOOBOROWIE.

May 7th.—Present: 12 members and two visitors.

Cultivators.—An address on this subject was given by Mr. F. E. Waddy. Cultivation was necessary for the conservation of moisture, the destruction of weeds, and the preparation of the seed bed, he said. The time to cultivate was governed mainly by the rainfall. Rains caused the weeds to germinate on the fallow, and caked the surface so that in order to keep the fallow clean and conserve moisture it was necessary to cultivate after each rain, deeply shortly after fallowing and then shallower on towards seeding time. Cultivating, if done at the proper time, put the ground into a fairly fine nobbly condition. It neither left it lumpy (which encouraged takeall) nor did it pulverise it to a fine dust, which was liable to set down very hard at the next rain. The advantages and disadvantages of the various forms of cultivators were outlined as follows:—The lockspring cultivator, which could be obtained with tines arranged in form of a V or staggered, was good. The spring was not in action while the share was in the ground, but simply threw it into the ground after it had jumped. The staggered tine spring-tooth cultivator made a splendid seed bed in clean land, but easily became blocked with rubbish, straw, &c. The V-shaped spring-tooth cultivator became blocked less easily, but had the disadvantage of leaving the land ridged. Bridle draught cultivators were good on level country, but when the machine ran on the horses going down hill the shares were not held in the ground. The skim plough was a good implement, but had the disadvantage that it was necessary to work round and round a piece of ground, so that at seeding time it was not possible to work the drill close behind it. The speakers' views were freely discussed. Mr. Waddy said, in answer to a question, that he favored ploughing in straw at fallowing time when practicable, but the straw proved too troublesome at times as it blocked the plough.

CANOWIE BELT (Average annual rainfall, 20·04in.).

June 6th.—Present: 15 members and three visitors.

Livestock on the Farm.—Mr. G. Kirk read a paper. He preferred the medium draught horse for farm work. Breeding mares should be kept in good condition, and worked up till within a month of foaling, in a plough or cultivator; but not in a heavy dray or trolly. When being weaned, foals should be shut up for four or five weeks, and fed on hay chaff, with a little oats added. Rocksalt should be available to the animal, especially when dam or tank water was used. Molasses and chaff constituted a good feed, being of considerable medicinal value. Foals should be kept in good condition until they were broken in; kindness was essential in breaking. After the animal had been taught to lead, it should be placed between two quiet horses and driven about for a while. If the farmer could provide sufficient feed and water, and the necessary labor, it would pay him to keep six or eight cows. A good straw stack, with molasses added when it was being built, would provide shelter and a certain amount of feed. The animals should be milked twice daily, the milk being separated whilst still warm. They should be dried off six or eight weeks before calving. Calves should not remain with the mothers. Pigs, sheep, and poultry should be kept on the farm; the last-named being shut up at night. The Wyandotte-Black Orpington cross was best. It was generally agreed that foals would do well shut up and fed on hay chaff, with bran or molasses, if a yard for exercise were connected with the stable. Mares in good condition could be given light work up to within a few days of foaling. Hay chaff, with plenty of oats or bran, was best for working horses.

Stripper versus Harvester.—Mr. W. A. Carter, in a short paper, advocated the use of the stripper and motor winnower on large holdings. With this method the crop could be gathered more cheaply and more quickly. The general opinion of members was that in a district like this, where the holdings were small, the complete harvester was preferable to the stripper and winnower. Carriers could be fixed to the harvesters to save cocky chaff.

GLADSTONE (Average annual rainfall, 16in.).

May 2nd.—Present: 20 members and four visitors.

Farm Management.—Mr. R. Peters read a paper on this subject. In answer to questions, he advised breeding pigs and sheep rather than purchasing, although it would probably pay to buy on small farms. Oats and barley should be sown at this time of the year for feed. Summer fallowing was advisable, and the land should be worked with a light plough; the skim plough was better than the cultivator for this work. Difficulty in obtaining labor made ensilage unpayable on most small holdings. Cocky chaff made better feed than chaffed straw. Members generally agreed that it was advisable to harrow growing crops in heavy soil, but light or sandy land should be carefully treated in this respect.

GLADSTONE (Average annual rainfall, 16in.).

May 30th.—Present: 13 members and one visitor.

Pickling Wheat.—Mr. Coe read a paper. He advocated the disinfection of machines, and then outlined a method of pickling seed with bluestone. A box fitted with cross pieces for draining the bags, and a lever attached, should be used. The box, having sloping sides, should measure at the top 4½ft. by 2ft., and be 2½ft. deep. The bag should be lowered on its side into a 1¼ per cent. solution, left from two to three minutes, and then allowed to drain. The seed was ready for sowing next day. Mr. Coe then read an article upon the same subject by Mr. Ross, of New South Wales, who said a 1¼ per cent. solution of bluestone was the best pickle. Care should be taken not to drain the bags on galvanizd iron. Sowing should take place the day after pickling. A very strong solution of bluestone would destroy bunt, but it might also destroy the seed, and to avoid this danger the bluestone wheat should be placed in a solution of ½lb. lime to 10galls. of water. Fresh lime or a mixed solution of lime and bluestone should not be used. An interesting discussion then followed. Mr. Brayley advocated pickling on the floor with bluestone, but would use boiling water. He considered that the steam played an important part in the process. Mr. Humphris instanced a case in which very smutty seed, although not pickled, produced a clean crop. The reason for this was that the smut germinated and died before the wheat grew.

LEIGHTON (Average annual rainfall, 16in. to 17in.).

June 4th.—Present: 20 members.

Care of Harness.—In a paper on this subject, Mr. S. Cordon said that owing to the different system of tanning now adopted, leather produced at present was not equal to that produced a few years ago, consequently every attention should be paid by the farmer to his harness, more especially so as the prices of all kinds of leather were higher at the present time. On no account should harness be thrown down on the ground, or left out at night in the paddock. It should be hung in a dry shed or harness room when not in use. He preferred a round rail, fixed about 3ft. 6in. from the ground, on which to hang collars, each being passed over the rail. This made it easier to get just which collar was required. Pegs should be provided for winkers, spiders, saddles, &c. When stitches were noticed to be coming undone, or a breakage discovered, it should be attended to immediately, preferably by sewing, or by the use of copper rivets. The latter should not be too large, or used too plentifully, for too many rivets weakened the harness. Harness should be thoroughly cleaned and oiled at least twice a year, preferably at the beginning and end of winter. A tub half full of water, soapy if desired, and not too hot to preclude the harness being being placed in it, should be provided on a sunny day. In this the leather should be thoroughly washed. Traces, girths, belly bands, and all parts on which there was an accumulation of sweat, should be attended to first while the water was hot. After washing it should be placed in the sun to dry, this being followed by an application of neatsfoot oil, or some other good preparation. A mixture found useful for harness in wet rough work, and where mice or rats abounded, was two parts neatsfoot oil, one part resin, and one of tar. The oil kept the fat soft, the resin kept out the water, and the tar prevented the rats chewing it. Neatsfoot oil was also very good, and for a riding saddle the white of an egg rubbed over the neatsfoot oil kept the oil from coming off on the clothes, and gave the saddle a glossy appearance. Every farmer should have on hand a kit of needles, wax end, pincers, rivets, punches, &c. Members discussed the paper at length. Mr. W. Bailey did not agree that the white of an egg applied to a saddle previously treated with neatsfoot oil would prevent the oil soiling the clothes of the rider. Mr. Ham thought it would. Mr. J. McDonald used neatsfoot oil and tallow to soften and preserve harness. The Hon. Secretary (Mr. W. H. Lloyd) thought cod preferable to neatsfoot oil.

MOUNT BRYAN (Average annual rainfall, 15·81in.).

June 8th.—Present: seven members.

Irrigation.—This subject was dealt with in a paper by Mr. A. Jefferies. After drawing attention to the disabilities which were experienced in the absence of an adequate water supply, and detailing the steps which had been taken in the South-East to remove the surplus water by means of surface drains, the paper read—"One of the greatest drawbacks in our State is the scarcity of water suitable for irrigating. In nearly every district, however, water suitable for stock can be procured by sinking, although in many cases it is at a great depth; consequently dam sinking is resorted to. This, if carried out on a sufficiently large scale, is very suitable. There are many places suitable for the construction of large dams, which could be formed at a comparatively small cost by erecting embankments across watercourses or natural valleys, and the water thus conserved would be of great value in our dry districts for growing small quantities of green feed, which would be very valuable during the summer time. In this district good water can be obtained in most places by comparatively shallow sinking, and I am of opinion that the time is not far distant when this source of supply will be much more availed of than it is at present. Of course, with an underground supply there is always the question of raising and distributing. This is a matter of great importance and one which requires a good deal of consideration, as a mistake in the first place often costs the individual a great deal of time and money. The windmill is the cheapest method of raising water, and one would almost think, on a casual observation, that there was no limit to the motive power for this method, yet it is very unreliable. In my opinion, water for irrigating

must be raised with the motor engine. With one of these one can rely on the supply when it is needed, which is absolutely essential for successful irrigating."

MOUNT BRYAN EAST (Average annual rainfall, 16in.).

June 9th.—Present: 12 members.

Sheep.—In a paper dealing with sheep on the farm, Mr. W. Gare said sheep did well in the stubbles. Especially was this the case with forward lambs. Placing them there enabled the grass paddocks to be saved until lambing commenced. It was much better to feed the green stuff on the fallows to sheep than to plough it under. A good system was to run the flock on the stubbles and sell the fats, allowing the ewes to remain for two or three months.

The Chairman (Mr. J. Thomas) gave an instructive and interesting address dealing with a trip to Beltana Station.

NORTH BUNDALEER.

June 3rd.—Present: 13 members and four visitors.

Bulk Handling of Wheat.—Mr. P. E. Kelly read a paper on this subject. The gist of the finding of the Royal Commission which dealt with this subject, he said, was that bulk handling was feasible and desirable, and would result in a great saving to the farmers. As it had been stated that the jute business was in the hands of a combine, he thought the price of bags was likely to rise rather than fall. The money that the farmer would save in bags in a few years would enable him to erect a stone barn with a cement floor in which to store his grain. Members were divided in opinion as to the benefits to be derived from the proposed system.

PORT PIRIE (Average annual rainfall, 13·21in.).

June 6th.—Present: 11 members.

Experimental Plots.—The experimental plots laid down by the Branch, consisting of 20 half-acre plots, were reported as having been sown with different varities of wheat at the rate of 60lbs. per acre, together with 56lbs. of super. per acre.

Noxious Weeds.—A paper dealing with useless and noxious weeds which were found in this district, was read by Mr. E. J. Eagle. These included the star thistle, the Bathurst bur, and stinkwort. Potato weed was at times a nuisance on the fallow, but it was useful in that it tended to prevent sand drift. When dry it was easily broken up, or destroyed with a cultivator when young. Buckbush, like the potato weed, was a summer plant; but, being a valuable fodder, its appearance was welcome. Wild turnip was troublesome in a wheat crop, but stock ate it readily, although too much of it tainted both milk and meat. Sheepweed, poppy, cockspur, &c., could be kept under by cultivation. The star thistle was likely to cause most trouble in the district, and single plants should be destroyed immediately they appeared. Similar treatment should be meted out to the Bathurst bur. Mr. Hawkins mentioned that the paddymelon thrived luxuriantly in sandy soil; if left to develop to any size, and drift was prevalent, large banks of sand would result. The melon was easily destroyed in the early stages of its growth. The star thistle, nanny weed, and native horehound had given him considerable trouble. Mr. J. Greig said the iceplant was a curse where it established itself. He advised tramping it to a pulp. At certain stages of their growth. the Scotch and star thistles could be killed by mowing. Mr. Welch said cattle would fatten on paddymelon, and whilst on it would need little water. The three-cornered jack was very troublesome. Messrs. Munday, Kirchner, and the Chairman (Mr. McEwin) also spoke.

REDHILL (Average annual rainfall, 16·79in.).

June 9th.—Present: 16 members and one visitor.

Question Box.—A number of questions were replied to by members. Mr. Button recommended seeding at the rate of 1bush. to 1¼bush. per acre for grain. Mr. Stone would sow 1bush. and upwards, according to the nature of the season. Mr. F. A. Wheaton thought a lesser quantity of good seed would suffice. The fat lamb industry, he said, had been checked considerably by the drought, but with sufficient rainfall to enable fodder crops to be grown, lamb-raising should become profitable. Mr. Coffey favored cropping every two years, otherwise trouble was experienced with weeds. Mr. F. A. Wheaton thought cropping every two years would result in the fertility of the land being decreased, but this could profitably be adopted for several years and the land then left out for a period. Mr. Coffey thought hoes on the seed drill were too far apart. If the seed were sown closer the crop would not go down so easily, and Mr. McAvaney thought this would help to check the growth of weeds. Mr. Kelly said there should be two or three wheat standards, so that if a farmer cleaned his wheat well he would receive a higher price for it. Mr. F. Wheaton thought this would increase expenses at station yards and ports of shipment. Mr. Pengilly said the standard should be fixed earlier in the year. Mr. Stone mentioned a test which resulted in a crop harrowed when growing yielding twice as much as a similar area not so treated. He had harrowed wheat when it had reached a height of 6in. Mr. Coffey said care not to overstock was the best provision against shortages of forage. Mr. J. McAvaney advised saving cocky chaff and recommended using the header or thresher.

YONGALA VALE (Average annual rainfall, 13in. to 14in.).

June 6th.—Present: nine members and three visitors.

Sore Shoulders.—In a short paper on this subject Mr. J. Barker advised carefully brushing horses' shoulders before the collars were put on. If immediately a lump occurred on the shoulder a hole were made in the collar, and no bearing were allowed on the lump, it would disappear. A solution of bluestone, applied to the shoulders after each day's work, would tend to prevent the trouble. New collars should be soaked in water before being used. Members advised application of bluestone and kerosine in the case of sore shoulders, but if well-fitting collars were used there should be little difficulty with this trouble.

Rolling and Harrowing Crops.—Mr. E. Cooper read a short paper. The effect of rolling a crop, he said, was to consolidate the soil around the stems and roots of the wheat plant, thus ensuring better growth and to level the ground, and so facilitate harvesting. As the wheat plant required a firm seed bed the roller should precede the drill. The crop should be harrowed when it reached a height of 4in., the harrowing being across the drilling for preference. The paper provoked a lengthy discussion.

BEETALOO VALLEY, June 8th.—Mr. A. Bartrum read a short paper dealing with the care of farm horses, and an interesting account of a motor trip through the gardening districts of the State was given by Mr. Burton.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

BALAKLAVA (Average annual rainfall. 16·03in.).

June 13th.—Present: 11 members.

Co-Operation.—The Chairman (Mr. H. L. Twartz) introduced a discussion on this subject. He mentioned the need of farmers combining in the purchase of their requirements in order that they might keep the cost of producing wheat as low as possible. He drew attention to the success which had attended the efforts of producers in England and New Zealand in co-operation. The success of the movement rested on the loyalty of the farmers. Messrs. Butler, Neville, Goldney, Roediger, Anderson, and Spillane also spoke.

BLYTH (Average annual rainfall, 16·46in.).

June 6th.—Present: 22 members and two visitors.

Poultry.—Mr. Alf. Dunstone read a paper. In order to secure the best results from poultry, he said, it was necessary to have them penned up. When loose they were a nuisance about the yards and stables, caused waste at the haystacks, and there was no assurance that the eggs, when gathered, would be fresh. Losses, through accidents and foxes, also were heavy. Suitable roosting houses and yards, although involving a somewhat heavy initial outlay, would in time prove best. Separate yards should be provided for the breeding stock, the laying hens, and cockerels. The cockerels should be fattened and marketed at the age of from 14 to 18 weeks. Generally on the farm broody hens would be found more satisfactory for hatching than incubators. Stable manure could advantageously be placed in the yards; this would give the birds exercise and a certain amount of food. For egg production only the White Leghorn was the best fowl, but from the farmer's standpoint it had disadvantages. Eight feet fences were necessary to confine it; it was very poor for the table, and a poor mother. Better farmers' fowls, he thought, were the Andalusians, Black, White, and Buff Orpingtons, White, Silver, and Golden Wyandottes, and Barred and White Plymouth Rocks. White Orpingtons perhaps were best of these. Continuing, the paper read—" When keeping fowls in confinement it is necessary to keep a supply of clean water available, also grit of different sorts. The fowls should be fed twice a day; the grain food should be scattered amongst the litter as much as possible to give the birds exercise. Greenfeed should be given every day. This can easily be managed if the farmer has a small plot of lucerne. Even if fed to them long it will prove very beneficial, but to get the best results it should be chaffed, which can very easily be done when the hay is being chaffed for the stock. It will increase egg production and assist in keeping the fowls in a healthy condition. Silver beet is another good green food for fowls; it is easily grown, and if well watered can be cut very often and the plants will last for a long time without going to seed. The eggs should be gathered as often as possible: not less than once a day, and be kept in a cool place until sent to market. When packed for market they should be graded, as the smaller eggs will always reduce the value of the larger. The best time for hatching is July, August, and September, as it gives the chicks a chance to get strong before the hot weather sets in. The breeding pen should be broken up about October, and not mated up again until about February or March. This gives the male bird a chance to become strong and well, and hence his stock will be more vigorous and robust than if he is left with the hens. When choosing the rooster for the breeding pen select a bird that is strong and healthy, with plenty of life in him, and one that has been hatched from an egg laid by a good layer. It is not always the best bird from an exhibitor's point of view that will prove the most profitable bird from which to breed." Mr. Deland thought the White Orpington the hardiest and best all-round fowl. Mr. J. Pratt favored the White Wyandotte.

JULIA (Average annual rainfall, 18in. to 19in.).

May 9th.—Present: nine members and five visitors.

Handling Wheat in Bulk.—In a paper on this subject Mr. J. Dunstan said he failed to see that farmers would secure any benefit by the introduction of the system of handling wheat in bulk. The cost of the change would be considerable, and farmers would still have to provide bags in which to market the grain. The price received for the loose grain would not be so high as that paid for bagged wheat. Whilst it was admitted that the grain could be cleaned at the elevators this would have to be paid for, and it would be better for the farmers to do the work themselves and feed the small and cracked grain to poultry and other stock on the farm. As the cost of jute was between 3d. and 4d. per pound, and a wheat sack weighed 2¼lbs., the raw material, it would be seen, cost 6d. This would eventually be reduced, he said, by larger areas being planted in India. He advised farmers to order two-thirds of their estimated requirements of sacks as early in the season as practicable, thus avoiding "famine" prices. The co-operative purchase of sacks might be tried with advantage.

LYNDOCH (Average annual rainfall, 23·01in.).

June 4th.—Present: 16 members.

Fodder Crops and Stock.—The Chairman (Mr. G. W. Warren) contributed a lengthy paper. Owing to the popularity of the motor vehicle, he said, the market for hay was becoming rapidly restricted. As the price of grapes was now so good, growers were encouraged to plant extensively; but it should be remembered that the local demand for these was limited, and high prices would not be maintained when the vigneron had to depend on the export trade. It would be a wise policy, therefore, for those engaged in farming on high-priced lands, to give some of their attention to raising and fattening livestock, especially in view of the high prices prevailing for meat. On the smaller holdings in this district much more attention could profitably be given to pigs, which would consume a large amount of the waste from gardens and dairies. If first quality animals were bred, and properly cared for, a good export trade in frozen pork, bacon, and hams could be established. In a mixed farming area, such as that in which the holding of the writer of the paper was situated, sheep and lambs were the first consideration. Fat stock was at its highest value at the end of June, July, and in early August, thus it was essential that feed should be available during these months. He suggested that cereal crops should be planted earlier than was the general practice, and be fed off with sheep. This resulted in better crops, and also gave the grass paddocks a spell. *Rape.*—The value of this crop was enhanced if it were sown with barley and a little mustard. There was nothing better than this as an early fodder. Unless the seed germinated in March or early April, it did not make headway. Spring sowing was not satisfactory. On one occasion four acres of sandy soil was scarified after a thunderstorm, about the beginning of March, and drilled with rape. Over 100 wethers were fattened on this. Some of the land in the Lyndoch district, which had carried a cereal crop, could with advantage be gone over with a cultivator in the summer, and sown with about 4lbs. or 5lbs. or rape and 1bush. barley to the acre. With favorable rains in March an excellent growth of feed would be secured. Silver beet and rye might also be tried. Continuing, the paper read :—" Some of the farms about Reeve's Plains grow patches every year. The rye is cut as green feed for the cattle and horses, and allowed to mature about September, when it is stripped. The opinion is that rye grain has a higher feeding value for pigs than barley. The straw is twine bound, and a limited amount meets ready sale in Adelaide at the horse-collar factories at very payable prices. I understand, too, that if rye is not allowed to attain the height of more than 1ft. it will outlive a summer, and provide a crop the following year. *Peas.*—The value of this crop is not half recognised. I can but admit that this year's crop did not yield the results of the previous years, but the last erratic and bad season, no doubt, accounts for this. I, however, fattened 500 lambs on about 35 acres. The lambs were in very poor order when weaned. Everyone should give peas a fair trial in place of bare fallow; thus sowing a rotation, and the land producing a crop every year, although it may be beneficial to spell the paddock every third or fourth year. The pea crop could be followed, say, by wheat, and scarified up the following year for oats and rape for feeding. A light rain will practically spoil the feeding value of peas. I have had no success with summer crops, such as maize, sorghum, and millets, during the last few years. So much depends on planting just at the right time, and moisture must be applied by artificial means, although a good rain when the plant is well up ensures success. These crops should be planted wide enough between the rows to be horse-hoed, and are benefited very much by a summer stirring of the ground, even in the absence of rain. Millets grow far more stems than sorghums, and can be cut more than once. The stems do not grow so strong, resembling more a grass. I advocate planting maize and sorghum in the same drills, and cutting the maize when it matures in December or January. The sorghum is then available later, and in a favorable season a second or even a third cut can be made. The value is enhanced by putting the stalks through a chaffcutter. Maize is richest in feeding value; it is a great fodder for pigs. Care must be taken not to feed sorghum in its earliest stages of growth, as it contains prussic acid; this, as the plant matures, changes into sugar. In many countries the carob bean is used largely as a fodder, and although a slow grower, it is a very handsome tree, very shady and one that could with advantage be more widely planted. Tagasaste was boomed some time ago, and, in my opinion, it is very much over-rated. In Scotland gorse is cultivated very extensively on poor soils, and is worthy of a trial here on some of our scrub lands. It thrives practically everywhere, but must not be allowed to reach hedge dimensions. Horses, sheep, and cattle are very fond of it, and thrive on the young shoots. Lucerne will stand rougher treatment than is generally supposed, provided, if fed off, it is allowed to run to seed occasionally, and 1 ton of lucerne hay, well cured, contains as much nutriment as 1 ton of bran. It is cut with a binder at Turretfield, which makes the handling easier, and there is not so much waste through the leaves falling off when dry. *Phalaris commutata.*—After almost unlimited trials of various grasses I have discarded dozens in favor of *Phalaris commutata,* which I consider the most valuable introduced grass. It has the characteristics of our native grasses, grows whenever there is a vestige of moisture, comes on with the first rains, and produces abundance of fodder during the winter months. It fills the needs of the lamb grower, is invaluable to the dairyman, and provides feed during the winter when it is most wanted, and, in my opinion, is most valuable. This grass will do very well in this district; it is wonderfully strong-rooted, and grows into a tussock. I have on my best land a tussock 30in. in diameter, the outcome of one single seed in about five years. It throws out a wealth of flags up to 18in. in length during the winter, and then stalks for seeds tower up to 4ft. or 6ft. in height about spring. From a small bed of this I have cut hay at the rate of 4 tons to the acre without any attention or any extra moisture than that obtained naturally. It is my intention to plant this grass very largely on my farm. Probably the best introduced clover is the *Trifolium subterraneum.* Since the advent of phosphates the native clover has thrived wonderfully, especially on cultivated land, and one could not do better than instal *Trifolium subterraneum* in its stead. It produces more fodder, grows, if anything, more quickly, and does not carry the burr which is so harmful to wool. Every vestige of it is licked up by stock. It is the first grass to come on, with the exception of the native carrot, and the last to get dry. English clovers improve hay if grown with it, but as they seed in the air they do not propagate themselves well the following year. All clovers, which tend to collect nitrogen from the air, should be encouraged. The best of the other grasses I have tried are Paspalum and Johnson grass, but as these grow in the summer I have discarded them in favor of *Phalaris commutata.* Paspalum, however, especially the creeping variety, is a handy grass to plant in wet places, bogs and creeks especially, to bind the soil in a washout. Native couch grass is favorably spoken of. Rhodes grass and African Wonder grass have been tried in the Cockatoo Valley scrub. To sum up my experience, one cannot do better than stick to *Phalaris commutata* as a perennial, and encourage *Trifolium subterraneum* in cultivated fields. If a supply of water is available, lucerne should be grown. I thoroughly believe in small paddocks and shifting stock, say every fortnight. All grasses require a spell now and again, and I am convinced that they are benefited if allowed to run to seed every few years. They cannot go on producing unless they are manured occasionally. All grass paddocks are benefited by a light ploughing, or cultivating where possible. Fire burning through rank feed or stubble is splendid for the land."

MALLALA (Average annual rainfall, 16·88in.).

June 1st.—Present 11 members and one visitor.

Agricultural Bureau.—A paper on the subject of improving the effectiveness of the Branch's work was read by Mr. A. H. Marshman. He laid stress on the necessity for enthusiasm and regular attendance on the part of the individual members. The exchange of opinions on matters of agricultural experience was of great value, and homestead meetings, held twice a year, would prove very instructive. The inauguration of a question box would do away with the difficulty sometimes experienced in selecting suitable subjects for discussion, and the occasional tabling of farm products would probably encourage greater interest in the "side lines" of the farm. Branches might be well advised, also, to avail themselves more frequently of the services of the departmental experts. Once a year it was a good plan to hold a social night. As a result of the suggestions contained in the paper, it was decided that the Branch should have a question box, and a visit was to be paid to the holding of Mr. J. Nairn.

NANTAWARRA (Average annual rainfall, 15·90in.).

June 4th.—Present: 11 members.

Seed Wheat.—Mr. J. H. Nicholls read a paper. Particular note of the varieties which did best in the district should be taken, he said, and the wheat for seed should be selected from these. Barley was too prevalent in the early varieties, and to counteract this it was advisable to hand-pick the barley from the portion of the crop intended for seed subsequently. It should be reaped on a hot day when it was ripe and hard. Mustard, nanny wood, cracked grain, &c., should be carefully removed from the seed; these were much more profitable when fed to pigs than when sown. Wheat sown continuously on the same kind of soil deteriorated, especially was this the case with Federation. Therefore a frequent change of seed was advisable. Smut or bunt-infected grain should never be sown. The floor method of pickling was recommended. Mr. E. J. Herbert concurred that a hot day was preferable for garnering seed wheat. It should not go through the harvester or even stripper if it could otherwise be harvested. Years after the stripper was invented seed wheat was still selected by hand. He was of the opinion that in many things the farmers of to-day sacrificed efficiency to speed, and the time was coming when they would have to revert to some of the old-fashioned ways. Mr. Sleep preferred pulling the barley out of his seed wheat crop just as it came out in ear. He had tried going ahead of the stripper, but found he knocked down too much of the wheat crop. Farmers sowed too much per acre simply because of defective seed wheat. If all the grain sown, *i.e.*, a bushel and over to the acre, were to germinate he felt sure there would be insufficient room for the plants to mature. Therefore all the grain sown that failed to germinate was a waste. By pickling on the floor a great deal of the wheat was untouched by the solution. Mr. Uppill said it was imperative that good seed should be procured. Mr. Smith agreed that wheat gathered with the harvester was the worst to use for seed. Mr. Sutton tipped some seed wheat into a tub of weak pickle solution, and was astonished at the number of bunt balls and whiteheads that rose to the surface. He preferred the grader to the winnower for cleaning seed, as the former appeared to get rid of the barley better. Mr. Greenshields found that bluestone dissolved quite well in cold water. Mr. Dixon believed in pickling with bluestone, and had always found it a good preventive against smut. It was better to pull barley out of the seed wheat crop when it was in a green stage, otherwise the wheat stalks were brittle and were easily broken down. Mr. Nicholls, in reply, said he was quite convinced that pickling with bluestone prevented smut. He then explained that bunt was a parasitic fungus growth, and the spores required less moisture than wheat to germinate, consequently when wheat was sown in a dry state there was at times enough moisture in the soil to germinate the bunt spores but not the wheat. The bunt spores, having no host on which to subsist, died, and the wheat grew free from bunt. When wheat was sown under wet conditions, however, the spores and wheat sometimes germinated together, and the bunt spores flourished on the wheat. This accounted for self-sown crops being free from smut. Some of the bunt balls might not have been properly saturated with the pickle, consequently if broken when passing through the drill the live spores from the centre of the ball would affect the seed wheat on which they fell. The speaker confidently believed that all spores reached by the pickle were destroyed.

NORTHFIELD (Average annual rainfall, 19in.).

June 7th.—Present: 11 members and one visitor.

Tree-Planting.—Mr. Eastwood read a paper. Little attention had been given the cultivation of trees in this locality, he said. To provide an ample supply of firewood, fencing, &c., it was advisable to fence off three or four acres of the holding, and plant this with blue, white, or sugar gums, or better still, put half an acre in each paddock under these trees. The land should be ploughed to a depth of 5in. or 6in., and then harrowed, the trees being placed 20ft. apart in rows 25ft. apart. The holes for the trees should be 2ft. 6in. across, the soil being taken out to a depth of 15in., and then loosened with a pick. Planting could be done after seeding operations were completed. When the trees were five or six years old, one here and there through the plantation could be cut about 2ft. from the ground for use. Members agreed that trees added beauty to the homestead, checked the flow of storm waters, the drift of sand, provided shelter for cattle, timber for posts, and firewood, but land in this district was too valuable to be profitably used for afforestation purposes.

TWO WELLS (Average annual rainfall, 16·36in.).

June 9th.—Present: 11 members.

Hay.—In a paper on this subject, Mr. R. Kenner said the best wheats for hay were those of a light bright-green color, such as White Tuscan, Yandilla King, and Baroota Wonder. Cape and Algerian oats were good; these should not be cut before they commenced ripening. The best quality wheaten hay was secured from a crop about 3ft. high, cut before the grain ripened. The crop should not be cut or put into the stack when the temperature was very high, or when the hay was wet. Long, narrow stooks were preferable. The hay should be salted; in cool weather coarse salt should be sprinkled on each layer of the stack, and in hot weather the hay should be slightly damped, and then salted. A stack 21yds. by 6yds. would require 2galls. of salt to each layer. The centre of the stack should be kept full from the start. It should be built east and west, and covered with a thatch or layer of loose straw as soon as possible. The Chairman preferred the long, narrow stook. Mr. Dawkins said hay could be put into stooks of 50 to 60 sheaves, right after the binder, if the crop were cut when it was in the proper stage. Mr. Pratt preferred White Tuscan for hay; crossbred wheats, he thought, were not so nutritious. The crop should be in stooks three weeks before being stacked. The Hon. Secretary (Mr. H. Kenner) had grown mixed oats and wheat on light land, and this had met with a ready sale. Mr. Jenkins thought Baroota Wonder the best hay wheat. Oats should be grown on land that was wheat sick. Mr. Wasley thought it unwise to stook hay close behind the binder.

WATERVALE.—Mr. H. Baker gave an illustration of the method he adopted in pruning a Jonathan apple tree. Members discussed the method of pruning recommended.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

MAITLAND (Average annual rainfall, 20 08in.).

June 6th.—Present: eight members.

Fodder for Stock.—Mr. Hill read a paper in which he urged the wisdom of farmers making provision in years of plenty to tide their stock over lean seasons. Practices which could be adopted were to cut portion of the wheat crop with the binder, and thresh the grain, and after reaping go over the stubble with the binder, the horse rake, loose mower, or even drag a heavy railway rail over the straw on a hot day, and then rake it. Portion of the fallow each year should be sown with peas, rape, and mustard. He had ploughed in April a paddock which last year carried a hay crop. This now carried a self-sown crop 6in. high, which he proposed to feed off with sheep, and then work the land back as fallow for next year's wheat crop. Small paddocks near the homestead should be sown with (*a*) rye, mixed with white mustard; (*b*) barley and mustard, for second feeding; and (*c*) barley and tares, for ensilage. These plots should be heavily dressed with stable manure. Messrs. Jarrett and Bentley agreed with the remarks of the writer of the paper. The Hon. Secretary (Mr. Pitcher) thought it unwise to grow fodder crops on fallow, as the object of the fallowing was to conserve moisture, and this would be utilised by the fodder crops. Mr. Hill strongly urged members to test different fodders. He tabled a sample of Cape barley of fine growth from land that carried green feed last year, and was simply scarified and dressed with stable manure.

MINLATON (Average annual rainfall, 17·44in.).

May 7th.—Present: 10 members.

Classing Farmers' Clips.—In a short paper on this subject Mr. W. Bennett said it was not practicable for the farmer with a small clip to class it to any extent. When marketing, star lots should be avoided. The bellies and the leg ends should be taken off, and the fleece skirted right round, all wet and stained pieces being pulled off. Yellow fleeces, ewe fleeces, and wether fleeces should be kept separate. Every effort should be made to get the clip to market in as good condition as possible. Members agreed that on small farms classing clips to any extent was impracticable. They favored skirting the fleeces, and making the wool look as presentable as possible.

Afforestation.—The Hon. Secretary (Mr. J. McKenzie) read a paper. Tree-planting was much neglected in this locality, he said, notwithstanding the fact that the district was peculiarly adapted to the growth of trees, gums in particular doing exceedingly well. He drew attention to the probability of a shortage of timber in the near future, and enumerated some of the many uses to which it was put. Farmers were urged to plant a few trees every year on their holdings; these would not only beautify the farms, but in the course of years would be a source of revenue. Members agreed that tree-planting should receive more attention, and advised the preservation of native timber on portions of the farm.

MOONTA (Average annual rainfall, 15·22in.).

May 9th.—Present: 11 members and two visitors.

Mendelism.—An interesting and lengthy paper on this subject was read by Mr. W. Aplin. He dealt at length with the experiment which Mendel carried out to prove his theory of the laws of heredity. He detailed the practical applicability of these principles to plant breeding, and mentioned the difficulty in the fixation of types in hybrids. Members expressed a high appreciation of the paper.

June 6th.—A paper dealing with his impressions gathered during a visit to Western Australia was read by Mr. W. B. Stacey.

MINLATON, June 4th.—Feed was reported to be plentiful, and early-sown crops were looking well, although rain was needed, as the ground was setting down hard. Members agreed that producers could profitably co-operate in the purchase and sale of their produce and requirements, and especially in regard to co-operative wool sheds.

YORKETOWN, June 13th.—Mr. Rechner reported the death of a number of sheep through eating stinkwort. Other members stated that their sheep had frequently consumed quantities of this without ill effect. Mr. Heitmann exhibited a trombone, samples of millet, chillies, peanuts, and a luxurious growth of trefoil.

WESTERN DISTRICT.

COORABIE (Average annual rainfall, 11in. to 12in.).

June 6th.—Present: 10 members and two visitors.

Post and Shipping Facilities.—A resolution was adopted to the effect that the Branch should approach the authorities with the idea of having a post and telegraph office established at Coorabie. The Hon. Secretary (Mr. H. V. Hobbs) undertook, on behalf of the Branch, to communicate with the shipping companies trading with Fowler's Bay with the object of securing a reduction in landing charges.

Feed for Horses.—The Hon. Secretary drew attention to the scarcity of feed for stock, and suggested that the Branch should, as a body, ship their horses to Edithburgh, where good paddocking was available, until harvest time. It was resolved to call a special meeting to consider the matter.

ELBOW HILL (Average annual rainfall, 11in. to 12in.).

June 6th.—Present: 14 members.

Cultivation, Seed, and Stock.—Mr. H. Wheeler read a paper. He expressed the view that land in districts of light rainfall required more working than land in the heavier rainfall areas. In this district the farmer who put in 300 acres of well-worked fallow would do better than that man who scratched in 800 or 900 acres of stubble or grass land. The holding should be divided so that one-third could be cropped each year, the following rotation being adopted :—Fallow, wheat, and pasture. This ensured seeding being done at the right time, and was much easier on the horses, as the heavy ploughing would be done in the winter. The harrows should be put over the fallow as frequently as possible in the spring, and it should be cultivated after a heavy fall of rain. In the event of it not being practicable to leave out all the stubble, 50 or 60 acres of oats could be sown for hay. Every farmer should prepare a piece of land especially for the growth of seed, great care being exercised to keep the varieties free of smut and unmixed. The best varieties for this district were Gluyas, and for the lighter lands on the plains J4. German Wonder yielded well in the hills. He characterised it as shameful that the district had not in the past produced sufficient fat stock to supply local needs. He advised carefully conserving a paddock of 100 acres during spring to provide feed to top up 200 sheep or so when the stubbles were cleaned up. These would then be ready for market when prices were ruling high. Mr. A. Chilman though pigs should receive more attention. Mr. C. K. Jacobs quoted instances where crops on well-worked fallow were standing throughout the present dry weather much better than other crops. Mr. T. F. Brooks urged the advisableness of sowing good seed only. Gluyas was the best variety for this district. The Chairman (Mr. W. T. Cooper) strongly advocated sowing smaller areas better tilled. The Hon. Secretary (Mr. G. F. Wake) thought the frequent use of harrows on the fallowed loamy flats abutting the coast would consolidate the land. Mr. F. Spencer would sow the seed to a depth of 3in.

GOODE (Average annual rainfall, 12in. to 13in.).

June 10th.—Present: 12 members.

Scrub-Farming.—Mr. L. Will read a paper. For the homestead on a scrub block, he said, a site should be selected on a rise which would make a good catchment. A track should then be cut to the nearest point on the main road. On a plan of the holding the paddocks should be marked off as squarely as possible, and this should be used as a guide in laying out the block. The first paddock cleared should be that on the opposite side of the block to the prevailing winds; this would then act as a break when the others were being burned. Sufficient scrub for windbreaks and shelter should be left around the homestead, and also in the paddocks. in one or two corners if the land were firm; but if it were sandy, and liable to drift, narrow strips along the fences were preferable. When no natural water catchment was available 1 ton of iron should be put up as a shed roof. Mr. Hughes thought paddocks should be about 200 acres in extent. Mr. J. Nicholls strongly advised leaving belts of scrub on the holding. Rabbits would then seek shelter in these, and were more easily poisoned. Mr. W. Morcomb thought a five-wire fence the best and cheapest for sheep; larger meshed netting was too often destroyed by great stock. Mr. J. Whitelaw agreed.

KOPPIO (Average annual rainfall, 22·40in.).

June 11th.—Present: 10 members and two visitors.

Farm Accounts.—Mr. F. Brennand read a short paper. It was altogether too great a tax on the mind, he said, to attempt to memorise the many affairs connected with the working of a fair sized farm, and to a great extent it was unnecessary. The practice of recording transactions on odd pieces of paper, and reference to the heel of a cheque book, or a file of receipts, was equally unsatisfactory. To enable a farmer to correctly estimate the amounts of his profits and losses, it was absolutely necessary for him to keep books. He directed attention to the "Farmers' Simplex Bookkeeper," which he considered of service to the man on the land. Members agreed that it was very necessary that accounts should be kept of the proceedings of the farm.

PLOUGHING.—Members thought that as rain had held off so long, it was wise, where possible, to plough the land dry, provided it was worked again after rain. The general opinion was that the spring draught was far ahead of the bridle draught plough for this district.

MILTALIE Average annual rainfall, 14·55in.).

May 9th.—Present: 12 members and seven visitors.

MIXED FARMING.—Mr. W. G. Smith read a paper. The high prices which prevailed, and apparently would continue, for meat, wool, and skins, he said, should be an inducement for farmers to put portion of their fallow under fodder crops to provide feed for sheep, as well as improve the fertility of the soil. Continuing, the paper read :—"Thousand-headed kale is specially suited for our hill land, and if sown on fallow, benefits the following wheat crop. I have grown this for the last eight years, and find it a good summer fodder, making a good growth soon after the first autumn rains, when grazing is generally at its worst. It keeps up the milk supply, keeps the cows healthy, and the butter is good. It is also splendid for poultry when most other vegetation is dry. One acre of thousand-headed kale, with a little cocky chaff or other hard feed, will keep two cows well for the greater part of the summer. Field peas do remarkably well here, and it would be wise for the farmers in our hills to revise their farm management by including fodder crops in their practice. A good mixture to drill on fallow in August, with about 40lbs. or 50lbs. of super., is ¾lb. thousand-headed kale seed mixed with super. just before drilling, and ¾bush. field peas. The former protects the latter from wind. The cost of the seed of some fodders is rather high, so it is advisable to sow a small area for seed ; this will reduce the cost of putting in the fodder crop. Thousand-headed kale seed is cheap enough to the grower, as from seven plants after finishing with them as fodder, I gathered 19½lbs. of seed. Peas, lucerne, and other fodder seeds can be grown more cheaply than they can be bought. Lucerne will do well here in the hills, and every farmer should put in a trial plot of this. Last August I put in half an acre, without manure, and I am well pleased with the result, and intend to increase the area. To establish lucerne it is very important to give it a good start on well-prepared fallow, either sowing early in autumn or as soon in spring as the ground is warm enough to cause the seed to germinate. The seed should only just be covered. All stock must be kept off until the plant is well established. *Trifolium subterraneum*, of the clover species, but burrless, which is much grown in Mount Barker district, is worth a trial here. This makes good growth in early winter, and stands grazing well, and, according to my own experience, does not need cultivation. It should be sown early in March on grazing land. By cropping smaller areas and carrying out a system of more intense culture, a smaller farming plant is required, and an increased return received per acre all round. This district is capable of carrying a very much increased number of stock, and, if we are to be prosperous farmers, we must look to this. Farming is one of the most uncertain occupations when everything but the growth of cereals is neglected. We should go on increasing the number of stock according to the area of the farm, at the same time taking care to provide accommodation and not to over stock." The Chairman (Mr. P. G. Wilson) advised the growth of fodder crops. Mr. W. E. Hier considered that the practice of growing summer fodder on fallow was good. Mr. J. S. Jacobs believed farmers should go in for more intense culture. Many farmers would grow better crops if they would only farm systematically. He did not think such crops as kale should be grown on fallow, but should be sown in plots which were not used for wheat-growing purposes. A farmer should secure a good supply of water. Mr. A. M. Wilson thought that for the land to receive much benefit from a crop of peas they should be ploughed under instead of being eaten off. Mr. J. P. Story said sheep were very profitable on a farm, even if the farmer only got the skin at the end of the 12 months. Cows were also a payable adjunct, but should be in charge of the women folk. Some parts of the district were suited for fodder growing, but the plains, he thought, would not be found satisfactory. Mr. L. Aunger thought the country was not suited for growing summer fodder. As the farmer advanced he could go in for more intense culture, but he must do the most profitable thing first. Dairying might be all right in itself, but as a by-product for the farmer it did not warrant the extra labor and expense involved. A few fowls for home use were handy, but a farmer could not go in for producing eggs for market Mr. Smith, in reply, said that early fallow would grow peas to great advantage, especially for sheep raising. Such fodders as those helped to clear the land of weeds. Mr. Smith tabled a fine plant of kale that had been transplanted in October last. The plant showed fine growth, and was healthy and free from blight of any sort.

MITCHELL.

June 6th.—Present: nine members and two visitors.

Care of Machinery.—A short paper was read by Mr. Sinapius. He advised the provision of a shed with large pine uprights for preference, covered with straw, and then a layer of thatching grass tightly secured with wire, for farm machinery. An iron roof was less dangerous on account of fire, and would afford a water catchment, but was more expensive. Raw linseed oil should be applied to the woodwork of the machinery every other year, and to the nuts and bolts holding the binder fingers in place. Belts and leather work required a coat of neatsfoot oil annually, and belts could be prevented from slipping by being dressed with melted resin, to which had been added sufficient machine oil to keep it soft. Bolts on ploughs should be kept tight, and the bodies should be kept in alignment to prevent one furrow cutting more than the others. Axles should not be allowed to wear too much or the wheel boxes would be worn unevenly. Mr. Trimble advised repairing breakages before putting the machinery into the sheds.

Destroying Shoots.—In a short paper Mr. W. Ness advised cutting shoots and allowing them to remain on the stumps until the next growth was about 6in. high, and then burning them. Mr. J. H. Vigar had found the disc cultivator a great labor saver where shoots were numerous. Members generally favored fire-raking the stubble as one of the most effective ways of destroying shoots.

ROBERTS AND VERRAN.

June 2nd.—Present: 10 members.

Poultry.—In a paper dealing with this subject Mr. [illegible] A. Buttfield said—"In selecting sites for poultry-houses attention should be paid to—(*a*) The health of the fowls; (*b*) convenience of attendance; (*c*) protection from vermin. It is essential that the house and run be clean and free from damp. A dry and porous soil is naturally the best, but a wet and heavy soil will do if the land is well underdrained. The evils of the heavy soil are that it not only retains all the droppings on the surface, but, by retarding the percolation in times of frequent rains, it soon becomes covered with a coating of filth. The best situation is a slightly raised elevation, with the ground sloping gently from the building to ensure good surface draining. To get as much sunshine as possible it should have a southern aspect, a point or two to the east. Sunshine imparts vigor to the birds and stimulates egg production. The yard must be on the south side of the house, so that the fowls may get protection from the north-east winds. Permanent fowlhouses are not to be recommended for farms. They should be vermin-proof and so constructed as to exclude draught. Grain should not be kept in the fowlhouses, as it attracts vermin. Warmth, light, and cleanliness are chiefly to be considered in construction. The perches should be broad and not more than 3ft. from the ground, and movable. The nests should be in a more or less dark place and easily accessible to the fowls. The material for the bottom of the nests must not be of such a character as to stain the eggs. Moss litter laid about 6in. thick is a fine thing for the bottom of the house. Fowls confined in a run must have a plentiful supply of dust in order to keep themselves free from lice. On the farm movable houses can be used in the fields, but the movable runs can be dispensed with. If other farm stock be kept on the field great care should be exercised in moving the houses about constantly, so that no one stretch of land is fouled. A movable house that will shelter from 25 to 40 head of poultry can be kept to the acre if the house be moved a few yards each week. The birds scratching for food will improve the pasture by aerating the roots of the grasses, and they will spread the animal droppings and keep down insects. After harvest is gathered, until the land is ploughed again, poultry placed upon the stubble will get their own living. Fowls also destroy vast quantities of noxious insects and their pupæ. An excellent method of guarding poultry in movable houses and runs against the depredations of foxes is to run a wire along which a good watch dog can slide its chain across the field. Egg breeds have been produced for laying at the expense of sitting. They are really egg-producing machines. The average egg production is about 80 to 100 eggs per head of fowl per annum through the country. If egg production be pushed too far the constitution of the fowl weakens. The egg breeds are active and industrious, always foraging about or being on the look out for food. This is why they do best on extensive runs. In a state of nature birds have to work and scratch for their feed, and when they are in confinement this should be remembered. Among the egg breeds the following varieties are notable :—Minorcas, Andalusians, Spanish, Leghorns, Dorkings, Orpingtons, and Indian Game. The purpose of food is to supply heat to the body and the energy and force to enable the bird to perform its natural functions; to build up bone, muscles, tissues, feathers, and repair them as they slowly waste away; to provide a sufficiency of nervous energy and physical power to enable them to lay." Mr. F. Masters said poultry in this district should be bred for egg production, and not for table purposes. Members generally favored movable houses and thought egg production a payable adjunct to farming in this locality.

YABMANA (Average annual rainfall, 15·14in.).

June 6th.—Present : nine members and one visitor.

Method.—Mr. J. F. Robertson read a paper, in which he emphasised the necessity for a young man setting a definite objective before him. With determination of purpose, thoroughness, energy, and commonsense, he should be successful, and this applied particularly to life on the farm. Messers. J. N. McCallum and F. A. Beinke agreed with the writer of the paper.

Smut.—Members thought wheat sown on stubble land that had borne a smut-infected crop would very likely develop the trouble ; but this depended very largely on weather conditions. Pickling with bluestone was considered the best preventive measure. The method of pickling was not of such importance as the thoroughness with which the work was carried out. Badly infected wheat should not be sown. Mr. J. McCallum had used formalin, but had come to the conclusion that in the absence of plenty of moisture there was more likelihood of the grain malting than was the case when bluestone was used. Members agreed that the plant from good plump grain was more likely to survive a dry spell than that from shrivelled wheat.

YADNARIE (Average annual rainfall, 14·09in.).

June 6th.—Present : 15 members and nine visitors.

Engines on the Farm.—Mr. E. C. Stubing read a paper. He said—"The engine cannot be too highly recommended for work such as chaff-cutting, grinding, &c. The horseworks are used in many cases, but although the initial cost of an engine is greater it will prove the cheaper in the long run. For time and labor saving it cannot be beaten. For farm work the petrol engine is preferable to the oil engine, as it may be started at a moment's notice. The amount of power required is a very important consideration when purchasing. No matter what style of engine is to be purchased it is advisable to secure one somewhat larger than at first seems necessary. More work than was at first contemplated is sure to present itself. It is always well also to have a little power in reserve, because with an engine laboring under an excessive load the fuel consumed and wear and tear are very considerable. The style of engine selected is determined by the location and the nature of the work to be performed. If the engine is to be used in one place only a stationary type answers, but if it is to be used at various points a portable type, mounted on skids or wheels, is desirable." The majority of members favored a stationary petrol engine.

BUTLER, June 8th.—**Experimental Plots.**—A committee to supervise the manurial and wheat variety tests to be conducted by the Branch was appointed as follows :—Messrs. Bawden, Morgan, Parker, and Young.

Members thought that there was most likelihood of killing stumps when shoots were cut in January and February.

Grass.—A fine sample of Teff grass 2ft. high, planted on fallow in November, was tabled by Mr. Bawden. It was a good sheep and cattle fodder, and the animals were very fond of it.

MILTALIE, June 6th.—Under the title of "Why be a Farmer?" Mr. A. W. Wilson read a paper, in which he dealt with the advantages of the commercial life, the life of the artisan and that of the unskilled laborer, and contrasted them with those of the farmer. A person should not become a farmer simply because his father had followed that avocation, he said. Members discussed the paper.

SALT CREEK (formerly Utera Plains), June 6th.—A number of papers from the *Journal* were read and discussed. Members generally favored early wheats for this district. The best means of ridding the stubble of straw was to burn it. Several questions were discussed at length.

YALLUNDA.—CORRECTION *re* PEACH TREES.—[In the report of the April meeting of this branch, Mr. Fairbrother was said to have stated that peach trees died out in th's district. This should have read that peach trees were subject to "die-back."—ED.]

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

BERRI.

May 9th.—Present: 15 members.

DECIDUOUS TREE-PLANTING.—An interesting and instructive paper by W. R. Lewis was, in the absence of the writer, read by F. R. Arndt. The paper dealt in a comprehensive manner with the planting of all kinds of deciduous trees. The writer recommended the planting of peaches and apricots on the looser soil of the holding, while pears, apples, and prunes should be planted on the stiffer land. Land that was liable to develop seepage was best planted with sultanas, while almonds and walnuts should have the driest situations. All land should be well graded before planting, and should be well ploughed. Where the land was hard gypsum should be applied to loosen it. The trees should be planted with care and headed low, as fruit was more cheaply gathered from low-headed trees than from standards. [This paper will be printed *in extenso* in a later issue.—ED.]

PEANUTS.—Mr. W. Morey exhibited a fine specimen of a peanut plant. He considered that for local conditions peanuts should be planted as soon as danger from frost was over, in rows 4ft. apart, the plants being 3ft. apart in the rows.

BORRIKA.

June 6th.—Present: 25 members and six visitors.

FALLOWING.—Papers on this subject were read by Messrs. J. E. Coombe and J. H. Gray. Mr. Coombe said fallowing should be commenced early, say in August. The land should be well turned over with a good mouldboard plough. The under surface was then exposed to the sun and frost, which sweetened it. Light sandy soil could be worked to a depth of from 3½in. to 4in. All the ground should be harrowed within a week of the time it was ploughed. It should be cultivated and harrowed after a good rain.

Mr. Gray said, "Fallowing is an important factor in wheat-growing. It has been proved in the older mallee districts that it will not pay to crop the land year after year without fallowing. Quite recently some statistics were published showing that the poor harvest returns in the Victorian mallee land were due to the farmers not adopting this system of cultivation. In the county of Weeah (mallee) the ratio of fallow to wheat was 11 per cent., and the average yield was nearly 5bush. In Borung (Wimmera) 95 per cent. of the land under wheat was fallow, and the average yield was 18bush. The majority of mallee scrub farmers have a knowledge of the advantages of fallowing; the trouble is that there are heavy expenditure and big liabilities to meet during the first few years; consequently the settlers crop their land several times in succession. While the wet seasons continued this kind of farming paid, but a dry season or two, such as we have just experienced, has proved disastrous. In my opinion it is a good plan to take off two crops and then fallow. By so doing one has a chance to get rid of some of the shoots by a stubble fire before leaving the land out for fallow. Fallowing is the systematic method of working the land to conserve the moisture from one season to the next, so that practically the crop will have the benefit of two years' rainfall. South Australian farmers were the first to cultivate the land in this way, and the farmers in other parts took the example from them. In the North the land is ploughed to a depth of about 4in. The harrows and cultivators are then used to destroy the weeds and maintain a fine tilth on the surface, to prevent evaporation of moisture. Sheep are run on the fallow to keep the plant growth in check. The cultivation of the fallow and the stock do the work of subpacking the soil. This heavy land sets firm after a rain, and where possible it is cultivated after a precipitation. The farmer in the mallee must adapt himself to local conditions. I do not think it wise to work the land down too fine with harrows, especially in this part, where there is so much sand. There will be trouble with drift if the land is left bare and worked fine. The ploughing should be commenced as soon as the seeding is over. The earlier it is ploughed the more moisture will be conserved. When the ploughing has been done early I would cultivate before harvest in the spring, and let the land remain rough. This will prevent it drifting. On our farm at Parilla they have not used the harrows on the fallow. A 300-acre paddock was ploughed in August, and only a small piece was cultivated. It was heavily stocked with horses to keep down self-sown growth of wheat, &c. It was sown about the end of June with early wheats, but the strong winds knocked the crop about. The average yield was 10bush., with about 2bush. or 3bush. waste. If the paddock had been sown with late varieties such as Marshall's or Yandilla King the yield would probably have been about 15bush. The best return from well-worked fallow in the Parilla district that I have heard of was 18bush. This was scoured with sheep when in fallow. In that part they have heavy flats, which do not drift, but the big sandhills drift badly. The low hills are not so bad. All bush must be cleared off and the drift given a clear sweep. It is difficult to get anything to grow on a drift mound. It may be necessary to grow some summer fodder, such as millet, sorghum, or maize, to prevent this drift, and this would provide feed for stock. This is what is termed "green fallow." At Roseworthy College tests have been made which show that results are better from bare fallow than green fallow; but conditions here are somewhat different. A heavy summer crop need not be grown on the fallow, but simply a light crop to prevent the drift. Summer fallow would be another means of dealing with the drift. It is best to plough the land after the harvest. When seeding is over, cultivate it lightly with a disc cultivator to conserve moisture. This implement, when worked in damp, showery weather, leaves sufficient plant growth to prevent drift. This method, of course, could only be practised where the land is not too dirty. It would be advisable to experiment in a small way to determine the point as to whether bare fallow is more productive than green fallow; whether it will pay to grow feed on the fallow, or allow it to remain bare and drift. It will be necessary to combine sheep-farming with wheat-growing, as the stock keep the weeds and self-sown wheat from seeding. The fallowing should be done when the land is in a moist condition to discourage takeall. Fallowing not only improves soil conditions, but enables the farmer to do some of the work, such as carting stumps in the winter, thus relieving the pressure of work in the seed time."

CLAYPAN BORE (Average annual rainfall, 16in. to 17in.).

June 3rd.—Present: 10 members and one visitor.

Farm Management.—Messrs. C. and S. Hill read a paper on this subject. It was bad policy to overstock, they said. Horses should have good, warm, roomy stables, divided into single stalls. If they were shut or tied up at night straw bedding should be provided in abundance. Small quantities of feed, at regular hours, were best. They preferred the large draught animal, which was much stronger than the lighter sort. Breeding was not profitable in this district with horses at such a low price. Care should be exercised to see that the animal's collar fitted well. White moleskin made the best lining. For a one-horse swing the distance should be 32in. from eyebolt to eyebolt, and for a two-horse swing 30in; this left the animals plenty of room to work. Farmers should keep a few sows; the Berkshire-Essex cross was preferable. Sheep greatly aided in keeping the fallow clean and provided meat for the household. Cows, poultry, fruit, and vegetables should also receive attention. Whatever crop was grown careful attention should be given the seed. Convenience of working should be studied; for instance, a race between the different paddocks and the water trough would save time and trouble. As each implement was finished with it should be cleaned, repaired (if necessary), and put under suitable cover. Mr. M. Robinson thought horses thrived better if allowed a free run in an open yard. They should have access to water only at definite intervals. Messrs. J. Entwistle, S. Gray, and E. Colwill also spoke and considered small paddocks approximately 200 acres in extent were essential to profitable working, and that each horse should be tied up in a separate stall. The last-named also made particular reference to thoroughly overhauling machinery at the end of each season, and keeping fowls away from stables and implement sheds, both of which could be made fowl-proof. Mr. J. Gray said it was essential to have implements in order and ready to commence work at once whenever the ground or crops were ready. "A place for everything and everything in its place" had always been his ideal. However, at times and under adverse circumstances it was difficult to reach this goal, and work was consequently delayed. He kept about 200 fowls, and although they were judiciously fed he had not found them very profitable. Every farmer should breed at least enough horses to replace losses from the team.

COONALPYN (Average annual rainfall, 17 49in.).

May 29th.—Present: nine members and two visitors.

Farm Buildings.—The following paper was read by Mr. E. E. Williams:—"Wherever it is possible, stone and iron buildings are to be recommended, as being most substantial and less liable to take fire. A more convenient grouping of the various sheds is made possible ; in fact, the greater portion may be included under one roof. With other work on hand, few are able to give the time to the erection of buildings of this class in the early stages of scrub farming, and as many of the buildings which are expected to be of a temporary nature often have to serve their purpose for a number of years, it might be well to confine my remarks to a few general observations as to position and design of farm buildings. In going from farm to farm one is scarcely likely to be struck with the idea that much thought has been given to the general plan of buildings to provide for convenience of working, or even to guard against the risks from fire. In scrub country it is a wise plan to place the house, &c., from 10 chains to 20 chains from any neighbor's land, to allow of a well-cleared break under one's own control. This will save much anxiety when the all too frequent bush fires are raging. Lack of this precaution has made it necessary for some to clear a break in an adjoining block for their own safety. It is not desirable to be in any way dependent upon a neighbor's good will in matters of this sort. Within one's own boundary, however, I would advocate some five or six acres as a protection from the wind, and would have all buildings on the eastern side of this windbreak—not in it. Having decided upon a site—which should cover enough ground to allow of all buildings being conveniently grouped—the next thing is to fix the spot for each building, insuring that the position of the haystack, chaffhouse, and stable shall be such as to give facility for handling feed and allowing for possible extensions, so arranged as to give protection to the horses from prevailing winds. This I regard as being the most important feature in connection with farm buildings. It is desirable that the harness-room be handy to the stable. Implement sheds should be as conveniently placed in relation to other buildings as a reasonable precaution will admit. Cow yards and sheds should be independent of other sheds. I have not attempted to describe what I should regard as the best design for buildings. It is safe to assume that when a farmer is in the position to erect ideal farm buildings he will give effect largely to his own ideas ; but it often happens that in the rush of new settlement, buildings are dumped down here, there, and everywhere in the most inconvenient way imaginable."

On June 5th a social gathering was held, there being a large attendance of members and friends. A paper on the subject of "Hobbies" was read by the President (Mr. A. J. R. Gurner), and Mr. H. J. Finnis (of the Department of Agriculture) delivered an address on the organization of the Agricultural Bureau. He urged the advisableness of Branches undertaking experimental and demonstration work, and mentioned various spheres in which the Bureau could do effective work.

FORSTER (Average annual rainfall, 10in. to 11in.)

June 6th.—Present: five members.

Waste on the Farm.—A paper under this heading was read by Mr. C. Hayman. He urged the need for systematically arranging the farm work. Inside work, such as bag-mending, bolt-cutting, &c., should be left for a rainy day. Expensive implements should not be left unprotected from the weather. Most farms here had a bore or well on them, and the landholders should have vegetable gardens and lucerne plots. A great deal of grain was wasted, he said, through the present method of harvesting, and he expressed the hope that shortly the portable thresher would be in more general use. This would leave straw to tide the stock over a period of drought. At seeding time wheat was wasted through cracked and shrivelled grain being sown. It would pay the farmers to co-operatively purchase a grader to obviate this. Mr. J. Searle thought it impracticable to use the thresher in this district at present on account of the difficulty in using the binder on land with stumps on it. A garden would be found payable, but he would not grow lucerne. Mr. W. J. Sears agreed. He would prefer to sow oats and wheat mixed for feed. Mr. T. Searle said lucerne well looked after would be found profitable.

LAMEROO (Average annual rainfall, 16·55in.).

June 6th.—Present: 18 members.

Sheep on the Mallee Farm.—Mr. W. Vivian (of Victoria) contributed a paper, which was read by the Hon. Secretary. Sheep on a mallee farm, he said, assured a regular income. They improved the land for cropping and lessened the cost of working the fallow. If the mallee were cut in November or December, so that the shoots developed when the feed was dry, the sheep would eat these, and thus obviate a good deal of trouble in killing shoots. Overstocking should be avoided. Where the climate was cool, and the grass good for wool, the best sheep for the mallee farmer was the bold, strong-constitutioned Merino ; the heavy-necked, wrinkled, small sheep should be avoided. When a market was available for lambs, good results could be secured by crossing the Merino ewes with Lincoln rams. Shropshire and Leicester lambs were not so good in the wool as the cross recommended above. The Romney Marsh was also good. Dipping, which did not cost ½d. per head when the animals were treated off the shears, was strongly recommended. Mr. E. J. Troubridge, who had 400 sheep on his holding, agreed that these animals paid. Mr. Jericho, sen., was doubtful if sheep would prove profitable. The cost of fencing would outweigh the returns. The land would drift, he said, if sheep were run over it, and the mallee shoots might prove injurious to the animals. Mr. Townsend advised keeping sheep, and Mr. Campbell recommended growing root crops and lucerne. Mr. Leckie said almost all varieties of grasses would grow in this district. The Chairman (Mr. A. J. A. Koch) had kept sheep all the while he had been in the district, and they had been profitable. Overstocking, he said, should be avoided.

Feeding off Wheat.—During July and August, when the plant had a good root system, was recommended as the best time to feed off wheat crops. Lucerne should be planted at the present time with a light sowing of oats or wheat.

MANTUNG.

May 7th.—Present: 11 members and one visitor.

Clearing Scrub.—Mr. E. Hannaford read a paper, in which he said—"For clearing scrub under the present conditions I prefer a 10ft. roller with a team of 10 or 12 bullocks. Horses suffer too much from the jarring of the roller, and there is also a danger of their being staked. The best roller for ordinary work is an old boiler cylinder, about 4ft. high, with the usual frame attached. For the bigger scrub of this district a cylinder standing about 5ft. to 6ft. high, with the frame built so that it can be adjusted to the height of the timber being rolled is best. I am not in favor of using a traction engine for the big timber on account of the difficulty of getting it over the trees and stumps, also on account of the expense of the engine; the average settler is not prepared to face this. Logging is another system which I think is much to be preferred to axe work for big timber. A framework built on two strong wheels, not more than 8ft. apart, with strong timber built in the usual roller pattern, will answer the purpose very well. A logger with a team on either end does not answer in this district, unless tracks are cut for the inside team. Either the 6ft. roller or the framework on two wheels is most suitable for high, heavy timber. For the light mallee the usual 4ft. roller is preferable. In all cases it is necessary to have plenty of strength." Mr. Nobes, in discussing the subject, said a 4ft. cylinder roller left too many snags; for large scrub he would use a bigger cylinder. Mr. A. Tonkin preferred a log for large scrub; Mr. L. J. Pearce concurred. Mr. J. P. Tonkin advised an 8ft. cylinder roller, Mr. E. Tonkin a 6ft. cylinder, and for small scrub Mr. Baker thought a 3ft. roller satisfactory. A double team log, he said, was not a success.

MONARTO SOUTH (Average annual rainfall, 14in. to 15in.).

June 6th.—Present: 25 members and five visitors.

Care of Harness.—Mr. F. C. Thiele, in a short paper, recommended hanging harness in the stables on hooks 7ft. from the ground. Leather punches, assorted copper rivets, and some good harness leather should always be kept on hand. Working harness should be greased with mutton tallow a year or two old and free from salt twice a year. If fresh mutton fat were used, oil should be put with it. The dressing should be applied hot, on a warm day, the harness being left in the sun until the leather absorbed all the grease. Buggy harness should be washed with warm water, dried, and then rubbed well with neatsfoot or vacuum leather oil. Several members preferred dressing their harness with whale oil. This should be done directly after harvest and seeding.

MONTEITH (Average annual rainfall, 14in. to 15in.).

May 29th.—Present: seven members and eight visitors.

Dairying on Swamp Land.—The Hon. Secretary (Mr. C. A. Bentley) read a paper There was ample room for improvement in the way farmers here treated their dairy herds, he said. Protection from the weather, by rugging or housing the cows and providing them with shelter-breaks, should be afforded. Only by attention being given to these matters could a good milk supply be assured. Too much feed was wasted under the feet of the cattle with the present system of feeding long hay in the paddocks. All maize, hay, &c., should be put through a chaffcutter. If chaffing were not practicable the feed should be placed in racks set over long mangers, into which all leaf and waste hay would fall. Whilst it was advisable to graze as much as possible, lucerne and clover should not be grazed, as the cows were liable to be blown. Barley was very satisfactory as winter feed. For summer grazing the millets and *panicum* were useful, and for late summer amber cane sorghum was available. Whilst lucerne could be cut and fed in the summer, as much as possible should be made into hay for winter feeding. Lucerne chaff and crushed oats given twice a day made good feed for cows during the coldest part of winter. Each animal's milk should be weighed and a record kept of the result. The milking Holstein cows were doing well of late in this district, but he would prefer to see the introduction of the Ayrshire, which could be crossed with either the Holstein or the Jersey and produce a suitable hardy animal. A lengthy and interesting discussion followed the reading of the paper.

MORGAN (Average annual rainfall, 9·29in.).

June 10th.—Present: seven members and two visitors.

Ensilage.—The Chairman (Mr. R. Wohling) reported having secured satisfactory feed for pigs by making pit ensilage of weeds, &c., growing on his holding.

Mallee Farming.—A visitor, Mr. Plue, gave an interesting and instructive address on the methods of cultivation adopted on the West Coast. He mentioned the difficulty that was experienced in ridding the land of mallee shoots, and expressed the opinion that many farmers were endeavoring to clean and crop too large an acreage.

PARRAKIE (Average annual rainfall, 16in. to 17in.).

June 6th.—Present: 12 members and three visitors.

Fallowing.—Mr. S. R. Good read a paper. He said—"Fallowing should be commenced as soon after seeding as possible, say about the first week in July, and finished about the middle of August. It is far better to fallow 300 acres and work it well than to plough 500 acres and not work it at all. I favor the use of a six-furrow share plough, cutting not more than 7in. furrows, and ploughing at least 4in. deep in wide lands. The fallow should be harrowed down as soon as possible and then crossed with a disc cultivator. Should there be a fall of rain just about hay time, the harrows should be put over the fallow again. Frequent and good working is necessary." Mr. Temby favored the share plough, as he could pull out a greater quantity of stumps with this implement than if using the disc plough. He would use disc implements to work back fallow. If the fallow were at all dirty the disc ran through it better than the tine cultivator. Weeds grew better on early fallow, and the farmer could then put more time on the ground later on. It was more profitable to have a small quantity of clean fallow than a big area of dirty and badly-worked ground. Mr. Diener spoke strongly on the advisability of farmers confining themselves to small areas of fallow rather than working an area beyond the possibility of being handled thoroughly. Poor harvest returns were largely attributable to poorly-worked ground. He advised good working, whatever the implement used might be, and heavy manuring. Mr. N. J. Good doubted if fallow in this district was going to prove a success until sheep were put on the land.

Seeding.—Mr. J. Parkinson read a paper, in which he said—"If farmers graded their seed thoroughly every year a much higher standard of wheat would be the result. Carmichael's Eclipse and Marshall's No. 3 are wheats which should suit this district. When sowing after rain a bushel of graded wheat per acre is enough, but for dry sowing it is advisable to sow a little more, as some may not germinate. Whether sown wet or dry, all wheat should be pickled and allowed to stand three or four days to dry. A solution of about ½lb. bluestone and 10galls. of water is strong enough to kill smut, and this will not retard the germination of the grain as much as a stronger solution. I prefer dividing the bags into two butts and dipping them into the solution. This is quite as effective, quicker and much easier than the floor method. About 60lbs. of super. per acre is ample on light sandy soil, especially when the crop is intended for grain. The growth of the plant on sandy country with a heavy application of super. is so soft that it is very easily affected by hot winds, &c. On firm red flats it is preferable to apply a little more, *i.e.*, about 70lbs. or 80lbs. per acre." In preference to a grader, Mr. J. Temby would use a winnower with a fairly open screen. This was a quicker method and answered the purpose in so far as making a good sample of seed was concerned. His best results were from ground sown with ½cwt. super. per acre, but a lot depended on the season. With good fallow, and in good seasons 1bush. seed and 1cwt. super. could safely be used. Mr. C. Heinzel would use a stronger solution of pickle. He always pickled on the floor, and had never been troubled with smut. He sowed ¾bush. of late wheats and 1bush. of early varieties. He would apply super. heavily on good fallow. He favored the use of the grader. Last season a good deal of shrivelled and pinched grain was harvested, and

25 per cent. of this was taken out by the grader. Mr. N. J. Good favored sowing ¾bush. seed and ¾cwt. super. With heavy seedings numbers of the heads were small and yielded less. Mr. Diener favored the use of the grader. The quantity of super. applied should be regulated according to the manner in which the ground was worked. One hundredweight could be put on good fallow, and ½cwt. on stubble or rough ground. The Chairman (Mr. A. J. Beelitz) favored bone manure. He preferred the grader to the winnower, for removing drake. In reply Mr. Parkinson thought the grader was better than the winnower, as everything but the plumpest and biggest grain was removed. The plump grain always produced the best plant.

PARILLA (Average annual rainfall, 16in. to 17in.).

June 4th.—Present: 17 members and two visitors.

Fallowing.—Mr. H. G. Johnston read a paper on this subject. After a holding, in new country, had been worked for four or five years, he said, it should be divided into smaller paddocks and fallowing practised. By this means the heaviest work was done during the winter months, when the ground was in a better state for ploughing than after harvest. Ploughing should commence as early as possible after seeding, and in land likely to be affected with takeall. it should be finished by the end of August. The depth of working should be 2½in. on the sandhills, and from 3in. to 4in. on the flats. Large stumps should be picked up and the land cross harrowed. After rain the flats could be cultivated and harrowed, but on no account should they be worked when dry. Sandhills did not require cultivating if sheep were run on them. Without these animals it was impossible to keep the land clean. Mr. J. Roachock advised deeper cultivation of sandhills than was recommended in the paper. Mr. Shannon was opposed to dry cultivation. Sandy land would drift when it was worked, he said. Mr. Tee advised working the land irrespective of whether it was dry or wet. Mr. C. Foale advised shallow ploughing on the sandhills. Mr. J. Foale agreed, and said sheep saved a good deal of work. Mr. E. J. Kerley advised deep ploughing in sand, with which Mr. C. E. Moyle agreed.

PINNAROO (Average annual rainfall, 16·74in.).

June 15th.—Present: 14 members and two visitors.

Harvest Report.—At the close of the last harvest the Branch circularised practically every farmer in the district with the idea of securing reliable information with regard to the yields of different varieties of wheat on stubble, fallow, and new land. From the information secured the Hon. Secretary (Mr. P. H. Jones) extracted the following data. The figures are instructive, but will, of course, be of greater value as the experience of future seasons is added. The results over a number of years tabulated in like manner will enable the deduction of reliable and valuable facts as to the behaviour of different wheats in the district:—Yandilla King—Five plots on stubble yielded 9·7bush. average (included in this was one plot on oat stubble, which yielded 13bush.); five plots, fallow, 9·81bush.; one plot, grass, 9·13bush. Federation—Seven plots, stubble, 6·3bush.; five plots, fallow, 8·59bush.; one plot, new, 7bush. Gluyas—Three plots, stubble, 8bush. Walker's Wonder—Two plots, stubble, 11·5bush.; two plots, fallow, 16·53bush.; Golden Drop—Four plots, stubble, 6·79bush.; one plot, fallow, 8·5bush. Cumberland—One plot, stubble, 5bush.; three plots, fallow, 11bush.; one plot, grass, 3bush. Early Baart—One plot, stubble, 7bush.; one plot, fallow, 7·41bush. Lots—One plot, stubble, 11bush.; four plots, fallow, 9·12bush. Budd's Early—Three plots, fallow, 12bush. The results of the following varieties were also handed in, each one plot lots:—Marshall's—New land, 6·5bush. Red Gamma—Stubble, 7bush.; fallow, 6·9bush. Hungarian—Fallow, 4·82bush. Crossbred 53—Fallow, 10·5bush. King's Red—Fallow, 6bush. Comeback—Stubble, 7bush. Taragon—Stubble, 3bush. Bluey—Fallow, 9·1bush. Blue Federation—Stubble, 7bush. Le Hugeunot—Stubble, 9bush. Leather Head—Fallow, 8bush. Bearded Gluyas—Stubble, 7·4bush.; grass, 3·4bush. Bunyip—Grass, 6bush.; fallow, 6bush. Viking—Fallow, 7bush.; grass, 6·75. American No. 8—Fallow, 6bush. White Tuscan—Fallow, 7bush.; stubble, 10bush. King's Early—Fallow, 6bush. Correll's No. 7—Grass, 6bush. Bayah—Fallow, 15bush. Thew—Fallow, 5bush. The last two mentioned were grown on the one farm under exactly similar conditions.

WILKAWATT (Average annual rainfall, 16in. to 17in.).

June 6th.—Present: 20 members and six visitors.

Reclaimed Swamps.—Mr. W. J. Bowman read a paper describing matters of interest which had come under his notice during a trip to the reclaimed swamp areas at Murray Bridge.

Farm Management.—The Hon. Secretary (Mr. W. J. Tylor) contributed a paper. He mentioned several matters which, if given proper attention, would augment the profit derived from farms in this district. The utmost care, he said, should be exercised by the farmer in the selection of his machinery. Field trials were an excellent means of education in this direction. It was unwise to attempt to plough, for instance, with an implement that repeatedly fouled and was quite unsuited for the work. In the near future, he thought, it would be necessary to sow fallow land only in this district. During the past two seasons the climatic conditions had pointed strongly against working up stubble land for seeding. The practice he advised was to plough to a depth of 4in. (the depth being increased yearly), and allowing the land to remain rough until September, when sheep could be turned on the fallow. In the event of a good rain in September, the ploughing could be crossed with a tine cultivator to half the depth of the fallowing. Sheep would pack the soil and tend to prevent drift. In the event of rain after harvest, the harrows should be put lightly over the ground, and the tine cultivator should immediately precede the drill, which should be followed by the harrows. Graded seed, free from smut, should be sown. Mr. D. F. Bowman agreed that it would become necessary to practise fallowing in the near future. Mr. M. Neville advocated fallowing to as great a depth as possible. Mr. McAvery favored a plough with eight-furrow frame, carrying five furrows. This took the ground well, and went through the rubbish.

WYNARKA.

June 13th.—Present: 11 members and four visitors.

Light Mallee Land.—Mr. C. Schultz, in a paper dealing with farming in light mallee land, advised rolling and clearing as much as possible at the beginning of operations and cropping an area of new land each year. The latter would yield better than the stubble, and could be put in more cheaply. After the crop was taken off a log should be dragged over the straw and a fire put into it on the first suitable day. After the burn the land should be lightly worked, and if it were quite dry or damp enough to ensure germination, late wheats should be drilled in April. The best implement was a skim plough or tine cultivator, a good set of harrows being used after the drill. The amount of super. applied and the seeding should be liberal; this would ensure a good burn, which was frequently worth several bushels of wheat per acre in the succeeding crop. From 70lbs. to 100lbs. of super. with 45lbs. to 50lbs. of late wheat on new land, slightly less on stubble, and 55lbs. to 65lbs. of early wheats, according to how they stooled, were the best quantities. After two crops of wheat had been taken off the land, 1bush. oats with about 70lbs. to 80lbs. of super. should be drilled in. This could be grazed or reaped, and providing the majority of the stumps were dead, the paddock could be left out to grass for several years. Following this the land should be ploughed after seeding to a depth of 2in. to 3in., harrowed and cultivated when damp. It was unwise to fallow paddocks carrying many green shoots. Mr. Schultz did not think it advisable to fallow land after it had been cropped for only two years, but advised two stubble burns, cutting the shoots the following year, and burning in February. Members were of the opinion that land treated in this way would yield as well as fallow land with dense shoots on it.

LAMEROO, May 9th.—**Demonstration Plots.**—Mr. A. J. A. Koch had arranged to conduct manurial tests with three plots—No. 1 treated with Beats All, No. 2 with Beats All and 20lbs. super., and No. 3 treated with 60lbs. super. Mr. Bull was treating three plots with lime, Beats All, and super. and lime respectively.

WAIKERIE, June 7th.—It was reported that wheat crops were looking well, but rain was needed. Pruning had commenced, and a few settlers were preparing for planting. A strange weed was tabled, and subsequently forwarded to the department for identification.

SOUTH AND HILLS DISTRICT.

BLACKWOOD (Average annual rainfall, 27in. to 29in.).

June 15th.—Present: 90 members and visitors.

Annual Social.—The annual social of this Branch was held in the Coromandel Valley Institute. The chair was occupied by Mr. W. L. Summers, and the following toast list was honored :—"The King," "The Parliament" (proposed by Mr. A. W. Carlos and responded to by Mr. G. R. Laffer, M.P.), "The Department of Agriculture and Advisory Board" (at the instance of Mr. T. C. A. Magarey, and replied to by the Hon. T. Pascoe, M.L.C., Minister of Agriculture, and Mr. G. G. Nicholls, Secretary Advisory Board), "The Blackwood Branch" (proposed by Mr. Geo. Jeffrey and responded to by the Chairman, Mr. W. L. Summers), "Neighboring Branches" (Mr. C. G. Savage, and replied to by Messrs. Chapman, Cherry Gardens; T. B. Brooks, Clarendon; and W. H. Hughes, Longwood), "The District" (Mr. A. J. Penno, and responded to by Mr. F. Dall). and "The Ladies, Committee, and Performers" (Mr. R. J. Wilson. responded to by Messrs. L. V. Porter and L. G. Moody).

CHERRY GARDENS (Average annual rainfall, 35·03in.).

June 2nd.—Present: 12 members.

Fallowing.—Mr. G. Hicks read a paper. As the holdings in this district were too small to allow of fallowing in spring, he advised working the land, say in January or February, and allowing it to remain rough until the first rains fell in winter. It should then be worked down loose, and ploughed again before the drill. Cultivating was unsatisfactory if the weeds were thick. Last year he fallowed in February and ploughed again in May. One bushel of White Tuscan wheat, 1bush. of Algerian oats, and 1cwt. of bone manure were drilled in, and the crop cut 3 tons of hay per acre. Land that was not fallowed, but otherwise worked and seeded similarly, returned 1½cwts. per acre. As a general rule, in a dry season, the more the land was worked at seeding the better. It was mentioned that by practising thorough cultivation, Mr. Hicks had secured very good returns from land which previously had yielded disappointing crops. Mr. J. Lewis said it did not pay to work the hills lands whilst they were very wet, as the stiff clay, with clay subsoil, set very hard, and baked. Mr. C. Ricks thought fallowing assured a better seed bed, and a better and cleaner crop was the result. The writer of the paper, in reply to questions, said the land should be worked to a depth of about 5in. during September or October. A light working should follow a fall of rain.

HARTLEY (Average annual rainfall, 16in. to 17in.).

June 3rd.—Present: 13 members.

Horses.—The subject of the management of horses was dealt with in a paper by Mr. J. Stanton. The disposition of the animal should be studied, he said, and kind treatment would be found the best means of getting the maximum out of the beast. It was only in exceptional cases that a horse was naturally vicious or stubborn, generally bad horsemanship was responsible. An animal that shied should be induced to inspect the object which frightened it; this would most likely obviate a recurrence. Defective eyesight was the most frequent cause of this trouble. Kicking was a habit hard to break. Young horses, therefore, should be well handled about the legs before the harness was put on them. As a horse that once ran away could not be afterwards trusted, it was unwise to let it stand without tying it up securely. Jibbing was often caused by bad breaking, overloading, or bad driving. A horse that was a confirmed jib was practically useless. Hanging back in the stable could be cured by fixing a rope under the horse's tail, bringing the two ends forward, crossing the rope over the animal's back, and tying it tightly in front of its breast, so that there is no slack. The rope should then be run through the nose strap of the halter, fixed to the neck, then through the ring on the manger, and tied to the rope across the breast. The beast should then be frightened and so induced to pull back. Members agreed that it paid the owner to treat his horses kindly.

Afforestation.—This formed the subject of a paper by Mr. A. Wundersitz. It was the duty of every landholder, he said, to give the matter of tree-planting his attention. A few gums should be planted each year on all holdings, and district councils would be well advised to consider the advisableness of planting roads and reserves. As this district was rather dry, June was the best month for planting. The land should be ploughed, the holes for the trees having been sunk, about 18in. deep, two months before. The bottom of the holes should be well loosened with a sharp crowbar, and the trees should be placed about 30ft. apart. An old super. bag should be supported on four stakes to protect the young tree from the wind, and it should also be attached to a stake. Up to a height of 10ft. or 12ft. the trunks of the trees should be kept free of branches. The corners of paddocks, and sandy or stony spots should be planted. Members thought the district rather dry for tree-planting; it would take a considerable time for them to grow to useful size.

KANMANTOO (Average annual rainfall, 17·90in.).

June 6th.—Present: 16 members and two visitors.

The Agricultural Bureau.—Under the title of "Help Received from the Agricultural Bureau," Mr. W. G. Mills, who has been associated with the Bureau practically since its inception, read a paper, in which he said this institution was responsible to a large extent for the up-to-date farming methods adopted in this State. The practice of conducting experimental plots, he said, was a very desirable one. It was principally by comparison that they could determine the best system of working, and the Bureau meetings enabled comparisons to be made. He referred to the practice of distributing seeds among Branches, which he thought had served a good purpose in the early history of the Bureau. This had led him to take an active interest in grasses, and he had successfully established *Trifolium subterraneum*, as well as other clovers, on his holding. He had also demonstrated that the native bunch grass would readily grow from seed collected and sown through a drill.

LONGWOOD (Average annual rainfall, 37in. to 38in.).

June 6th.—Present: 10 members and four visitors.

Irrigation.—The meeting was held at the homestead of Mr. W. Nicholls. The chief matter of interest was a large dam, estimated to hold 2,000,000galls., being excavated to hold water for irrigation purposes. It was proposed to water 10 to 12 acres of land, by means of gravitation, from this.

Fodder for Dairy Cows.—In a paper on this subject Mr. A. F. Furniss said—"For about three months, say from the beginning of October till Christmas, there should be enough grass, &c., to keep a cow in full milk with very little, if any, bran and chaff. After that, as a rule hand-feeding has to be resorted to more or less if the cow is to be kept up to concert pitch, and my idea is that that should be the aim in order to prolong the milking period and get the best results. In August, or early in September, I sow mangolds to make fodder for the following winter, or the leaves may be used during the summer if short of other food. White carrots are also good food, and may be sown at this time. Towards the end of September I sow maize, which should be ready to cut for green fodder in January, about the time the natural pasture is going off. Maize can be planted any time till the end of January, or even later, and will provide fodder until well into June unless frosts are too severe. I always sow in drills about 2ft. 6in. apart but close in the drills, as feed and not grain is required, and cultivate between the rows with a scuffler. When the stalks become too hard for the cows to chew they may be chaffed up, and every particle will be consumed. I do not recommend maize solely at any time, and when chaffing it up I always mix in some oaten hay. Amber cane and Planter's Friend may be sown in the spring, and can stand drought better than maize, and will grow again when cut. Of the two I prefer Planter's Friend. Barley and rye can be sown in February or March, and by June should be ready to cut. As a rule I sow them when the ground is quite dry, and then they are ready to come up with the first rain. Rye will grow on poorer ground than barley but it is not so much relished. Swedes are a good root crop for winter use, and may be sown early in the year until, say, the end of February, and will produce good bulbs by winter. Thus, with maize and sorghum from January till June, then barley, rye, mangolds, and swedes through the winter and up till early September at least, provision is made for the greater part of the year. If the ground is available, say, after a late crop of potatoes, it might be well to sow it with barley. It will move slowly during the winter if the ground is rich, and in the spring will be fit to cut after the March sown barley is all gone. It is as well to grow as much hay as possible, more particularly to mix with the maize. With the succession of fodders I have mentioned it is quite possible to do without a silo, though it would be handy sometimes to tip surplus green stuff into. I turn all my surplus clover, rye grass, and any other herbage into hay, and it is readily eaten by horses or cows, or it may be chaffed along with the oaten hay. Lucerne will grow all right once it gets well started, but farmers in this district like to change the crops pretty often. There may be other fodders or grasses that will do just as well as the ones I have mentioned, but I have not had personal experience of them. Many think that growing feed for cows all the year round is too much bother, and would rather buy bran and chaff, or follow the still easier plan of letting the cows roam around to pick up what they can on the roads. Cows so treated have no chance to show what they can do. For the want of a continuous supply of good food the majority of the cows in this State, if not all Australia, fall far short of what they are capable of producing. In the course of time large quantities of milk will be forwarded to the city from the hills to meet the ever-growing demand. The growing of fodders, which can be so easily done in the hills, will tend to keep up that regular supply which is so desirable. The only feed I ever have to purchase is bran to mix with the chaffed maize and oaten hay."

Broom Millet.—The following paper, written by Mr. Coles, was compiled from information supplied by Mr. J Rook, of the Royal Institution for the Blind:—"The soil most suitable for the growth of millets is an alluvial or rich strong loam capable of being worked up fine; but almost any well-wrought farm lands which will carry good maize, potatoes, and the ordinary crops will answer very well. It is necessary that the land for this crop, especially if intended for broom-making (and I shall keep this latter point in view all through my remarks), should be well prepared and clean. It should have one or two good deep ploughings and cross ploughings with harrowings to pulverise it and bring it to good tilth. Sowing may commence any time after the beginning of September, or whenever is the local time for maize planting, and be continued as opportunity permits all through the spring and into the summer. As the early sowings give the finest crops, both in quality and quantity, it is in the interest of the farmer to endeavor to get the crop planted and well established as early in spring as he can. The land having been well and finely wrought and rolled down, the drills may be struck out 3ft. or 3ft. 6in. apart and about 4in. deep. The seed does not require a large amount of moisture to germinate it. but if the season inclines to be dry the drills should not be kept open or needlesly exposed to the sun or drying winds before sowing and covering in. About 6lbs. to 10lbs. of seed per acre should be sown. After the drills are closed a light roller should go over to help retain any moisture in the land. Care should be taken to let the seeds drop regularly in the drills, the plants being about 3in. apart in the rows should the land be in good heart. If, however, the land is inclined to be light or poor, less seeds must be put in so that the plants may be farther apart, otherwise they will not develop freely and the heads will not attain the desired length and perfection which alone brings the highest price in the market. At the same time, whilst length of head is desired, coarseness must be avoided. As soon as the drills or rows are discernible the crop should be cleaned by running the scarifier or horse hoe between them, and working close up to the plants. This will not merely kill the weeds, but will greatly stimulate the growth of the young plants, and is very important at this time. Then, should the plants stand too thickly, the weaker ones may be pulled or cut out with the hoe. With a thick growth the heads are frequently stunted and inferior. When the young plants are 6in. to 9in. high they should be hilled in the same manner as maize or potatoes. Whether this is done at one operation or two may be left to the discretion of the grower, but it is necessary that it be done early (earlier than is usual with maize) and before the surface roots extend between the rows, which they do very quickly. If possible this should be done immediately after rain, or whilst the dew is on the crop in early morning. The intervening space may be occasionally scarified to keep the ground clean and the soil loose and retentive of moisture. This may be continued during the time the crop is making its growth. Beyond the foregoing no special attention is required until such time as the crop is arriving at maturity, usually four or five months after sowing. *Harvesting and Curing.*—In selecting the time for cutting this crop the grower must exercise as much judgment as in determining the day on which he shall cut his wheat or hay. Presuming the crop is being grown for manufacturing purposes, it will reach maturity when the seed is properly formed and filling, but before the grain hardens or the seed stems color. Should the seeds, either by negligence or accident, be allowed to fully ripen, as in the case where the crop is grown specially for seed grain, the seed stems become pithy and brittle and of little or no value for manufacturing purposes. In the work of cutting, boys of 14 or 15 years may be employed, and are usually as good and quick as men. The heads are bent down by the cutter and taken off with a strong knife, leaving about 5in. to 6in. of stalk attached. A laborer follows and cuts down the stalks from which the heads have been removed, and they are left on the ground until ready for burning or otherwise disposed of. The heads, when cut, are placed in small thin heaps, on some of the fallen stalks in preference to the ground, and allowed to dry in the open air for a couple of days, or if the weather permits until they attain a bright silvery color; on no account should they be cut or handled whilst damp. Field curing may be facilitated by frequent turning. The crop is then removed to a large shed and stacked until it is convenient to strip off the seed. Should the weather not allow of the crop being cured in the field it must be carted to the shed and spread out on benches or straddles, or the floor, say, about 6in. deep, and then turned every day. When cured in this way, and some maintain that it is the correct method, the crop retains a light-green tint, which is desired by some manufacturers, who will sometimes pay a higher price for it, according to the special trade or work. It is not usual, however, to adopt this plan unless weather conditions compel it, because a very much larger shed is required for this purpose, and a great deal of extra labor is entailed. But whatever system of curing the grower may select, he must make every effort to give his product a fine color, as it so largely influences its selling value. Hackling or stripping the seed off the heads is the next operation. For this a small machine, consisting of a rapidly revolving roller or drum studded with iron teeth about 2in. long, is necessary. The heads are not put through the machine in the same manner as the cereal crops with the ordinary thresher, but are merely inserted to the depth requisite for cleaning off the seeds and then withdrawn, the work being effectively and expeditiously done, and the pins or stems remaining unbroken or otherwise injured. The cost of this machine or hackler is from 55s. to 70s. for handpower, and from £8 10s. to £10 for horse. The former is sufficient for a farmer growing only a few acres, and the work of hackling may be done at any time when most convenient, provided the heads are dry enough. The heads being now ready for sale are tied in bundles or put into bales and pressed. The size of bales most liked are those weighing 400lbs. to 500lbs. each."

MOUNT PLEASANT (Average annual rainfall, 26·37in.).

June 12th.—Present: seven members.

Dry Bible.—This subject was dealt with in a paper by Mr. F. Langsford. He related his experience with this disease some years ago, when he lost 13 cows out of a herd of 14. He expressed the opinion that there was no cure for the trouble, but it was easily prevented. The cause was that the digestive organs of the cows were ruined when they were calves by being fed on improper food, such as milk from which the butter fat had been extracted. The preventive measures to adopt were to give the calf a fair percentage of new milk or a good substitute until it was three months of age, and then put it on good succulent pasture. The provision of bone meal was a sure means of warding off the disease. Eighteen years ago he first purchased a supply of bone meal for his cows, and he had not lost a beast from dry bible since. If an animal was badly affected with the trouble he would give it one pint of meal mixed with ½gall. new milk per day for three or four days. Oatmeal gruel should also be fed at times. However, the impaction should be forestalled by the animals being given about a tablespoonful of bone meal in a feed of bran and chaff, the quantity being increased as the cattle took to it. Subsequently a supply could be kept in a box or tin in a dry place, where the animals could get it at will. The symptoms of the disease were that the droppings were softer and of darker color than usual; the animal moved as though injured across the loins; it would then lie down with the head to one side, and chew continuously. The next stage was paralysis, the animal lying flat on one side; death subsequently ensued. Mr. T. Miller attributed dry bible to dry feed and insufficient water. A few pounds of ensilage fed daily would prevent the disease developing. The Chairman (Mr. H. A. Giles) thought it unnecessary to feed whole milk to calves after three weeks if pollard were judiciously mixed with the skim milk.

PORT ELLIOT (Average annual rainfall, 20·33in.).

June 20th.—Present: nine members.

Fruit and Afforestation.—Mr. J. Brown read a paper, in which he said there was a large extent of country, commencing two or three miles inland from the coast, in this locality eminently suited to fruit and forest tree cultivation. The gullies, particularly, were well adapted to fruit growing. It would be necessary to grub and thoroughly plough land for orchard purposes, and the use of the stump-jump implement was advised on land being prepared for forest trees. Three varieties which might well be grown were *Pinus insignis* (for apple cases, &c.), Tasmanian blue gum and sugar gum (for posts).

Experimental Plots.—Mr. Hargreaves undertook to conduct experiments in the manuring of fruit trees.

URAIDLA AND SUMMERTOWN (Average annual rainfall, 44·25in.).

June 1st.—Present: 14 members and two visitors.

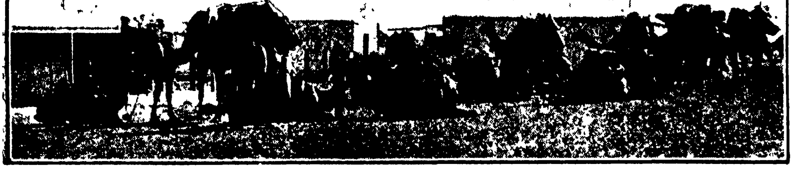
Strawberry-Growing.—The Hon. Secretary (Mr. G. Prentice) read a short paper. The Melba variety of strawberry, he said, was the only suitable sort for this district. They could be grown equally well on old or newly broken land, responded well to irrigation, cropped well through the summer, *i.e.*, from November to March, were of good color, and sold well. Land for this crop should be worked deeply and to a good tilth. One hundredweight of bonedust should be applied to every five rods of land, although well-rotted stable manure would answer well. After the first year a light dressing of sulphate of ammonia should be applied; this resulted in more and larger fruit and bushes. The best runners of the first year should be planted in rows 2ft. apart with, say, 1ft. between the plants. The ground should be kept well hoed, to destroy all weeds. Just before the crop ripened, the spaces between the rows should be covered with straw; this would keep the berries clean in the event of a heavy fall of rain. Picking should be frequent; the fruit being carefully placed in punnets, packed in crates, and marketed immediately. Mr. E. Hawke thought super. and bonedust mixed the best manure for this crop. Melba was the best variety for this district. Mr. Bonython concurred. Mr. Johnson thought sulphate of potash might be applied with advantage.

WOODSIDE (Average annual rainfall, 31·95in.).

June 3rd.—Present: nine members.

Lamb-Raising.—Mr. W. King read the following paper:—"In the Lower North, South, and South-Eastern districts, on a farm of 160 acres of arable land, there should be a flock of 200 breeding ewes. Two crops of lambs per year could be obtained by keeping the ewes in good condition, by allowing them 1½cwts. of chaffed hay each, principally in the beginning of winter. The farm should be divided into eight blocks of 20 acres. Each year there could be 40 acres of fallow, 40 acres of hay crops, and 20 acres of peas. The peas, after the first year, could be grown on half of the hay ground, and the hay grown on the fallow. After the first year, very little, if any, artificial manures would be required, as the land, being so heavily stocked, would be kept in good heart by the droppings. Half of the fallow ground should be sown with sorghum or rape, and fed off by the sheep, which would also clean up the hay and pea paddocks. With what they could get in the paddocks, and with good management in keeping them well supplied with water, and changing their paddocks occasionally, at the outside 20 tons of hay only would be required. Under these conditions there should be no trouble in raising good lambs. Where sufficient water is obtainable for irrigation double the above number of ewes could be kept by growing summer crops." Mr. S. Pearson thought two lambs per year was too much to expect from the ewes, unless they had abundance of feed. Mr. H. Rollbush thought the idea a practicable one for farms on which irrigation could be practised so that the ewes could have plenty of green feed to nourish their summer lambs. Mr. J. Lauterbach thought the idea of dividing the farm up into small paddocks a very good one, as in dairying this scheme had proved itself very profitable. In replying, Mr. King said that it had been proved that sheep could be fattened on 1lb. of chaffed hay per day, or 350lbs. a year per sheep. With reference to farms on which irrigation could be carried out, he would suggest that 10 acres be set aside for this purpose. Lucerne was best for summer feeding. In the case of ewes becoming too old to stand another year's breeding, he suggested fattening them in the summer on the lucerne, and replacing them by younger sheep.

NARRUNG, June 6th.—Pigs.—Members favored the medium-sized, quick-maturing pigs. Fresh blood of the Middle Yorkshire, Poland-China, and Berkshire breeds had just been introduced by several members, and the results would be watched with interest In the past the most popular pig in the district had been the Berkshire and Berkshire-Essex cross.



Camel Team, Oodnadatta.

much larger shed is required for this purpose, and a great deal of [illegible] labor is entailed. But whatever system of curing the grower may select, he must mak[illegible]ry effort to give his product a fine color, as it so largely influences its selling value. Hackling or stripping the seed off the heads is the next operation. For this a small machine, consisting of a rapidly revolving roller or drum studded with iron teeth about 2in. long, is necessary. The heads are not put through the machine in the same manner as the cereal crops with the ordinary thresher, but are merely inserted to the depth requisite for cleaning off the seeds and then withdrawn, the work being effectively and expeditiously done, and the pins or stems remaining unbroken or otherwise injured. The cost of this machine or hackler is from 55s. to 70s. for handpower, and from £8 10s. to £10 for horse. The former is sufficient for a farmer growing only a few acres, and the work of hackling may be done at any time when most convenient, provided the heads are dry enough. The heads being now ready for sale are tied in bundles or put into bales and pressed. The size of bales most liked are those weighing 400lbs. to 500lbs. each."

MOUNT PLEASANT (Average annual rainfall, 26·37in.).

June 12th.—Present: seven members.

Dry Bible.—This subject was dealt with in a paper by Mr. F. Langsford. He related his experience with this disease some years ago, when he lost 13 cows out of a herd of 14. He expressed the opinion that there was no cure for the trouble, but it was easily prevented. The cause was that the digestive organs of the cows were ruined when they were calves by being fed on improper food, such as milk from which the butter fat had been extracted. The preventive measures to adopt were to give the calf a fair percentage of new milk or a good substitute until it was three months of age, and then put it on good succulent pasture. The provision of bone meal was a sure means of warding off the disease. Eighteen years ago he first purchased a supply of bone meal for his cows, and he had not lost a beast from dry bible since. If an animal was badly affected with the trouble he would give it one pint of meal mixed with ½gall. new milk per day for three or four days. Oatmeal gruel should also be fed at times. However, the impaction should be forestalled by the animals being given about a tablespoonful of bone meal in a feed of bran and chaff, the quantity being increased as the cattle took to it. Subsequently a supply could be kept in a box or tin in a dry place, where the animals could get it at will. The symptoms of the disease were that the droppings were softer and of darker color than usual; the animal moved as though injured across the loins; it would then lie down with the head to one side, and chew continuously. The next stage was paralysis, the animal lying flat on one side; death subsequently ensued. Mr. T. Miller attributed dry bible to dry feed and insufficient water. A few pounds of ensilage fed daily would prevent the disease developing. The Chairman (Mr. H. A. Giles) thought it unnecessary to feed whole milk to calves after three weeks if pollard were judiciously mixed with the skim milk.

PORT ELLIOT (Average annual rainfall, 20·33in.).

June 20th.—Present: nine members.

Fruit and Afforestation.—Mr. J. Brown read a paper, in which he said there was a large extent of country, commencing two or three miles inland from the coast, in this locality eminently suited to fruit and forest tree cultivation. The gullies, particularly, were well adapted to fruit growing. It would be necessary to grub and thoroughly plough land for orchard purposes, and the use of the stump-jump implement was advised on land being prepared for forest trees. Three varieties which might well be grown were *Pinus insignis* (for apple cases, &c.), Tasmanian blue gum and sugar gum (for posts).

Experimental Plots.—Mr. Hargreaves undertook to conduct experiments in the manuring of fruit trees.

URAIDLA AND SUMMERTOWN (Average annual rainfall, 44·25in.).

June 1st.—Present: 14 members and two visitors.

Strawberry-Growing.—The Hon. Secretary (Mr. G. Prentice) read a short paper. The Melba variety of strawberry, he said, was the only suitable sort for this district. They could be grown equally well on old or newly broken land, responded well to irrigation, cropped well through the summer, *i.e.*, from November to March, were of good color, and sold well. Land for this crop should be worked deeply and to a good tilth. One hundredweight of bonedust should be applied to every five rods of land, although well-rotted stable manure would answer well. After the first year a light dressing of sulphate of ammonia
